As cleaning intervals are largely determined by the ash accumulation, Fig. 7 shows the depth of pure ash produced in each hour under various conditions.

Operating Results. With good firing and cleaning, combustible in the ash will be as low as 12 to 18 per cent; and CO_2 of from 10 to 12 per cent can be carried continuously without danger of CO.

Light-Load Firing. As has been stated 6 to 8 in. is a proper "full-load" fuel-bed depth for hand-fired barley. However, in periods of light loads, the attention required may be considerably decreased by firing considerably heavier.

HAND OR SEMISTOKERS

A type of semiautomatic equipment especially suitable for barley coal is the semistoker, such as is shown in Fig. 8. These stokers consist of a suitably inclined dumping grate usually of the slotted type having openings approximately $^5/_{64}$ in. wide, and a total air space of approximately 8 per cent.

By means of an ingenious arrangement of gates, coal may be dropped onto a convenient hearth at the upper edge of the inclined grate. It is then spread over the live coals manually by means of a long-handled spreader bar.

While not a stoker in a sense of being motor-driven, this equipment does have the advantage of hopper storage of coal with manual attention reduced to the actual operation of spreading the coal, cleaning the fire, and dumping the ash or clinker. The amount of manual attention involved is thus comparable or even better than the removal of clinker from the familiar bituminous underfeed stoker. Installations of this nature have been made in outstanding schools, office buildings, and industrial plants with perfect success, and extremely satisfactory operation.

Sizes Available. Semi-stokers are available in a full range of sizes up to about 12 ft long and 14 ft wide, with capacities from 100 to 600 developed hp. Approximately 7 to 10 ft of setting height is required for their installation.

Operating Characteristics. The operating characteristics of the semistoker are similar to those on dumping grates. As has been stated, labor is less, and, because of the type of firing, operators feel that more uniform better conditioned fuel beds can be carried. Somewhat higher loads can thus be carried, as are reflected in the ratings given in Table 2. Typical operating methods for a semistoker are shown in Fig. 9.

CHAIN- AND TRAVELING-GRATE STOKERS

The ultimate in the mechanical-firing of barley and the No. 4 buckwheat sizes of anthracite is through the use of moving grates of the endless or "belt" type. There are two familiar versions of these, i.e., chain-grate stokers, and traveling-grate stokers. The latter type is shown in Fig. 10.

Chain-Grate Stokers. In principle, the chain of a chain grate

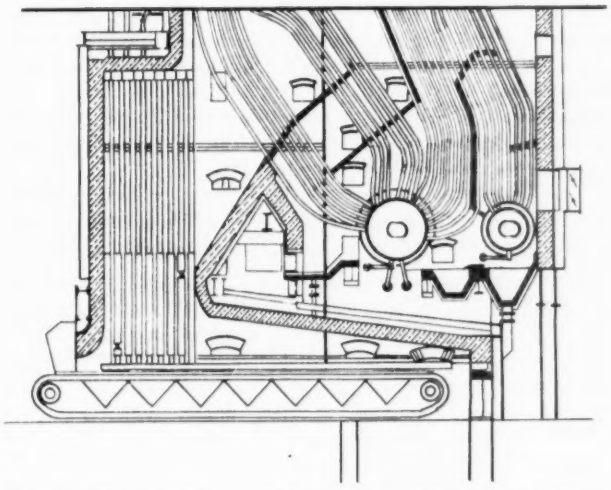

FIG. 10 MODERN TRAVELING GRATE WITH ARCHES FOR ANTHRACITE

consists of a series of individual links made up into the form of an endless chain. The edges of the links are usually serrated to provide from 7½ to 10 per cent free air space for the passage of combustion air.

Traveling-Grate Stokers. The traveling-grate stoker is similar to the chain-grate stoker, the difference being that in traveling grates the grate bars consist of small individual castings or keys carried forward in endless-belt fashion on chains but not being in themselves a part of the chain. The free-air openings are usually about the same as on the true chain-grate type.

A characteristic advantage of the traveling grate is the ability to replace and add burned keys without disassembling the chain.

As all other points of construction and operation are practically identical, the remainder of this section applies equally to chain and traveling grates, even though for the sake of simplicity the term "traveling grate" is used.

An outstanding advantage of these types of stokers lies in the fact that the air can be carefully regulated and zoned as combustion proceeds. As the coal burns progressively from its ignition at the front of the grate to ash at the rear, from three to seven (or even more) partitioned wind boxes are employed to divide the air supply into zones. In extremely large installations, the rear wind box is also subdivided longitudinally to equalize the burning-out of the tail end of the fire.

Size and Design Data. Traveling-grate stokers are manufactured in a wide range of sizes. The largest stoker of this type so far built is located at the Calco Chemical Company, Bound Brook, N. J. This stoker is 24 ft wide × 28 ft long with 672 sq ft of grate. Another outstanding traveling grate is at the Cedar Street Plant of the Pennsylvania Power and Light Company in Harrisburg, which is 23 ft wide × 25½ ft long with 586 sq ft of grate.

It has been authoritatively stated that, with No. 3 buckwheat (barley) of 12,900 Btu, it is possible to design and build a stoker to deliver 300,000 lb of steam per hr continuously. This is given as the present practical limit of size for stokers on anthracite.

At the other extreme, traveling grates are manufactured as small as 3 ft wide × 7 or 8 ft in length, but it is not usually economically feasible to install them for less than 100 developed hp.

The development of the traveling grate has seen many changes with material improvement in both flexibility and combustion. Grate speeds, originally 15 fph, now range from 40 to as high as 100 fph. Fuel-bed thicknesses have decreased from 6 to 8 in. to a present maximum of 4 to 4½ in. (with barley). Vastly improved arch design has stepped up combustion rates from 25 lb to a present practice of 35 to 40 lb, and on extremely large jobs where provision for the re-use of siftings and fly ash has been made, 45 to 50 lb per sq ft have been reported.

Performance Characteristics. With old-style front-arch furnaces, combustible in the ash of 25 to 30 per cent is considered good practice on traveling grates. With the new-type rear arches, the combustible in the ash will be as low as 10 per cent. CO_2 of 12 to 14 per cent can be consistently carried without CO.

CONCLUSIONS

In conclusion, with adherence to a very few fundamental rules, satisfactory economical performance may be expected from barley on several classes of equipment:

1 The coal should be as free from fine undersize or dust as practical.

2 Low ash content is preferable unless the plant has been specifically designed for high-ash fuel.

3 The fundamental rule of firing anthracite is "let it alone."

4 A selection of hand-firing, semi-hand-firing, or fully automatic stokers is available on a basis of initial equipment cost, cost of operating labor, capacity which can be developed in a given boiler, and maintenance cost.

5 Regardless of the firing method, anthracite is free from all smoke and soot and not subject to spontaneous combustion.

ACKNOWLEDGMENT

For assistance in preparing the material for this paper the author is grateful to C. H. Frick, Plant Betterment Engineer, Pennsylvania Power & Light Company, Allentown, Pa.; Roy Johnson, Carbondale Grate Bar Company, Scranton, Pa.; J. H. Kerrick, Fuel Engineer, Philadelphia & Reading Coal & Iron Company, Philadelphia, Pa.; Christian Schillinger, President, Coxe Stoker Engineering Company, Hazleton, Pa.; Charles Warg, Chief Engineer, The McClave Company, Allentown, Pa.; Harvey Rettew, Chief Mechanical Engineer, Philadelphia School Board; John Van Brunt, Vice-President, Combustion Engineering Company; Otto de Lorenzi, Combustion Engineering Company; A. Discussion

A. A. BATO.[3] In the present fuel shortage, the author has rendered a most valuable service in directing attention to barley anthracite, a fuel available in large quantities, yet neglected even in cases in which it could be used with little or no difficulty. Every bit of information in connection with the use of this fuel is welcome, because, in the present emergency, plant managements cannot experiment with new fuels, unless they get full and

[3] Consulting Engineer, 227 Park Avenue, East Orange, N. J. Mem. A.S.M.E.

reliable data enabling them to use such fuels readily in an efficient manner. On the other hand, due warning should be given concerning cases in which the fuel cannot be used without creating disturbances in plant operation.

The writer can state from actual experience that the use of steam jets in the ashpit to avoid clinkering, concerning which the author says that it is believed to be helpful, is actually of great help, easy to install, and comparatively economical, as the amount of steam used does not exceed 2 to 3 per cent of the steam generated, even in extreme cases.

The importance of proper grates has been somewhat overemphasized. There are two points involved; (*a*) excessive sifting of coal into the ashpit, and (*b*) the danger of holes being blown into the fuel bed in the case of too large air openings. As to item (*a*), it must be remembered that on hand-fired grates the coal does not rest on the grate but on the ashes of the coal burned previously, except immediately after fire-cleaning. Accordingly, if grates with small openings are not readily available, the fireman may either cover the grates after fire-cleaning with a thin layer of ashes or preferably small-sized clinkers, or use a small quantity of larger-sized coal for this purpose. As for item (*b*), the danger of holes being blown into the fuel bed is somewhat more serious, but prevails only during the first half hour or so after fire-cleaning, and can be minimized with a little care and frequent checking of the fire. This settles also the question of the grates of various shapes claimed to direct the jets of air at various angles, crosscurrent, etc., into the fuel bed, usually illustrated with "trained arrows." As a matter of fact, the direction, shape, etc., of the air jets reaching the live coal are determined by the ashes immediately under the latter.

The statement concerning furnace draft, "drafts in excess of about 0.10 in. of water can be considered to carry an unnecessary amount of heat to the stack," can be accepted only for cases in which the boiler setting is not tight, or in which other features of the design permit the infiltration of outside air into the furnace or the passes. If the setting is practically airtight, the stack loss depends upon the amount of combustion air only, independent of whether the draft was produced by low forced-draft pressure and high furnace draft, or vice versa. In the case of a heating plant serving a very tall building, the height of the chimney is likely to be determined not by the draft requirements but by the height of the building, resulting in a very high furnace draft. In such a case, it might be more economical to provide the boiler setting with a steel casing to prevent air infiltration, or to install a barometeric damper to reduce the stack draft and thus to save on the power used to produce forced draft.

The low volatile content of barley anthracite, especially when combined with a high moisture content, results in a characteristic of slow and difficult ignition, as compared with the flashy, high-volatile soft coal. This may cause some difficulty, as in the case of traveling-grate stokers, where the ignition of the coal may proceed more slowly than the velocity of the grate, in which event the fire "runs away" from the hopper gate. When this occurs, the grate must be stopped for a short time or slowed down, resulting in reduced performance. Such a condition may be due to faulty arch design, etc., and is likely to prevail when the stoker designer had to adapt the stoker to a narrow and long boiler. It is not likely to happen to a wide and short grate traveling at a slower speed for the same performance.

Slow ignition naturally causes difficulties in picking up sudden peak loads; consequently the real field for the use of barley coal is in plants having uniform loads.

As to mixing barley with bituminous coals, the following procedure should be adopted to avoid difficulties: Suppose the minimum volatile content at which the equipment can operate was found to be, let us say, 22 per cent, this being the volatile content of the coal used in the past. Suppose also, that barley coal of 5 per cent volatile content and bituminous coal of 35 per cent volatile are available. In such a case, the proper mixture will be about 42 per cent anthracite to 58 per cent bituminous coal, giving a volatile content of 22 per cent. In addition to the volatile content, the texture of the coal may have an influence upon ignition characteristics.

The information concerning the importance of the undersized coal is especially interesting. The paper is quite comprehensive, covering the field in a full and practical manner.

J. F. Barkley.[4] For some months, the Bureau of Mines, in co-operation with the War Department, and Athracite Industries, Inc., has been experimenting with the use of mixtures of barley anthracite and slack-size bituminous coal on underfeed stokers. Successful results have been obtained at several plants now regularly using a mixture; trials at further plants are proceeding.

With the eastern caking coals on single-retort stokers, the addition of some 15 to 20 per cent of barley is usually sufficient to open up the fuel bed and give less trouble from caking. At one plant, where the bituminous coal was high in ash, the air-pressure drop through the fuel bed lessened with the increase of barley, making it possible to carry higher ratings than with straight bituminous slack. At this plant, as much as 80 per cent barley gave satisfactory operation and carried the required load. At another plant, 50 per cent of barley was decided upon as the best ratio. At this plant, the number of times the fireman resorted to hand-working the fuel bed was reduced as the percentage of anthracite increased.

The effect of the anthracite varies with the amount of ash in the bituminous coal with which it is mixed. For low-ash bituminous coals, lower percentages of anthracite give better results, the higher percentages giving less flexibility on load changes and lower ratings. For high-ash bituminous coals, higher percentages of anthracite can be used satisfactorily in obtaining similar loads.

The combustible in the ash and refuse from single-retort stokers varied from about 18 per cent for straight bituminous up to 35 for an 80 per cent anthracite mixture. Combustible in the flue ash also increased with the percentage of anthracite.

As a broad general statement, the efficiencies obtained on single-retort stokers with various percentages of anthracite were about the same as with straight bituminous, the gain in better fuel-bed conditions due to the anthracite being offset to some extent by the increase in combustible in the ash and refuse.

The amount of smoke produced lessened as the percentage of anthracite increased.

Author's Closure

Both Mr. Bato's and Mr. Barkley's discussions are appreciated as being valuable additions to this paper. With reference to Mr. Bato's comment with regard to the relatively slow ignition of anthracite, we believe that this can be largely offset by modern arch design to a point which will permit a sufficiently high degree of flexibility on chain-grate stokers for all practical purposes.

The writer is familiar with several installations in dyehouses and other plants having wide fluctuations in load, and in no instance has the lack of flexibility been cited as a disadvantage where arch and furnace design was at all modern.

Mr. Barkley's comments relative to the use of mixtures of barley and bituminous are particularly important since in view of current shortages of soft coal, this subject is receiving very serious attention from many plant owners at this time.

New Combustion-Control Methods for All Standard Fuels

By ROBERT REED,[1] TULSA, OKLA.

As a result of extensive study and field experience with combustion problems, the author offers suggestions for increasing the accuracy of combustion control in all types of furnaces and with all types of standard fuels. This is accomplished by overcoming the existing limitations of flue-gas-analyzing methods either by recorded CO_2 concentrations, or by Orsat analysis. Curves are given which provide a simple means for determining "excess air by CO_2" and "excess air by O_2," by the use of which excess-air control can be quickly adjusted for any change in fuel to obtain unimpaired combustion. The importance of determining the presence of aldehydes in flue gases is recognized and a positive method for their indication has been developed in the form of a simple apparatus which is described. This check on combustion may save considerable fuel, and a great deal of mechanical difficulty with furnaces.

IT is the purpose of this paper to offer some new and perhaps revolutionary suggestions for obtaining genuinely accurate control of combustion in all types of furnaces and with all types of standard fuels. It is needless to say that very precise standards for such control have already been set up and within their limitations these standards have real value for the engineer.

The fact that existing control standards have limitations which are universally recognized justified further thought toward arriving at means of eliminating the limitations as far as possible. We have done considerable research on this problem and offer the results thereof.

It is to be recognized that in a furnace fired with fuel which has fixed characteristics as to analysis and heating value such suggestions as we make will have less bearing than in the case of a furnace fired with two or more different types of fuels. We find, however, that furnaces fired with but one fuel are comparatively rare except in the Gulf Coast area where an abundance of cheap natural gas relegates auxiliary fuels to emergency status. Many such furnaces operate for years without change of fuel.

In the average installation where two, three, or even more types of fuel must be used to maintain operating conditions, or where the analysis of a given type of fuel is subject to change without notice (such as is the case in all refineries), the engineer is confronted with a serious problem in maintaining control of combustion through all the fuel changes.

Limitations of Flue-Gas-Analyzing Methods

Again, as we all know, control is taken through either recorded concentration of CO_2 in the flue gases or by Orsat analysis. If the first is the case, the engineer must estimate the amount of excess air as represented by a given CO_2 indication based upon the ultimate CO_2 available from the fuel being fired. If two or more fuels are being fired in combination in the same furnace the recorded CO_2 will have almost no value at all unless the precise volume of each fuel is known, and it would be necessary to resort to Orsat analysis to find the true condition of excess air.

Orsat analysis, where time and trained technicians are available, is far more satisfactory; but even here we find much room for improvement. The principal fault with such procedure lies in the fact that the Orsat reveals conditions existing at the time the sample was taken and these are subject to change many times during the course of a day. Other sources of error lie in faulty technique with the Orsat; dilution of the sample by air and exhausted or contaminated reagents, or leveling water in the burette.

We hasten to say that through long association we have the greatest respect for the Orsat flue-gas-analyzing apparatus but we must recognize its limitations. It will, if properly operated, indicate the concentrations of CO_2, O_2, and CO in the sample being tested, but beyond that it is no longer valuable.

The engineer may wonder just what further information on the analysis of flue gas might be needed. In order to answer this question, the author will review a little of the theory of combustion and cite some experiences in the field pertaining to this matter.

Combustion Theory

It seems to us that combustion theory is just that, as we have encountered conditions which seem to refute most of it; but after having made such a qualifying statement we will say combustion of hydrocarbons proceeds as a race between hydroxylation and thermal decomposition according to the type of fuel being burned and the manner in which it is burned. A clear flame indicates hydroxylation and a luminous flame indicates thermal decomposition, but neither condition denies or makes impossible the presence of the other. In both cases the end products of complete combustion are CO_2 and H_2O.

In the case of thermal decomposition which produces a luminous flame, the luminosity comes from the presence of glowing free carbon which would, in complete combustion, burn to CO_2 in the normal manner. If this free carbon should, however, be chilled to a temperature below its kindling point before combustion is complete, it will appear as soot. It will also appear as soot if sufficient O_2 is not immediately available.

In the case of thermal decomposition in the course of hydroxylation caused by either a lack of turbulence to force mixture with O_2, lack of O_2, or chilling to a temperature slightly below the kindling point of the intermediate compound, aldehydes will appear in the flue gas. At times free H_2 in quite appreciable quantity has been found in flue-gas samples, but such conditions are rare.

We would point out, therefore, that if the true condition of combustion is to be found, means of indicating the presence of soot, aldehydes, and free H_2 might be necessary in addition to the classical CO_2, O_2, and CO. Soot, if present in appreciable quantity, may be seen emerging from the stack. The presence of free H_2 is rare, so for all practical purposes we need only consider the aldehydes as important.

Some fuels, such as blast-furnace gas, burn with a clear flame

[1] Engineer, John Zink Company.

Contributed by the Fuels Division and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

in which no hydroxylation is involved because the nature of the burning of such combustible elements precludes possibility of luminosity in the flame. With such a fuel the Orsat is entirely sufficient. Coke also falls within this classification as long as its volatile content is very low.

Combustion Experiences in the Field

One of the author's most unusual experiences in connection with combustion problems related to the operation of an HRT boiler in a relatively small, but exceedingly well-managed plant in the Southwest where only one very closely controlled fuel was used.

In this particular plant the management had spent some $5000 improving conditions in the boiler room. New burners had been purchased; the furnaces had been rebuilt; steam leaks had been hunted down relentlessly, and in general no means of obtaining efficient operation of the boilers and the boiler plant had been overlooked. Hourly Orsat samples were taken from the breeching of the boilers and at no time was the excess-air factor as indicated by the Orsat analysis allowed to exceed 10 per cent.

Any engineer would say that with such operation the management could reasonably expect to make steam at a very low cost. Such was not the case, however, for immediately upon starting up the reconditioned plant the fuel costs rose 10 per cent for the same steam production. For 6 months the plant operated in this manner, despite frantic efforts on the part of the plant personnel and various other engineers.

The hourly Orsat checks showed, with minor variations, as follows: CO_2, 10.7 per cent; O_2, 2.0 per cent; CO, 0.0 per cent.

This analysis indicates an excess-air factor of 10 per cent when using a 0.55-specific-gravity natural gas which was the condition set as a standard. Since no CO was indicated, it was felt that satisfactory results were being obtained and the 10 per cent increase in fuel cost was due to some other factor in the plant.

It was at this point that the author entered the picture, merely as a person who had heard of an interesting condition and wanted to examine it firsthand. We found the burner making a beautiful clear fire with no haze. We found the furnace draft was being held at 0.02 in. w.c. and we checked the flue-gas condition with our own Orsat to get identically the same analysis as had been obtained by the plant personnel for some hours previous to the time of our visit. We noted the flue-gas analysis checked with the fuel H/C ratio by weight. We were prepared to agree that the trouble with the plant lay in some other condition, until we went to the back end of the furnace to look through a peephole at the burner in order the better to admire the beautiful fire it was making.

Remember that furnace draft of 0.02 in. at the burner level. The peephole was considerably above the level of the burner so a pressure existed at the peephole level to cause the furnace gases to pour out into the boiler room. The furnace gases were heavy with the odor of formaldehyde and at once we had a clue to the 10 per cent increase in fuel cost.

We suggested increasing the furnace draft and despite some opposition from the plant management, the draft was raised to 0.08 in. w.c. to see what would happen. The load on the boilers was very constant and the fuel flow remained exactly as it had been before the draft was increased; yet the boilers popped within a minute of the time the draft was increased.

The next hourly Orsat sample showed as follows: CO_2, 11.4 per cent; O_2, 2.0 per cent; CO, 0.0 per cent.

This, while it reflected a decidedly improved condition in the furnace, did not check with the H/C ratio of the fuel. A union in the flue-gas sampling line was found to be leaking and, after being tightened, the flue gas checked as follows: CO_2, 11.7 per cent; O_2, 0.0 per cent; CO, 0.0 per cent.

This analysis checked with the H/C ratio of the fuel and was presumed to be correct. The furnace draft was raised again until a true indication of 10 per cent excess air was obtained, and the fuel costs instantly dropped to a level which would justify the installation of the new equipment.

In this case tremendous fuel loss was suffered for more than 6 months despite very careful control according to accepted methods. The errors in this case were the inability of the Orsat to show the presence of aldehydes in the flue gas, and the fact that the leak in the flue-gas sampling line allowed sufficient O_2 to appear in the sample to check the sample against the H/C ratio-by-weight of the fuel.

Another incident, which is very much in point concerns the operation of a large boiler in an Eastern refinery. Fuels being burned were refinery gas and oil. Close control was being maintained according to accepted standards, yet this boiler operated for weeks in such a manner that numerous heat balances refused to check by about 10 per cent. No smoke appeared at the stack and the Orsat showed no CO in the flue gas.

A corps of engineers set about trying to discover the difficulty and failed completely to do so until a most fortunate mistake occurred. A fireman was instructed to raise the draft on an adjoining boiler but misunderstood his orders. He raised the draft on the boiler being checked, and the increased draft produced some startling results.

One of the results was an almost instant increase of about 10 per cent in the production of steam with the same fuel flow, and the other result was that the heat balance checked very closely.

In order to determine just what conditions existed in the furnace with the original furnace draft, the damper was returned to its original setting. Steam production fell off 10 per cent as had been the case before. Samples of flue gas were sent to a laboratory for analysis which revealed the presence of free H_2 along with other unburned hydrocarbons.

In this case, because two fuels were being burned in combination, it is evident that checking the H/C ratio of the fuel against the flue-gas analysis had been neglected and leakage of air into the samples was not detected. The leakage of air into the samples caused O_2 to show in the analysis while in the furnace there was actually a deficiency of O_2 for complete combustion.

Checking CO by Orsat Unnecessary

The author's experience in the field has been almost entirely with oil- and gas-fired furnaces of all types, forms, and sizes. In the course of a number of years of work with such furnaces, we are compelled in all honesty to admit that we have never found CO in detectable quantities with Orsat analysis of flue gas. We do not question its presence in very minute quantity but, without resorting to very painstaking analysis by the iodine-pentoxide method (which is far too exacting and expensive for ordinary use) we have found checking for CO a formality which has an almost inevitable answer of "zero per cent."

In order to avoid confusion, it must be said that, in the burning of coal or coke where carbon is burned directly and alone, following the evolution of such volatile elements as may be present in the fuel, CO in very appreciable quantities may by found. Our remarks do not, then, apply for the burning of such fuels.

We have discussed the issue of CO with many engineers in the field and the consensus is that the CO reagent in the Orsat unless coke or coal is being burned, is more or less useless. Many say frankly that they never use it in ordinary checking. We

recognize this statement as being highly revolutionary but we submit it is concurred in by a majority of operating engineers in the field. Even where coal is being burned, combustion deficiency is not fully indicated by the CO reagent since the volatile elements burn partly by hydroxylation and unburned substances other than CO can, therefore, readily appear in the flue gases.

Controversial as our statements have been, we hope it will be agreed that steps to correct for Orsat deficiencies should be taken in the operation of a majority of the furnaces in America, in order that high efficiencies may be maintained and precious fuel saved.

It has been indicated that by far the greater portion of the deficiency may be taken care of by obtaining suitable means for indicating the presence of aldehydes in the flue gases. It has also been pointed out that there is a very definite relationship between flue-gas analysis and the H/C ratio by weight of the fuel being burned. If the Orsat analysis does not check with this ratio, something is wrong in the operation of the furnace or the method of sampling.

Simple Means for Determining Excess-Air Factor of Fuels

In the course of poring over data on flue-gas analysis, we have also come across a most singular fact which, up to this time, seems to have escaped the notice of the profession at large. This concerns the fact that a certain concentration of O_2 in the flue gases indicates almost exactly the same excess-air factor for any fuel from natural gas to coke within the limits of accuracy of analysis and observation. This also is applicable for firing any of the fuels in the range previously noted in combinations of two or more.

It is our observation that the O_2-excess-air relationship is independent of the CO_2 concentration of the flue gases which would change with variations in the H/C ratios by weight of the fuels being burned. The CO_2 concentration of the flue gas is therefore relegated to the provision of a means of checking the flue-gas analysis against the H/C ratio of the fuel or fuels.

We have plotted two sets of curves on "Excess Air by CO_2" and "Excess Air by O_2" for consideration and use in the field. These curves, Figs. 1 and 2, are based upon data provided by various excess-air charts now in common use. These charts are very accurate as is proved by the fact that the data, shown on the curves as plotted, check calculation of excess air based on the N_2 content of the flue gases. This is true for the entire H/C ranges covered by the curves.

In the use of the curves it is to be presumed that there is no dilution or contamination of the flue-gas sample by air which would confuse results and make the sample useless.

As an example, consider the case of a power-plant boiler being fired with natural gas when, because of an emergency, it is necessary quickly to shift the firing to 75 per cent oil and 25 per cent gas. The use of oil would make it necessary to raise the excess-air factor from, say, 10 to 15 per cent. If excess-air control is being taken on the basis of the CO_2 concentration of the flue gases, only a mathematical wizard could tell the operator in anything like a reasonable time what CO_2 indication he should have and hold to maintain efficiency.

It is here that the "Excess Air by O_2" curves become genuinely valuable as a time and efficiency saver. The chief engineer could instruct his operator to hold the O_2 concentration of the flue gases at 2.9 per cent and let the CO_2 go where it will. If it is necessary later to go 100 per cent on oil, the operator may continue to disregard the CO_2 indicator and hold the O_2 at the same 2.9 per cent to remain with very close limits of the 15 per cent excess-air factor. The same conditions would prevail if the fuel

Natural gas (mean)	$R = 0.33$

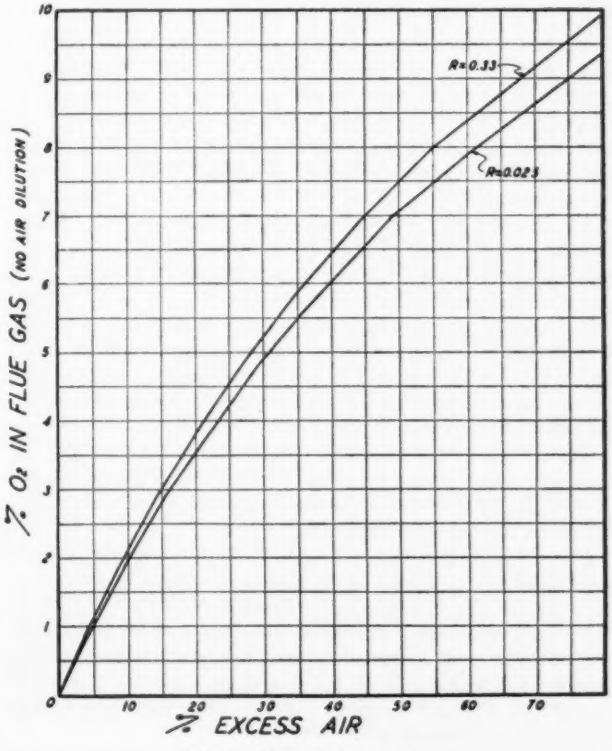

Fig. 2 Excess Air by O_2

$R = H/C$ Ratio by Weight

Coke	$R = 0.025$
Anthracite coal (mean)	$R = 0.025$
Bituminous coal (mean)	$R = 0.05$
Oil (mean)	$R = 0.15$
Refinery gas (mean)	$R = 0.24$
Natural gas (0.55 sp. gr.)	$R = 0.33$

change was from oil to coal or any other combination or combinations necessary to maintain operation.

The O_2 observation may be taken either by Orsat or by any one of a number of continuous recorders which are available. That these recorders are reliable is proved by the fact that they are being used in the control of very delicate catalytic operations in the refining industry with excellent results.

If CO is present in the flue gas, the amount of air necessary to burn it must be subtracted from the indicated excess air to arrive at a true condition. Fuels bearing high concentrations of N_2 will require additional calculation to arrive at true excess-air conditions.

The curves may also be used to check the flue-gas analysis against the H/C ratio by weight of the fuel. As an example, consider a furnace being fired with oil having an H/C ratio of 0.15. If the excess-air factor has been set at 30 per cent, the Orsat analysis should be as follows: CO_2, 11.75 per cent; O_2, 5.07 per cent; CO, 0.0 per cent. If the analysis is at variance something is wrong either by dilution of the sample, lack of sufficient air for combustion, poor mixture of fuel and air, or some other more obscure error. Checking should continue until the flue-gas analysis checks the conditions which should exist with the fuel being burned.

Determining the Presence of Aldehydes in Flue Gases

In considering the presence of aldehydes in the flue gases, we have pointed out that their presence should be indicated by failure of the Orsat analysis to check with the H/C ratio of the fuel being burned. At times, however, because of air dilution of the sample or for some other reasons, this check may become unreliable. Further and more positive means of indicating the presence of the aldehydes becomes necessary.

In collaboration with J. A. Hart and L. N. Hollis, chemists of a major oil company, we have arrived at what we think is a simple and most effective means of indicating the presence of aldehydes in flue gases through the use of a standard reagent in connection with some very simple apparatus. Fig. 3 is a more or less self-explanatory sketch of the apparatus. The reagent is prepared as follows:

Dissolve 0.2 g of certified basic fuchsin in 10 cc of a freshly prepared cold saturated aqueous solution of SO_2. Allow this solution to stand for several hours until all pink color disappears and the solution becomes either colorless or pale yellow. Dilute with distilled water to 200 cc and preserve in a tightly stoppered dark bottle. The reagent must be protected from both light and air. Particular attention is to be directed to the fact that acid fuchsin may not be used. The solution thus prepared is a standard aldehyde indicator.

About 15 cc of the reagent is poured into the flask of the test apparatus which is then connected to a tube leading to the source of flue gas. Before the connection is made, the tube must first have been thoroughly purged of air.

Flue gas is then caused to bubble through the reagent for not less than 2 min by means of the aspirator. The apparatus may then be disconnected from the sampling tube and allowed to stand for 2 min more. Any pink, red, purple or blue discoloration of the reagent indicates the presence of aldehydes, and the operator will know that all the fuel being introduced into the furnace is not being consumed. He may then take steps to find the trouble and correct it.

We think that since the test is so simple and easy to run, it would be well to check the flue gases thus at hourly intervals or (in boiler plants) at the time boiler-water samples are taken.

It should, perhaps, be pointed out that incomplete combustion may exist despite the presence of ample O_2 to burn all the fuel because of failure of the burners to provide a thorough mixture

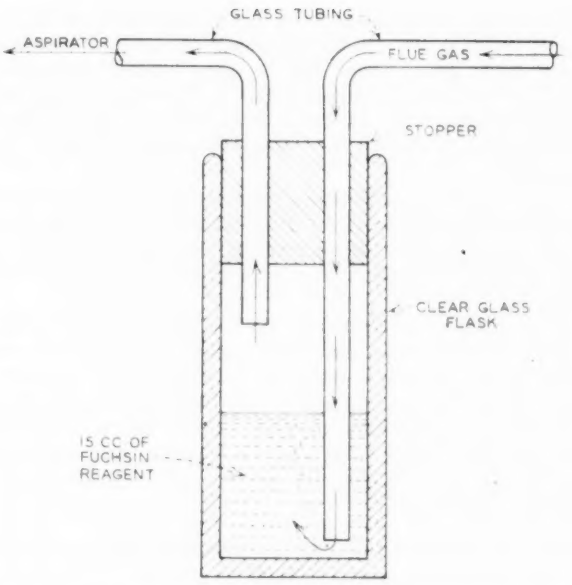

Fig. 3 Apparatus for Fuchsin Aldehyde Indicator as Suggested for Checking Flue Gas

of air and fuel. This failure may be due to plugging, clogging, or obstruction of portions of the burner. A radical change in fuel characteristics, which may not be noted by the plant personnel, may also result in incomplete combustion. The aldehyde test is really a double check which may save a great deal of fuel and mechanical difficulty with the furnace.

Perhaps the greatest source of error in flue-gas analysis lies in dilution of the samples by air. Chinks, cracks, and holes in the furnace, breeching, and stack are chief offenders, while leaks in sampling tubes come in for their share of condemnation. No pains should be spared to see that such sources of dilution are closed.

The best place from which to take a sample is from the furnace proper at a point where combustion has been completed some distance away and also at a point where minimum draft or subatmospheric pressure exists.

Such a point will be found near the arch of the furnace or, in the case of a boiler or generator, in or near the first pass. If the sample is to be taken from a zone of high temperature, it is necessary to use a water-cooled sampling tube to avoid loss of O_2 from the sample in oxidation of the tube metal. Means of obtaining an average sample should be considered important.

Discussion

A. A. Bato.[2] So far we have heard mostly of the presence of hydrocarbons only in the unburned flue gases, but this paper reports other cases involving aldehydes, that is, carbohydrates.

The importance of checking the flue-gas analysis against the H/C ratio, or, to be more exact, against the ratio of $H_2 - \frac{H_2}{8}$ to C, cannot be too strongly emphasized. In a previous paper,[3] the writer showed mathematically that a flue gas may contain CO and unburned H_2 in some form in such proportions that a check of the CO_2 and O_2 content against the H/C ratio may indicate the absence of CO, and therefore be misleading. A. H.

[3] "Flue Gas Computations," by A. A. Bato, *Mechanical Engineering*, vol. 48, 1926, pp. 330–336.

Senner[4] of the Bureau of Agricultural Engineering published the results of some tests made on domestic oil burners with a Bureau of Mines analyzer which involved such cases. Out of eight tests, about six check more or less closely in the manner mentioned, with the gases containing considerable quantities of hydrocarbons, also CO up to 5.1 per cent, with 1.2 per cent as the average.

They also indicate that the gases should be tested for CO with the Orsat, especially when burning light oils, notwithstanding the opinions of the many engineers quoted by the author as saying that the CO reagent in the Orsat is more or less useless. Their opinions may have had their origins in the assumption that, where there is no smoke in an oil- or gas-fired furnace, there is no CO either, consequently, it is enough to set the burner for smokeless combustion and test the gases for CO_2 and eventually for O_2 only. Senner's tests show heat balances with "unaccounted-for" losses up to 15 per cent, which, however, were explained with the aid of the complete gas analysis.

Concerning the effect of leaks in the gas-sampling pipe line, it must be emphasized that it can be misleading in one respect only, i.e., it may give the result that there is more excess air present in the gases than in reality. The analysis will be the same if some air got into the gases through the burner, crack in the brickwork, checkerwork, or any other opening, or a leak in the sampling pipe, and it will be impossible to tell the difference, unless there is some other instrument or control device connected to the furnace indicating the amount of excess air. It is impossible, however, that a gas analysis which does not check with the H/C ratio of the fuel with a leaking sampling tube should check when the leak was removed, as described by the author in connection with the first case mentioned in the paper. An analysis will check or not check with the H/C ratio independently of the amount of excess air, whichever way this air got into the sample, through a leak in the sampling tube, or with the combustion air into the furnace. Accordingly, there must have been an error in the second analysis of the first case given by the author which can be demonstrated mathematically as follows: This analysis gave 11.4 per cent CO_2, 2.0 per cent O_2, and 0.0 per cent CO, consequently, the N_2 content was 86.6 per cent. After the analysis was taken, a leak was discovered and removed in the gas-sampling pipe line, with the result that the gas analysis changed to 11.7 per cent CO_2, 0.0 per cent O_2, and 0.0 per cent CO. In the following it will be proved that this change could not have been the result of the stopping of the leak.

Before the leak was stopped 100 cc of gas contained 11.4 cc of CO_2, 2 cc of O_2, and 86.6 cc of N_2. If as a result of stopping the leak 2 cc of O_2 were removed from the sample, a corresponding amount of N_2 equaling 7.75 cc also was removed, leaving a total of 90.25 cc, while the amount of CO_2 remained the same, that is, 11.4 cc. The latter amount, however, equals 12.6 per cent of the 90.25 cc, and not 11.7 per cent as the analysis taken after the removal of the leakage showed, consequently, there must have been some other cause than the leakage for the 2 per cent O_2 in the second analysis. It seems to be certain, however, that the second analysis, made immediately before the discovery of the leak, was the erroneous one, whatever the cause might have been, as it did not check with the H/C ratio of the fuel, while the others did. These two analyses indicate an H/C ratio of 0.33, which in turn checks with the specific gravity of the fuel gas given as 0.55 of the air, indicating methane, more than 99 per cent pure. The H/C ratio corresponding to the second analysis would have been 0.28, or in order to check with the 0.33 value the O_2 content should have been 0.4 per cent.

A more thorough mathematical evaluation of the results may lead to an explanation of the first gas analysis combined with the 10 per cent loss in the following manner:

It is possible that aldehydes, for instance formaldehyde, is present in the gases, and yet the analysis checks with the H/C ratio, provided some unburned hydrogen is also present. The presence of formaldehyde decreases the percentage of CO_2 in the gases, while that of hydrogen increases it, if the carbon that formed the methane with this hydrogen burns to CO_2. The quantities of formaldehyde and hydrogen may be present in such proportion that they balance each other, with the result that the gas analysis checks with the H/C ratio. To this ratio corresponds a ratio of the two quantities of methane, of the one quantity that was hydroxylated to formaldehyde and water vapor, to the other quantity that was dissociated to hydrogen and carbon, with the latter burned to CO_2. A simple calculation shows that if for 100 parts of methane decomposed with the carbon burned to CO_2 and the hydrogen escaping unburned, there are 35.3 parts of methane hydroxylated to formaldehyde and water vapor, with the latter condensed, both without any excess air, the resulting gas mixture will have a CO_2 content of 11.7 per cent, which is the same as when methane is burned to CO_2 and water vapor without excess air, that is, it will check with the H/C ratio. Evidently, any amount of this mixture can be added to the products of a complete combustion of methane, with or without excess air, and the analysis of the gases will check with the H/C ratio as if there were no hydrogen and formaldehyde in the mixture. This requirement, that for every 100 parts of decomposed methane there shall be 35.3 parts of methane hydroxylated, can be put down in the form of one equation.

Another requirement, furnishing another equation, is that the hydrogen and the formaldehyde present in the proportion just described shall represent a loss of 10 per cent. The solution of the two equations shows that this requirement is fulfilled if 11.4 per cent of the methane burned is decomposed and 4.05 per cent hydroxylated. The loss through decomposition is equal to the heat value of the escaped hydrogen, in this case 7.46 per cent, while the loss due to hydroxylation is equal to the heat value of the escaped formaldehyde, in this case 2.54 per cent of the heat value of the total methane burned.

Under these conditions, the hydrogen content of the flue gases will be 2.76 per cent, which is not impossible, as for instance Senner,[4] in his tests mentioned, found 2.2 per cent. At the same time the formaldehyde content will be 0.515 per cent by volume.

This explains the results of the first test with the exception that it admits decomposition, while the flame is described as not "luminous," that is, indicating decomposition, but "clear." As both decomposition and hydroxylation might have taken place, this point may or may not be a sure indication of the phenomena which actually occurred.

Figs. 1 and 2 of the paper are slight but handy modifications and extensions of Figs. 2 and 3 in Ostwald's "Contributions to Graphic Combustion Engineering."[5] These curves can be used to check the accuracy of the analysis in the Orsat as to the presence or absence of CO, but not the accuracy of the sample-taking from the point of view of possible admixture of air.

The otherwise well-known fuchsin test for aldehydes comes certainly very handy in connection with flue-gas analysis, as it is very simple; still it must be emphasized that it is only qualitative and not quantitative, and that even if used in combination with the Orsat it does not settle the question of hydrocarbons and carbohydrates other than aldehydes. Although the author

[5] "Beiträge zur graphischen Feuerungstechnik," by Walter Ostwald, Otto Spamer, Leipzig, Germany, 1920. An instance in American literature, Heating, Ventilating, Air-Conditioning Guide, 1942, p. 162.

mentions the presence of aldehydes in connection with gaseous and liquid fuels only, it would be worth while to investigate the flue gases of solid fuels as well. The importance of volatile matter in solid fuels appears if we consider that such matter may be contained in a coal to the extent of 35 per cent by weight only and yet represent 41 per cent of the heat value at the same time. Thus, elusive as the hydrocarbons and carbohydrates are when flue gases are analyzed, they may represent considerable losses. That carbohydrates may be present in the products of combustion of solid fuels in some special cases is illustrated in the case of Highland Scotch whiskey, which gets its special flavor due to the fact that the malt used in preparing it is dried in kilns fired with peat. All this is also a warning that flue gases of anthracite and some other "smokeless" fuels should be tested for hydrocarbons.

Altogether, the paper represents a very good contribution to our knowledge of flue gases and their analysis and is excellent proof of the faculty of observation and resourcefulness of the author.

Author's Closure

It was the intention of the author to call the attention of the power industry to the fact that existing methods of combustion control were inadequate. The inadequacy exists through human error as much as in any other manner it is true but this in no wise mitigates the urgent need to save every possible heat unit in the fuel being burned.

It is probable that through weight of sheer numbers of Orsat tests made by him, the author may consider himself quite well trained in Orsat technique, yet as has been pointed out in the discussion it is entirely possible that Orsat data as presented in the paper were incorrect.

Mr. Bato has pointed out evidence of error in the first field test as reported. The author agrees with Mr. Bato with reservations.

If increased draft should cause air to enter the flue-gas passage at a point where the temperature was above the kindling point of such unburned products as might exist, the complete or partial burning of these products might be expected to change the Orsat data obtained. It is also entirely possible for the incomplete combustion to occur in such manner as to cause the Orsat data to check the H/C ratio of the fuel. If such a condition existed before the draft increase it is entirely possible for such burning as might result through leakage after the draft increase to upset the Orsat-H/C relationship.

The question of quantitative as well as qualitative analysis of flue gases for aldehydes has been raised. It is the author's thought that such analysis is hardly justified for two reasons. The first is that if combustion exists in a marked shortage of O_2, products other than aldehydes may easily appear in the flue gases along with the aldehydes, therefore quantitative analysis of the aldehydes alone would not necessarily indicate the true fuel loss. The second reason is that if aldehydes are found in the flue gases the operator should be concerned with means for burning his fuel completely rather than with the fuel loss due to their presence.

Particular care should be taken to check for the presence of aldehydes in the flue gases coming from a furnace in which haze, flame, or terminal combustion exists in the immediate vicinity of cold surfaces such as the pass from the furnace into the boiler tubes, etc. Chilling of the gases in contact with the relatively cold tubes is a very potent source of incomplete combustion. So-called "cold" furnaces such as those in water-wall furnaces, oil-processing furnaces, steel and cast-iron boiler furnaces, or any furnace in which heat is transferred with extreme rapidity from the flame directly to the absorbing surfaces should be checked closely.

Investigation of Blade Characteristics

Performance and Efficiency of Turbine and Axial-Flow Compressor Stages

By J. R. WESKE,[1] CLEVELAND, OHIO

The investigation reported in this paper deals with the flow through blade rows of turbine or axial-flow compressor stages on the basis of airfoil theory. Correlation was established by means of this theory between the aerodynamic characteristics of blade elements and the performance characteristics of the blade row. Test results from a rotating grid of sufficiently low solidity to eliminate interaction of neighboring blades are presented. It was found that the coefficients of lift of blade sections in rotating grids, especially near the hub of the wheel, are higher than might be expected from wind-tunnel tests. Methods of experimental aerodynamic investigation were adapted to the rotating-blade grid for the determination of the profile drag, in an attempt to broaden the basis for a rational determination of the efficiency of turbine and compressor stages.

Introduction

CONSIDERABLE progress has been made in the calculation of the performance of turbine and compressor stages through the development of mathematical theory of potential flow of the working fluid through the blade row. Solutions have been obtained for the lift forces on blades in axial-flow blade rows as related to the lift force on a similar airfoil in the wind tunnel, for the performance of a radial-flow impeller with a given number of blades as related to the corresponding hypothetical impeller with infinite number of blades. Furthermore, the potential theory gives numerical data, e.g., in regard to the effect of thickness of profiles in axial-flow grids upon performance. Thus the potential theory is justifying its value in design, since the results obtained with it are in closer correlation with actual performance data than those of earlier theories.

These advances in potential-flow theory, which strictly apply to perfect fluid, accentuate the need for a logical procedure of calculation relating the known basic laws of fluid flow of the real fluid, in particular the laws of fluid resistance to the performance of the turbine or compressor stage. Of particular interest are (*a*) the effect of skin friction and turbulent-energy dissipation upon efficiency, and (*b*) the effect of fluid resistance in causing deviation from the performance characteristics postulated by potential-flow theory and in limiting the performance of stages.

Review of Earlier Work

The theoretical treatment of the problem of fluid resistance in blade rows and of its effect upon stage efficiency of turbines and compressors has received attention in publications of the following authors: Keller (1),[2] Ruden (2), Amstutz (3), Kraft and Berry (4), New (5), Dozinsky (6), and Soerensen (7).

Amstutz (3) analyzed the losses in a Kaplan turbine and was able to calculate an efficiency curve closely corresponding to the actual curve obtained by test.

Methods of direct measurement of the losses in fixed-blade rows by means of the wake-traverse method were developed by Kraft and Berry (4), by New (5), and are currently used as an effective aid in the design of turbines.

There is justification for the assumption that the three-dimensional nature of the flow through blade rows, whether of the axial- or radial-flow type, has a greater effect upon the efficiency in the stage than it has upon other factors of performance. Under certain conditions, as in the case of very short blades (aspect ratio: $\frac{\text{span}}{\text{chord}} \approx$ unity), the treatment of the flow as a two-dimensional flow may lead to results in regard to losses which are utterly at variance with actual losses. This fact was recognized by Dozinsky (6), who derives relations for the flow through blade rows from analogies drawn with the flow in curved ducts. However, it seems that as long as the nature of flow in curved ducts is not more fully understood in its details than at present, it would appear to be more expedient to analyze the problem of losses in blade rows in first approximation as a two-dimensional problem as done by Keller and Ruden. The effect resulting from the three-dimensional nature of the flow in that case would find consideration in the choice of the numerical quantities involved, or through correction factors applied to the results obtained by the two-dimensional approach. It is obvious that three-dimensional effects are more prominent in blades of small span than in blades of long span.

It is known that the results obtained from measurements of the efficiency of fixed-blade rows cannot be applied directly to moving rows even in the case where the main flow of the working fluid takes place on concentric cylinders. Attempts to measure with fixed instruments the losses in moving rows, however, encounter disproportionately greater difficulties because of the kinematic transformation required when applying the measurements obtained in the absolute system to the determination of the drag of the moving blades.

In view of this, an investigation of the blade characteristics of a rotating-blade row and of their relation to the performance characteristics of the row seemed of timely importance.

Theoretical Analysis

The performance of turbine stages can be related to the interaction of the fluid and the immersed blades, which in the last analysis is a result of the stresses in the fluid working on the surface of the blades. Distinction is made between normal stress or the pressure and the tangential stress or the shear stress because of basic differences of these two types of stresses in regard to their origin and their nature.

The distribution of pressure over the surface of the blade is largely a function of the flow in the main body of the fluid outside of the thin boundary layer in the immediate vicinity of the solid surface. This flow may be regarded as potential flow and can be calculated by mathematical methods (8, 9), developed for its determination.

The distribution of tangential or shear stresses, i.e., skin friction, on the other hand is related to fluid friction, including turbu-

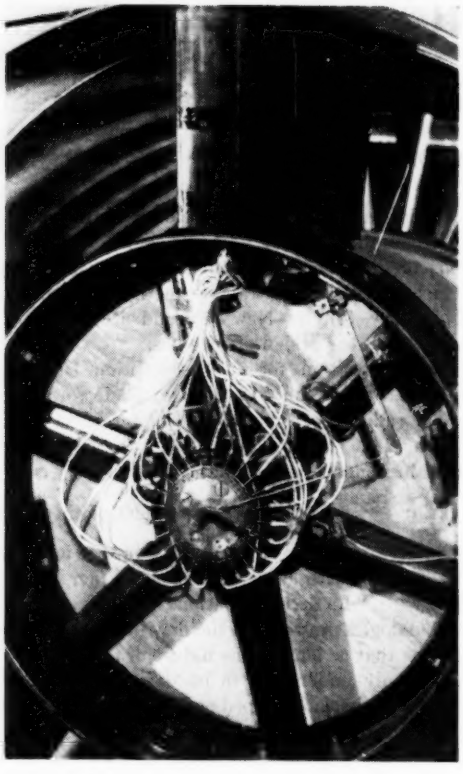

FIG. 1 MASTER AIRFOIL, SELECTOR DEVICE AND WAKE-TRAVERSE MECHANISM

lent momentum transfer. Shear stresses are a function largely of the flow in the boundary layer and depend to a lesser extent upon the pressure distribution over the surface of the blade. The tangential stresses are the source of losses in the blade row, and therefore affect the efficiency of the stage directly. It is seen that the division, originated by Prandtl, of the region of flow into a region in which the effect of viscosity can be neglected, in which the flow consequently may be regarded as potential flow, and into a boundary-layer region, is justified by the contrasting physical nature of the two flows. The present investigation is concerned primarily with the losses, and therefore with the flow, in the boundary layer.

It will be necessary to establish a relation between the factors influencing the interaction of the blades and the fluid resulting from motion of the two relative to each other and the performance data of the blade row. These relations are expressed in a number of equations which are conveniently presented in three groups, each group representing a distinctive link in the chain of the interrelation.

The three groups define the following functional relationships:

(*a*) Between the pressure and shear-stress distribution on the blade element and the resultant force and its direction.

(*b*) Between the force acting on the blade and the quantities of the velocity diagram.

(*c*) Between the quantities of the velocity diagram and the performance data.

NOMENCLATURE

Equations will be formulated embodying the foregoing relations, in which the following nomenclature will be used:

r = radius
z = number of blades
l = chord
$t = \frac{2\pi r}{z}$ = pitch
$\frac{l}{t}$ = solidity ratio
ω = angular velocity
c = absolute velocity
w = relative velocity
β = angles in relative system
β_p = angle of profile section
$\alpha = \beta_p - \beta'$ = angle of attack
$'$ refers to mean condition
Subscript 1 refers to inlet condition
Subscript 2 refers to outlet condition
Subscript u indicates component in circumferential direction
Subscript m indicates component in axial ("meridional") direction
R = resultant force per unit radial length
N = component normal to chord of blade section
M = component parallel to chord of blade section
L = lift component
D = drag component
D_p = pressure-drag component
D_f = friction-drag component
S = component normal to grid
T = component tangential to grid
$C_L = \frac{L}{lq'}$ = lift coefficient
$C_D = \frac{D}{lq'}$ = drag coefficient
ρ = mass density
p = static pressure
η_r = efficiency of blade element
Δh = total head
$q = \frac{\rho w^2}{2}$ = velocity pressure

(*a*) The pressure distribution about a blade section may be obtained theoretically by potential-flow theory or experimentally, e.g., by the method described hereafter. It may be presented as a plot against distance along the chord of the blade section and against distance normal to the chord. Integration of the area under these two curves leads to the component normal to the chord N, and the chordwise component M, of the resultant-pressure force per unit length of blade along the radius, R. Let the component of the resultant force parallel to the grid be denoted by T, normal to the grid by S. Before the lift component L, defined as the component normal to the direction of the mean relative velocity w' past the blade, and the drag component D parallel to w' may be found, this velocity is to be determined from the equation

$$w' = \sqrt{C'_m{}^2 + \left(r\omega - \frac{C_{u1} - C_{u2}}{2}\right)^2} \quad \ldots\ldots [1]$$

and its direction from

$$\tan \beta' = \frac{C'_m}{r\omega - \frac{C_{u1} - C_{u2}}{2}} \quad \ldots\ldots [2]$$

where

$$C'_m = \frac{C_{m1} + C_{m2}}{2}$$

These and the other quantities, defined in the nomenclature, may be identified in Fig. 3.

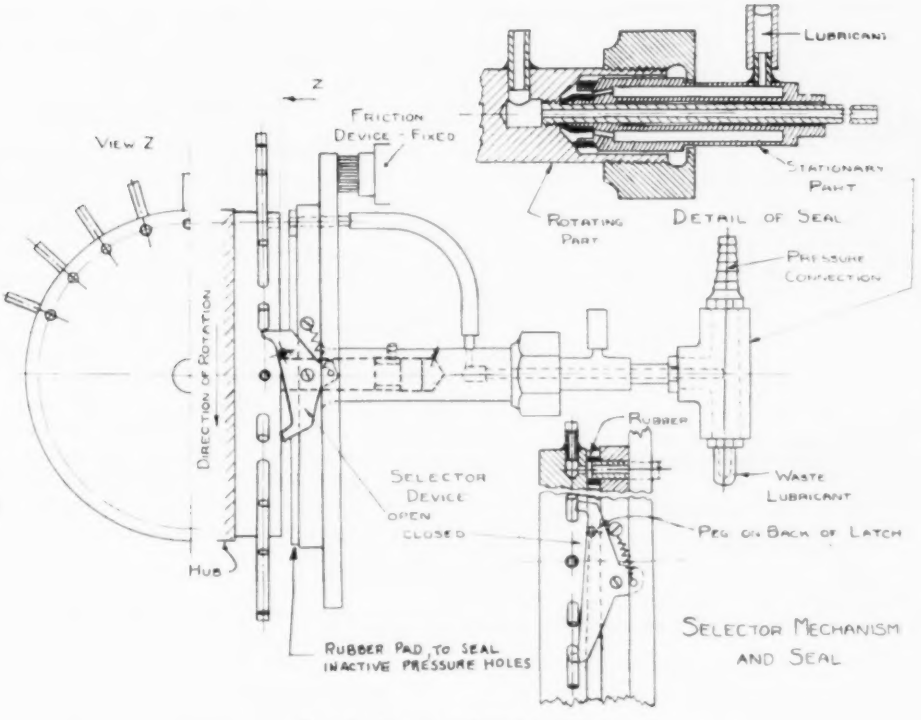

FIG. 2 SELECTOR VALVE AND SEAL

The drag component, obtained from pressure distribution, constitutes only a part of the drag of the blade section, namely, the pressure drag D_p. For conditions of operation of the grid sufficiently close to design conditions so that the circulation

$$\Gamma = (C_{u1} - C_{u2}) \frac{2\pi r}{z}$$

does not vary appreciably along the radius, the induced drag may be neglected, and the skin-friction drag D_f only need be considered, in addition to D_p, since in that case $D = D_p + D_f$. Methods of calculation (10) have been developed by which the skin friction may be calculated theoretically from local shear stresses for airfoils in indefinite flow. These calculations, however, are tedious and do not appear to be readily applicable to blade grids. Experimentally the most promising approach seems to be the measurement of wake traverses, discussed in a later section, which yields the profile-drag directly.

The following nondimensional forms have been used in calculations relating to blade forces

Lift coefficient $C_L = \dfrac{L}{lq'}$

Drag coefficient $C_D = \dfrac{D}{lq'}$

further

$$C_T = \frac{T}{lq'} = C_L \sin \beta' + C_D \cos \beta' \quad \ldots\ldots [3]$$

$$C_S = \frac{S}{lq'} = C_L \cos \beta' \pm C_D \sin \beta' \quad \ldots\ldots [4]$$

where the upper sign applies to turbine the lower to compressor operation.

(*b*) In calculating the velocity diagram of the moving row, it is assumed that the inlet conditions and the axial-velocity component at the outlet are known. The velocity diagram may then

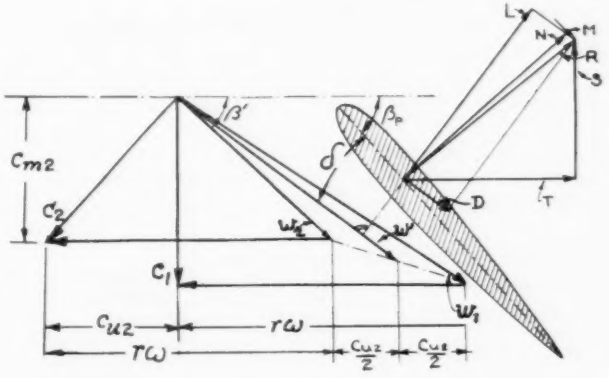

FIG. 3 VELOCITY AND FORCE DIAGRAM

be drawn after the change of circumferential-velocity component has been calculated from the momentum equation

$$2\pi r C'_m \rho' (C_{u1} - C_{u2}) = zT$$

which may be reduced to

$$C_{u1} - C_{u2} = \frac{l}{t} \cdot \frac{C_T}{2} \cdot \frac{C'_m}{\sin^2 \beta'} \quad \ldots\ldots [5]$$

(*c*) The total head Δh across the blade element is given by the energy equation

$$\Delta h = \frac{zSC'_m}{2\pi r C'_m \rho' g} = \frac{C_S}{\sin^2 \beta'} \cdot \frac{l}{t} \cdot \frac{\overline{C'_m}^2}{2g} \quad \ldots\ldots [6]$$

and the efficiency of the blade element

$$\eta_r = \frac{C_T r\omega}{C_S C'_m} \quad \ldots\ldots [7a]$$

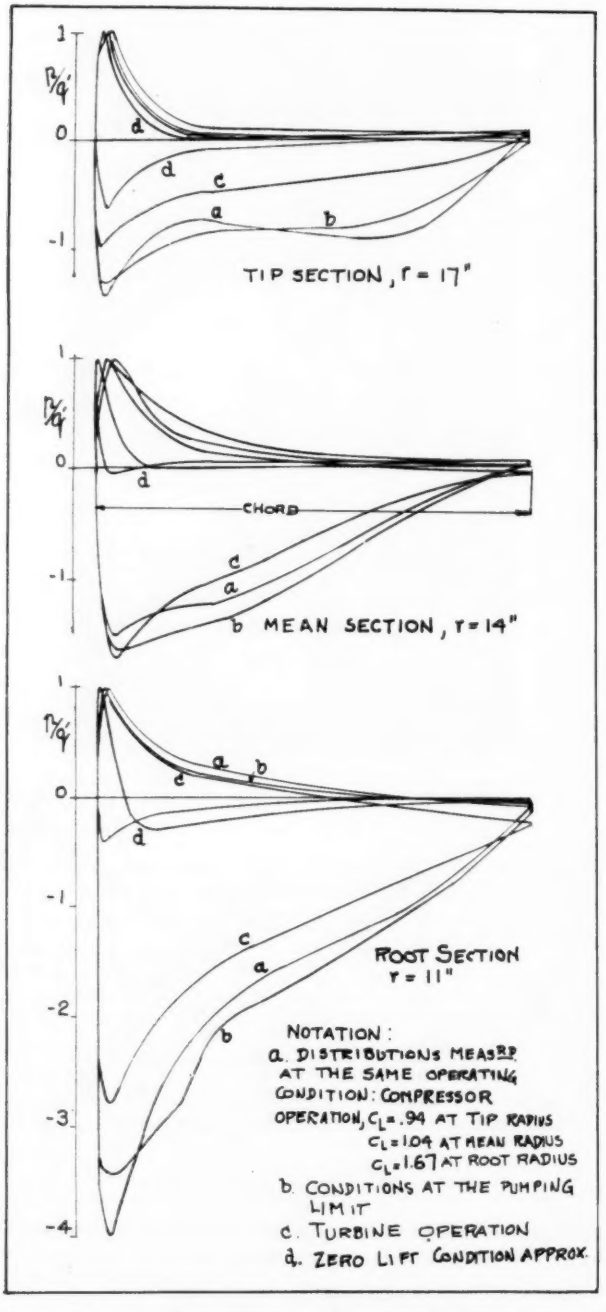

FIG. 4 (*a* to *c*) NONDIMENSIONAL PRESSURE DISTRIBUTION p/q FOR TIP, MEAN, AND ROOT SECTION OF THE BLADE
(Grid with a single airfoil; solidity $1/t$ = 0.09.)

for turbine operation and

$$\eta_r = \frac{C_S C'_m}{C_T r\omega} \quad \ldots\ldots\ldots\ldots\ldots\ldots [7b]$$

for compressor operation.

The efficiency, as formulated here, being based upon lift and profile drag of the blade element, does not take account of certain losses resulting from turbulent momentum transfer associated with the decay of the wake downstream of the row. These losses, however, are small compared with the profile drag in the case of two-dimensional flow for rows of conventional solidity ratios. The equations given in this section are applicable to both compressible and incompressible flow.

EXPERIMENTAL WORK

In developing an experimental program, it seemed important to reduce the test conditions to the greatest possible simplicity. To this end choice was made of a symmetrical profile for the blade section. The direction of flow upstream was chosen to be axial for turbine and compressor operation. Test results of the single-bladed grid only have been included in the analysis, in order to exclude problems of blade-to-blade interference.

Experimental investigations were conducted on a rotating axial-flow grid of 36 in. tip diam and 20 in. root diam, consisting of blades of symmetrical airfoil section N.A.C.A. 0010, twisted for constant geometric pitch when the angle at the root section is 45 deg. The rim was rigidly connected to the blades and rotated with the wheel, thus adding to the rigidity of the latter and eliminating tip leakage. The blades have a chord of 8 in. The number of blades in the grid may be varied and grids of 1, 2, 3, 4, 6, or 12 equally spaced blades may be tested giving a range of solidity ratios $= \frac{\text{chord}}{\text{pitch}}$ on mean diameter of from 0.09 to 1.09. Spacer bolts were provided through each blade, or in place of the blades to hold rim and hub together. One of the blades referred to as the master blade, Fig. 1, was made of lucite and provided with numerous pressure holes arranged in three cylindrical sections, namely, 23 each on the mean radius, 1 in. above the root radius and 1 in. below the tip radius.

The pressure holes in each cylindrical section can be connected successively to a stationary pressure manometer by means of a selector device and seal, shown in Figs. 1 and 2, the latter figure explaining its mechanism. An earlier design of the device was described in (10).

The grid was mounted on the shaft of an electric motor and made a part of a test setup, also described in (10), which was placed into the working section of the return-type wind tunnel of the aerodynamics laboratory of Case School of Applied Science.

Provisions were made to operate the grid both as a compressor and as a turbine. The grid was rotated at speeds ranging from 500 to 1000 rpm. Conditions of operation were varied (*a*) by varying the quantity of air circulated in the wind tunnel, and (*b*) by varying the passage area of an adjustable diaphragm located at the outlet of the cylindrical section, 4 ft downstream of the grid, shown in Fig. 1. This diaphram was found necessary to obtain operation at and beyond the pumping limit, for compressor operation of the grid.

Since the blades are twisted for constant geometrical pitch at the setting just indicated the condition of constancy of circulation, hence of flow on concentric cylinders, is fulfilled only at the point of operation which divides the regions of turbine and compressor operation. Deviations from the assumed condition of flow on concentric cylinders, while inappreciable at small lift coefficients, are presumed to become more severe as the lift coefficients become large. These deviations cause a variation of axial-velocity component between inlet and outlet for which reasons each of these quantities had to be determined separately.

The following measurements were taken:

1 Total- and static-pressure measurements both upstream and downstream of the grid.

2 Measurements of static pressures at the hub and at the casing, both upstream and downstream.

3 Pressure distribution measurements.

4 The rotative speeds were held constant at specified values by a stroboscopic device.

5 Special measurements were obtained of the profile drag of blade sections by means of wake traverses.

TEST RESULTS

Measured pressure was plotted along the chord of the blade section and normal to the cord. The force components per unit length of blade in a radial direction normal and tangential to the chord, respectively, were obtained from these pressure-distribution diagrams and the corresponding resultant force by vector addition, Fig. 3. Not included in the latter is the skin-friction drag which will be treated later.

The data of the velocity diagram, Fig. 3, were calculated directly from measured data, namely, C_{m1}, C_{m2}, and $r\omega$, or from pressure-distribution measurements, namely, C_{u2} from Equation [5], ω' and β' from Equations [1] and [2].

The lift coefficient $C_L = \dfrac{L}{lq'}$ and the pressure-drag coefficient $C_{Dp} = \dfrac{D_p}{lq'}$ were calculated from the respective components of the resultant force, Fig. 2.

The experimental data thus obtained are presented in the following figures:

Fig. 4 (*a* to *c*) shows nondimensional pressure distributions $\dfrac{p}{q'}$ for tip, mean, root radius, for one airfoil in the grid, solidity 0.09.

Fig. 5 shows lift and pressure-drag coefficients, solidity 0.09. For purpose of comparison, Fig. 5 also shows the corresponding coefficients from wind-tunnel tests, reduced to infinite aspect ratio, replotted from (12). The large increase of measured drag coefficients over corresponding wind-tunnel values may be ascribed partly to impairment of the aerodynamic properties of the airfoil surface by the pressure holes and partly to low effective aspect ratio.

It was of interest to ascertain experimentally the magnitude of the profile drag of the blade sections, only a part of which is represented by the pressure drag. To this purpose a total-pressure tube was mounted on the rotating hub placed at a distance of 1.2 in. in the chordwise direction downstream of the airfoil, as shown in Fig. 1. This tube was pointed upstream in the direction of the mean relative flow and connected through the seal to a stationary pressure gage. A simple mechanism was constructed by which the total-pressure tube could be moved between measurements a known small distance in the circumferential direction through operation of the selector device. In this manner, complete total-pressure traverses of the wake were obtained without requiring stoppage of the unit between individual measurements.

While in the present stage, the results of these tests fail to give all the information needed to determine the profile drag precisely, due to the fact that it was not possible to obtain static-pressure readings in the wake simultaneously and coincidently with the total-pressure readings, nevertheless they permit a qualitative insight.

Fig. 5 shows three typical wake traverses obtained from the grid with a single airfoil in place (solidity ratio 0.09) at the same condition of operation at three different radii, namely, at 1 in. above the hub, at the mean radius, and at 1 in. below the rim. Given are the lift coefficients obtained from pressure-distribution measurements, and the areas of the wake profiles. It is noted

that the wake area divided by the velocity pressure of mean relative velocity is smaller for the mean blade section than the corresponding quantity for the section near the tip, although the lift coefficient of the latter is smaller. If the ratio, wake area/velocity pressure of mean velocity, may be taken as proportional to the profile drag, it may be concluded that contrary to what might be expected from the two-dimensional theory, the profile drag near the tip is larger. Three possible explanations are:

1 It may be argued that, since the circulation is not constant along the radial extent of the blade, this result may have been caused by a displacement of the flow outside the wake.

2 The apparent increase of profile drag near the tip may be the result of losses from interference originating in the corners between the blade and the rim. That this latter cannot be the only cause is brought out by the fact that a correspondingly larger value of the ratio was not measured at the section near the hub.

3 The boundary layer of the airfoil and likewise the wake are displaced radially outward by centrifugal force. In order to substantiate the theory of radial displacement of the wake, unexposed Ozalid paper was glued on the surface of the blade around certain of the pressure holes. A mixture of air and ammonia vapor was then emitted by way of the pressure seal through these holes, and an indication of the direction of flow in the boundary layer was obtained by a darkened streak produced by the ammonia vapor on the Ozalid paper. Available photographs of these records are not suitable for reproduction but they indicate clearly that at all points there is an appreciable radial velocity in the boundary layer, particularly on the suction side of the airfoil.

It is concluded from the foregoing that, in determining the profile drag of a blade section of rotating axial-flow grids, account must be taken of the three-dimensional nature of the flow in the boundary layer and in the wake of the blade.

Performance Characteristics

The performance characteristics of the rotating-blade row were calculated from the results of the pressure-distribution measurements for the three blade sections investigated, namely, the total head from Equation [6], and the efficiency of the blade element η_r from Equations [7*a*] and [7*b*]. The results are plotted in Fig. 7. Also plotted on this figure for comparison are corresponding curves calculated from the wind-tunnel characteristics of the symmetrical airfoil profile N.A.C.A. 0009, for infinite aspect ratio. The experimental efficiency curves are based upon the pressure drag only, and no account has been taken of the friction drag of the blade sections.

Conclusions From Experimental Investigation

The following conclusions are derived from the results of the experimental investigation:

1 Tests of blades, placed at wide spacing in a rotating-blade row, show that the range of lift coefficients for the root and mean section exceed the range available for the fixed blade, and maximum-lift coefficients are higher than corresponding wind-tunnel data for compressor operation, as well as for turbine operation.

2 Stalling of the three blade sections investigated was found to occur at the same condition of operation. The stalling characteristics of the blade as far as could be discovered from pressure-distribution measurement, were much less critical than those of the same profile obtained in the wind tunnel.

3 Evidence is presented by the tests that the displacement of the boundary layer and of the wake of the blades radially outward by centrifugal force affects both the lift characteristics and the profile drag, in both cases to the advantage of the root sections of the blades.

4 Performance curves of blade sections, based upon experimental data calculated from pressure-distribution measurement

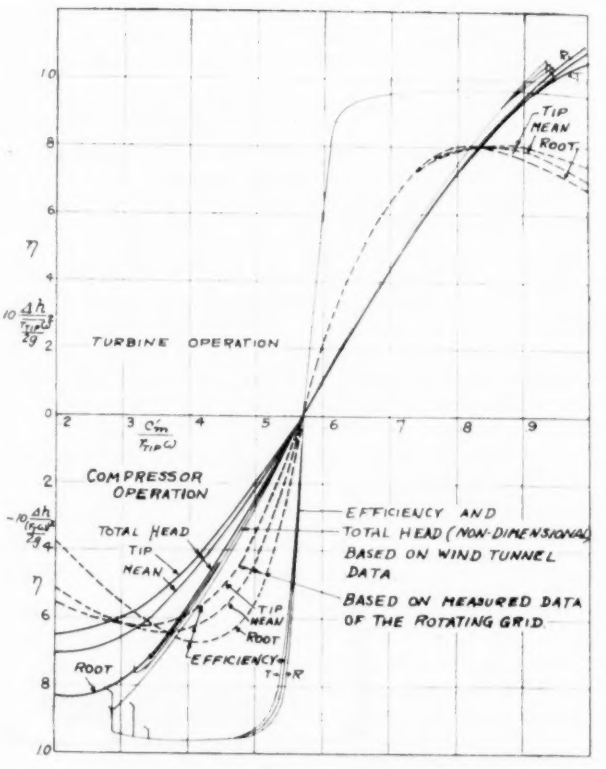

Fig. 7 Total Head and Efficiency

of a rotating-blade row, show lower efficiencies and a higher pumping or stalling limit than corresponding characteristics calculated from airfoil data obtained in the wind tunnel.

Discussion

G. F. Wislicenus.[3] This paper is a most important contribution and one whose significance is obvious at this time, in view of current developments in the field of compressors and turbines. While investigations of a similar nature are being carried out in the industry, to the best knowledge of this writer no one particular study duplicates the author's work. At Worthington, for example, there has been in progress for some time a series of investigations on parallel-vane systems. As a consequence of detailed work in this line, the writer is only too familiar with the inherent difficulties of the problem. The author is to be congratulated on overcoming some of the more serious technical difficulties involved, particularly in the test arrangement.

Perhaps his most valuable single finding is the experimental confirmation of the important difference between the flow in a rotating-vane system, as compared with that in a parallel stationary-vane system, that difference being the "radial" motion of the fluid particles in the boundary layer. While this writer, and doubtless other engineers, had suspected this to be a fact, the experimental proof is of great significance. The author's findings are conclusively demonstrated by his comparison between vane characteristics obtained in the wind tunnel and measurements on the inside of the rotating vane. The writer is referring to the ingenious use of ammonia-vapor traces on Ozalid paper, as well as to the critical study of the change of the maximum lift coefficient. The verification of the idea of radial motion in the boundary layer would alone justify the paper.

As for the theoretical aspects, an explanation of the difference between the through-flow components C_{m2} and C_{m1} (Fig. 3) would be helpful. From the information given in the paper, it seems evident that both the hub and outside periphery are cylindrical; in that case wherein lies the difference between C_{m2} and C_{m1}? From the velocity diagram it is seen that C'_m is assumed to be the arithmetic mean between C_{m2} and C_{m1}. This cannot be explained by the contraction due to the thickness of the vanes, since this thickness would cause C'_m to be larger than either C_{m2} or C_{m1}. Use of the arithmetic mean seems to indicate that the variations in C_m refer to the compression of the fluid. However, for the dimensions and speed of rotation given, the compression of the air must have been practically negligible, particularly with a single-vane grid. The velocity diagram is stated to have been constructed on the basis of measured data. Perhaps some amplification of this statement would clarify the points just mentioned.

The writer assumes that the "pressure drag" is that drag which is caused by a change in the static pressure distribution due to surface friction, since obviously in an ideal fluid the pressures must necessarily be distributed in such a manner that there exists no component in the direction of the flow and, consequently, no pressure drag. The differentiation between pressure drag D_p and the skin-friction drag D_f is new to this writer and an explanation would be appreciated.

In Equation [6] of the paper, Δh is stated to be the total head across the blade element. As given in this equation, it represents rather the change in the static head only, since it expresses the work due to the axial motion under the influence of the axial component S of the vane forces; it does not take into account the change in kinetic energy due to the change in rotation. As a consequence of this fact, the turbine efficiency (Equation [7*a*]) is actually too high and the compressor efficiency (Equation [7*b*]) too low. (Equation [7*b*] is strictly valid for a ship or airplane propeller.) With the present test arrangement, using only a single vane, this discrepancy is quite small, but would be appreciable in actual turbine or compressor wheels.

The author's conclusions are of great interest. It would be helpful if he would explain further what is meant by the statement that the stalling characteristics of the blade were "much less critical." Fig. 5 seems to indicate that, with the exception of one of the curves, the change in lift coefficient during stalling appears to be less drastic than in wind-tunnel tests. Is this the correct interpretation of item 2 of the "Conclusions?"

Does the difference (Fig. 5) between the measured drag and wind-tunnel data hold true for current designs, or has this particular setup certain features which may be responsible for this difference as well as for the low efficiency of the compressor (Fig. 7)? It is of interest to note that the drag coefficients of the turbine and the compressor bear a close resemblance (Fig. 5) but the efficiencies are quite different.

With respect to results obtained with a single vane, the average pressure change through the system would be practically negligible. This is probably responsible for the fact that the maximum-lift coefficients (Fig. 5) are nearly the same for compressor and turbine operation. If the vanes were to be more closely spaced, the pressure increase or drop through the runner would become appreciable as compared with the local pressures on the vanes. Consequently, the vane characteristics in turbine and pumping operation could be expected to differ considerably, the compressor vane acting in a field of increasing static pressure, and vice versa.

The writer is wholeheartedly in agreement with the author's policy of starting his investigations under the simplest conditions possible. It would be most valuable if these experiments could be extended to include more closely spaced vanes. Provisions have evidently been made to increase the solidity ratio to about 1.09. An even higher ratio would yield profitable results, possibly in connection with slightly thinner and suitably curved vanes. It is particularly with such higher solidity ratios that results such as those given in this paper would be of the greatest practical value for compressor and turbine development. For this reason, continuation of this work would constitute a real help to the industry.

Additional details of the technique of pressure measurements in a rotating system and the derivation of the methods of evaluation would be of great interest to many engineers who have been working with similar mechanisms. For instance, Mr. Arthur Oschwald, Jr., of the writer's company brought up the questions: How is it possible to check the measuring system for leakage during rotation; and what steps have been taken to minimize the effect of any possible leakage on the readings? It is hoped that these and other questions can be covered by subsequent publication of information on this interesting and important line of research.

Author's Closure

Dr. Wislicenus' generous comments and constructive criticism are greatly appreciated. An attempt is made to answer the questions raised in the discussion in the following paragraphs.

The velocity and force diagram, Fig. 3, of the paper, was drawn to explain the general relations involved and does not represent any of the diagrams used for the calculation of a particular operating condition. The variation of axial-velocity component was intentionally assumed to be large to show the relation of the mean relative velocity to the relative velocities at inlet and outlet. As pointed out in the discussion, variations of axial velocity are, in the absence of compressibility effects, related to variations of the axial-flow area. A virtual decrease of the axial-flow area downstream of the grid is caused by the wakes of the blades which

[3] Research Engineer, Worthington Pump and Machinery Corporation, Harrison, N. J. Mem. A.S.M.E.

is of significance, however, only in grids of high solidity. No consideration has been given in the paper to the effect of blade thickness.

The designation "pressure drag" was used with reference to the drag calculated from the measured pressure distribution about the airfoil.

The equations for the efficiency, Equations [7*a*] and [7*b*], apply specifically only to the blade grid under investigation, namely, to a single rotating grid without stationary grid upstream or downstream.

As an expression for the efficiency generally applicable to an annular element of a stage consisting of two grids, indicated by subscripts I and II, respectively, either one moving or both moving (the latter case being that of a counter-rotating stage), the following equations, corresponding to Equations [7*a*] and [7*b*] are proposed:

$$\text{turbine} \qquad \eta_r = \frac{(C_T r\omega)_{\mathrm{I}} + (C_T r\omega)_{\mathrm{II}}}{(C_a C'_m)_{\mathrm{I}} + (C_a C'_m)_{\mathrm{II}}}$$

$$\text{pump} \qquad \eta_r = \frac{(C_a C'_m)_{\mathrm{I}} + (C_a C'_m)_{\mathrm{II}}}{(C_T r\omega)_{\mathrm{I}} + (C_T r\omega)_{\mathrm{II}}}$$

It is seen that, for the case of the experimental grid, these equations reduce to the form given in the paper. The form of the equation as just given should have merit in calculations relating stage performance directly to the basic airfoil characteristics. They are believed to apply without restriction to the ducted blade grid.

Available information is insufficient to analyze fully the measured efficiencies, Fig. 7. The low values may be explained partly by the absence of the fixed grid, further by the influence of particular features of the experimental equipment, such as the increase of effective roughness of the blade by the pressure holes, and the absence of fillets at the root and the tip of the blade. Losses in grids and their causes are receiving special attention in further investigations. An extensive investigation of these and other factors has been made by A. Meldahl.[4]

In regard to the experimental demonstration of the occurrence of radial velocities in the boundary layer of the blades of an axial-flow grid, it should be stated that the author, in 1934, presented photographic records of streamlines,[5] obtained by the same method as described in the paper. The same method was applied by P. Ruden to the investigation of an axial-flow fan.[6]

A simple method was developed for checking the experimental pressure-measuring apparatus for leaks. All pressure holes on the airfoil were closed off by a strip of Scotch tape, and a run was taken at which pressure measurements were obtained successively for all pressure connections. Leakage in the rotating portion of any of the pressure leads was then indicated by a negative pressure on the manometer, good connections giving zero reading. The magnitude of the suction pressure served as a clue for the location of the leak, as it is a rough indication of the radial distance of the leak from the axis of rotation.

Notch-Toughness Tests of Carbon-Molybdenum Pipe Material

By W. F. KINNEY,[1] I. A. ROHRIG,[2] AND H. S. WALKER[3]

The development of materials for high-temperature-steam piping is of considerable importance in view of the upward trend in power-plant operating temperatures. Chemical composition, steel-melting practice, and heat-treating procedure, and their effects upon physical properties and microstructure are important factors in appraising the probable behavior of a material in service. The metallurgist and power-plant engineer are particularly interested in the influence of these factors upon notch toughness of the material. Starting with the premise that there may be some correlation between notch toughnessand performance of high-temperature pipe and that significance should be attached to the interpretation of notch toughness with respect to the behavior of carbon-molybdenum pipe material in power-plant service, the authors give details of an investigation conducted in The Detroit Edison Company laboratory on notch-toughness testing. The specific problem studied was to determine the influence on the uniformity of test results and on the magnitude of average notch-toughness values, both at room temperature and at 925 F, of three variables, namely, (*a*) the type of specimen, (*b*) the heat of steel, and (*c*) the condition of the steel. In connection with this testing program, a survey of the literature was conducted and inquiries were directed to various authorities regarding their experience with this problem. The authors conclude that when the significance of notched-bar testing of carbon-molybdenum pipe material is fully understood, it may be possible to select material of the best quality for high-temperature service on the basis of notched-bar tests.

Introduction

As a result of the upward trend in steam-power-plant operating temperatures, considerable attention has been directed toward developing materials for high-temperature-steam piping. As a part of the development, much discussion has taken place regarding the application of carbon-molybdenum steel to superheated-steam piping service and the criteria by which its expected behavior in this service may be predicted. Chemical composition, steel-melting practice, and heat-treating procedure, each with its attendant effects upon physical properties and microstructure, are important factors in the appraisal of the probable behavior of a material in service. The influence of these factors upon one of the physical properties, namely, the notch toughness, is of interest to the metallurgist and the power-plant engineer, because it is believed that notch-toughness data reveal properties that cannot readily be evaluated on the basis of the usual hardness and tensile tests (1).[4]

It is recognized that the property of notch toughness is seldom used as a a measure of acceptability of carbon-molybdenum steel for high-temperature pipe, and notched-bar test failures generally have not been regarded as being analogous to pipe failures in the field. In this regard, McAdam and Clyne (2), in referring to impact tests using notched and unnotched specimens, stated: "An impact test should not be viewed as a simulation of shock in service, and should not be limited to metals that are to be subjected to impact in service." Further, Hoyt (3), in reviewing the likelihood of service failures, has stated: "We have another group of 'internal' notches which are less subject to control because they are not usually visible. Examples of these are . . . heat checks, grinding cracks, shrinkage cracks in castings and welds . . . To these may be added the fatigue crack which forms a very effective notch . . . Corrosion pits and corrosion cracks may also produce a serious notch effect."

Therefore it seems unwarranted to assume that there is no correlation between notch toughness and performance of high-temperature pipe; and a very real significance should be attached to the interpretation of notch-toughness data with respect to the behavior of carbon-molybdenum pipe material in power-plant service. However, information and test data of this nature are meager and controversial issues have been raised from time to time regarding notch toughness, particularly with reference to the apparent lack of uniformity of V-notch test results and the difference in magnitude of average V-notch values as compared with those of keyhole-notch or U-notch results.

In this regard, it might be well to consider for a moment the viewpoint expressed by Hoyt (4) in his statement: "Acceptance of the notched-bar test has not been at all unanimous. Perhaps the chief reason for this is that some experimenters report that the results are apt to be decidedly irregular among themselves and that they give one a feeling that the test lacks meaning and precision. On consecutive heats of steel the results are apt to vary considerably though they are made to the same specification and are otherwise replicas of each other. With such uncertainty and fluctuation it is difficult to correlate the results with other properties or with service records." With reference to tests upon groups of specimens from a material, Hoyt comments further (4): " . . . . . While the results are usually in satisfactory agreement one may and frequently does get quite wide variations . . . . . Does this lack of agreement reflect vagaries of the test itself or does it reveal actual variations in the material? . . . . . One frequently hears that the results are unreliable, by which is meant that, due to imperfections in the testing procedure, sometimes high results and sometimes low results will be secured from identical samples. The chance causes of the spread are assigned to the test procedure and not to the material itself." After further description of tests that were conducted to clarify this question, and in which satisfactory agreement among specimens of a homogeneous sample was obtained, Hoyt (4) concluded, "I could no longer ascribe real variations in test results to vagaries of the test and I believe the point is now seldom raised any more."

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 4, 1943, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

Carbon-molybdenum pipe material is subject to these uncertainties regarding notch-toughness testing. The present investigation in The Detroit Edison Company grew out of an attempt to account for discrepancies that were noticed between notch-toughness values obtained at an outside laboratory and at the Company's research laboratory on supposedly identical Charpy V-notch specimens, when only one or two specimens were tested at a time. Subsequent tests at both locations on a large number of specimens from the same carbon-molybdenum pipe sample in the "laboratory-normalized at 1725 F" condition revealed that the average values and range of values obtained on the two machines checked surprisingly well. It was thereupon concluded that, if a sufficient number of carefully prepared Charpy V-notch specimens were tested, a reasonably close check should be obtained on the material under consideration but that a wide variation in notch-toughness values among individual specimens in any group might be expected. However, this conclusion was predicated solely upon room-temperature tests of Charpy V-notch specimens of normalized pipe, and the question was immediately raised as to whether this conclusion were also warranted for tests both at room temperature and at operating temperature, on various types of standard specimens, on various heats of carbon-molybdenum pipe material, and in various heat-treated conditions encountered in the company's high-temperature piping investigations.

The specific problem therefore was to determine the influence on the uniformity of test results and on the magnitude of average notch-toughness values both at room temperature and at 925 F, of three variables, namely, (*a*) the type of specimen, (*b*) the heat of steel, and (*c*) the condition of the steel. In connection with this testing program, a survey of the literature was conducted and inquiries were directed to various authorities regarding their experience with this problem.

Test Procedure

The tests were conducted on specimens of 10 and 12 in-nps, schedule 100 carbon-molybdenum pipe material from a number of heats which have been furnished commercially during the past 5 years and which represent the more recent installations of this steel. The material tested was made according to the silicon-killed coarse-grained melting practice. The pipe sections were received in either the "hot-rolled and drawn at 1200 F" condition or the "shop-normalized[5] at 1725 F" condition;[6] the former provided the samples, approximately 4 × 6 in. in size, which were laboratory-normalized for 1 hr at the desired temperature in an electric muffle furnace. Specimens were cut longitudinally from the mid-section of each sample, following a pattern that distributed the various types of specimen at random throughout the sample. Notches were cut in that surface of the specimen nearest the outer surface of the pipe wall. Care was taken to see that test specimens were as nearly identical as possible and truly representative of the pipe section from which they were removed.

After a survey was made of the specimen dimensions recommended by A.S.M.E. (5), A.S.T.M. (6), A.S.M. (7), and in various technical articles, the dimensions shown in Fig. 1 were selected as corresponding to approved standards in the essential details.

The scope of the tests included the following:

[5] This term, as used in this paper, describes the normalizing treatment given to pipe in the fabricating shop and is intended to distinguish that procedure from laboratory normalizing of test samples. It is advisable to preserve such a distinction in all laboratory investigations of heat-treated material.

[6] In accordance with A.S.T.M. Designation A206-41T, except that the normalizing temperature specified by the authors' company was 1725 F rather than 1700 F.

TABLE 1 NOTCH TOUGHNESS AT ROOM TEMPERATURE OF A TYPICAL HEAT OF COARSE-GRAINED CARBON-MOLYBDENUM PIPE MATERIAL USING VARIOUS TYPES OF TEST SPECIMEN[a]

Type of specimen	Notch toughness, ft-lb		
Charpy V-notch	59, 82, 87, 78, 72, 80, 78	Avg	**77**

		Max 197	(+17%)
		Min 150	(−11%)

[a] Heat 5085, laboratory-normalized at 1725 F for 1 hr.
[b] Tests conducted at an outside laboratory.
[c] Variation of maximum and minimum values from average value in each group.

1 Tests on 19 Charpy V-notch specimens from a typical heat in the "laboratory-normalized at 1725 F" condition, 7 of which were tested at an outside laboratory.

2 Tests of 7 each of Charpy V-notch, Charpy keyhole-notch, Charpy U-notch, Izod V-notch, and tensile impact specimens all from the same heat in the "laboratory-normalized at 1725 F" condition.

3 Tests at room temperature and at 925 F of 2 typical heats in the "hot-rolled and drawn at 1200 F" condition, using Charpy V-notch, Charpy keyhole-notch, and Charpy U-notch specimens.

4 Tests at room temperature and at 925 F of the same two typical heats in the "laboratory-normalized at 1650 F" condition.

5 Tests at room temperature and at 925 F of the same two heats and two additional typical heats, all in the "laboratory-normalized at 1725 F" condition.

These data were augmented by data on file from inspection tests on several heats that had been shop-normalized at 1725 F.

The V-notch and U-notch specimens were machined using milling cutters whose profiles had been checked and were known to be within the specified tolerances. The keyhole notch was prepared in the standard manner using a fixture to align the specimens and guide the drill. The dimensions of all specimens were checked by means of a sharp-pointed needle on the shaft of a dial gage which was rigidly mounted above a ground face

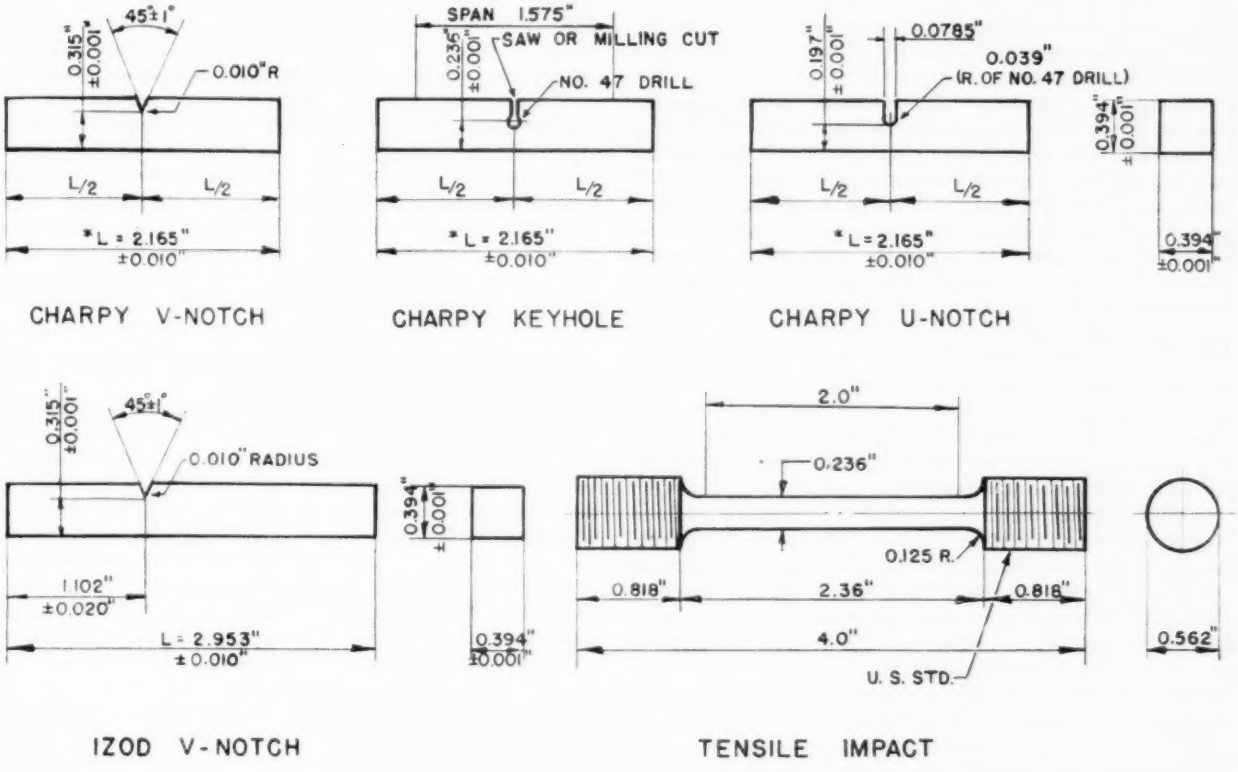

FIG. 1 DIMENSIONS AND PRESCRIBED TOLERANCES[7] OF TEST SPECIMENS

plate. The radius of each notch was checked by enlarging its profile 50 magnifications on a metallurgical microscope and comparing the curvature with the specified radius on the ground-glass viewing plate.

After machining, the specimens were heated at 160 F for about 16 hr to remove machining stresses.

All tests, except those that were made at the outside laboratory, were conducted on a Riehle universal impact-testing machine of 220 ft-lb capacity and of which the velocity of the striking head was about 18 fps. Inasmuch as the five different types of specimen under consideration were all tested on the same machine, this procedure obviously eliminated any variations that might be attributed to (*a*) differences among testing machines, i.e., whether of the Charpy or Izod type, or of different manufacture; (*b*) length of span; (*c*) velocity of the striking head; (*d*) shape and condition of the anvil, vise, and hammer.

The room-temperature tests were conducted at 70 to 75 F in all cases. The testing technique that was employed for the Charpy tests at 925 F was based upon similar tests that had been conducted a few years previously in which it was shown that, after soaking at 950 F for at least 1 hr, a specimen could be rapidly transferred with insulated tongs from the thermostatically controlled electric muffle furnace to the near-by testing machine in about 5 sec, in which time the temperature of the specimen would drop to about 925 F. Timing of the operation during the present tests indicated that there was only a very slight variation in the elapsed time, so the specimens were all at virtually the same temperature at the moment of impact, which is the significant factor in the technique.

The photomicrographs that were made for metallographic examination of each heat and condition of pipe material tested were taken of the V-notch specimen that broke at the value nearest the average for each respective group.

RESULTS OF TESTS

The results of the notch-toughness tests conducted at room temperature on a typical heat of carbon-molybdenum pipe material in the "laboratory-normalized at 1725 F" condition using various types of test specimens are shown in Table 1.[8]

The first two groups of data afford an interesting comparison among 14 supposedly identical Charpy V-notch specimens tested at two different laboratories. The agreement between the two groups is significant both with respect to the average values obtained and to the degree of variation among individual specimens. The average of the 5 extra Charpy V-notch specimens which were tested also agreed with the averages of these two groups. However, because of the wide variation observed, it was thenceforth considered necessary to test at least 7 Charpy V-notch specimens in any group, provided sufficient material were available, in order that the test results might be representative of the sample being studied.

Selection of Types of Specimen for Further Study. As shown in Table 1, the Charpy V-notch tests of this typical heat showed relatively high notch-toughness values, and the results covered a wide range among individual specimens, from 55 to 87 ft-lb in one case. Having established the reliability of the data obtained

[7] "The accuracy that is usually maintained is 0.001 in. although if it will lower the cost of preparing test bars this can be increased to 0.003 in. on harder steels and to 0.005 in. on softer steels without endangering the reliability of the results" (7).

[8] See Fig. 2(*f*) for photomicrograph of this normalized heat.

using Charpy V-notch specimens of this heat, on the basis of tests at two different laboratories, it was felt that the magnitude and variation of these results were typical of the particular heat of steel being tested.

A comparison of the test results on Charpy keyhole specimens with those on Charpy U-notch specimens reveals not only that the average notch toughness of 7 specimens of each type was the same but that the degree of uniformity among individual specimens was practically the same. Both sets of results were considered to be very uniform. In view of this conclusion, it was decided that tests of as few as 3 specimens of either type would suffice in most cases to represent the sample under consideration. For both types of specimen, the average value was considerably lower than that obtained with the Charpy V-notch specimen.

The Izod V-notch test results were somewhat more consistent than the Charpy V-notch results in that there was a smaller spread in the values for individual specimens, and the average value was lower. On the other hand, the Izod V-notch results were not as uniform as the Charpy keyhole and U-notch results, and the average value was much higher.

In the case of the tensile-impact tests, which were introduced to indicate the behavior of the material in the absence of a notch, the unexpected variation that was encountered in the results as the tests proceeded prompted the testing of 12 rather than 7 specimens. At least a part of the observed inconsistency in results has been attributed to improper alignment of the specimen owing to the lack of spherical seats[9] in the design of the testing machine. This prevented the application of the load at the correct angle and resulted in some instances in the bending of the reduced section of the specimen at the moment of impact. This difficulty with the tensile-impact specimens tended to mask differences which might have been present in the material and, for this reason, this type of specimen was dropped from further consideration.

Therefore in keeping with the general practice of most pipe manufacturers and fabricators, who prefer the Charpy keyhole type of specimen and because of the growing popularity of the Charpy U-notch specimen as evidenced by inclusion of it in the A.S.M.E. Boiler Construction Code (5), it was decided to subject these two types of specimen to further investigation along with the Charpy V-notch type of specimen, which had been found to give relatively high average notch-toughness values, and thus provide a significant comparison with the lower values obtained with the other two Charpy specimens.

The results of the subsequent notched-bar tests, conducted at room temperature and at 925 F on various heats of steel in different conditions, are given in Table 2. The photomicrographs in Fig. 2 show the representative microstructure of each group of specimens. An analysis of these data on Charpy V-notch, keyhole-notch, and U-notch specimens discloses the following:

Variations With Type of Specimen. In most cases the average V-notch results were higher than both the keyhole and U-notch values, but in a few cases they were lower. Therefore it cannot be taken for granted that the results obtained on V-notch specimens of carbon-molybdenum pipe material will be consistently higher or consistently lower than keyhole- and U-notch results.

In general, the keyhole- and U-notch results were more uniform among individual specimens than the V-notch results obtained at any test temperature on any heat in any condition in which specimens were tested. However, attention is called to the fact that, contrary to expectations, considerable variation, roughly ±20 per cent, was encountered in one group of keyhole-type specimens and in one group of U-notch type specimens, both from heat 6347 in the "hot-rolled and drawn at 1200 F" condition when tested at room temperature, as shown in (*a*), Table 2. A comparison of the test results on Charpy keyhole specimens with those on U-notch specimens reveals that there was very little difference between the two types as regards the variation among individual specimens or the magnitude of the average results obtained at any test temperature on any heat in any condition.

Variations With Heat of Steel. In the tests at room temperature, wide differences among average notch-toughness values were obtained for V-notch specimens from various heats in a given condition, ranging in one case from an average value of 56 to a value of 105 ft-lb, as shown by a comparison of (*e*), (*f*), (*g*), and (*h*) in Table 2. However, when tested at 925 F these differences ceased to exist and complete agreement among average notch-toughness values for V-notch specimens was obtained for different heats in a given condition.

In the tests at room temperature, it was generally true that the results obtained with the keyhole and U-notch specimens were alike for various heats in a given condition. The only exception was the difference noted in the case of heats 6347 and 5085 in the "laboratory-normalized at 1650 F" condition, shown in (*c*) and (*d*), Table 2, for which no explanation is apparent. However, as in the case of the V-notch tests, complete agreement was obtained when the tests were conducted at 925 F.

Although the average notch-toughness values varied among heats, no heat consistently gave a better degree of uniformity among individual specimens than another, irrespective of the type of specimen used or the test temperature.

Variations With Condition of Steel. For all three types of Charpy specimen, the average notch-toughness values obtained at room temperature for a given heat of steel increased as a result of normalizing at 1650 or 1725 F. Tests at 925 F showed no such improvement as a result of normalizing in that the average values were about the same for a given type of specimen, for all conditions of all heats. Further, good uniformity was obtained in the tests at 925 F for all three types of Charpy specimen, for all conditions of all heats. The greatest variation in any group of specimens tested at 925 F was +9 per cent and —15 per cent for the keyhole-notch specimens of heat 5085, hot-rolled and drawn at 1200 F, as shown in (*b*), Table 2.

It should be noted that tests of material in the "shop-normalized at 1725 F" condition, using both Charpy V-notch and keyhole-notch specimens, gave lower values than those on material in the "laboratory-normalized at 1725 F" condition, as shown in (*e*), (*f*), (*i*), and (*j*), Table 2. The values for individual specimens in each group varied about as much for the shop-normalized material as they did for the laboratory-normalized material.

Discussion of Results

There seem to be almost limitless avenues of approach to the interpretation of the results of the present notched-bar tests but for the sake of conciseness, the discussion will be confined to the factors involved in the practical problems at hand, namely, "how to conduct notched-bar tests on carbon-molybdenum pipe material," and "what is the significance of the results?"

Considering for a moment the broad aspects of the determination of notch toughness of materials, there are numerous variables that affect the magnitude and the uniformity of the results. Further, the relationship between the magnitude of notch-toughness values and the service behavior of the materials always enters into the interpretation of test results and is controversial. By means of correspondence and a review of the literature on the subject, some information but few specific and pertinent data were obtained relative to carbon-molybdenum pipe material. The articles contained in the Bibliography[4] have been reviewed, among others, and found to be the most pertinent to this subject.

[9] Discussed by S. W. Lyon (8).

Information from these sources forms the basis for much of the following discussion.

Variables. The influence of many variables on notch-toughness value has been stressed in the literature. It is acknowledged that these variables, such as the striking velocity, the temperature of the test, the type and dimensions of the specimen, the heat of the steel, and the condition of the steel, all contribute to some confusion in attempting to evaluate notch-toughness results.

Data presented in the literature revealed that striking velocities were commonly within the range of 12 to 20 fps, and that caution in the interpretation of results must be exercised if the striking velocity falls outside of this range. However, as long as all tests under the present investigation were conducted on the same machine, with a striking velocity of about 18 fps, the effect of this variable on the comparability of test results does not enter into the problem.

Temperatures at which notch-toughness tests have been conducted by various investigators range from about —300 to 1000 F. Within that range, the effect of the temperature variable on both the magnitude and uniformity of notch-toughness values is of extreme importance.

Many investigators have commented to the effect that "Temperature has a prominent effect on notch toughness . . . The standard test is made at room temperature and ignores the circumstances that the same notch might produce brittle failure and a low impact value at a temperature but slightly lower" (3). Further, a recent theory regarding the importance of the test temperature on the transition point in notched-bar testing is expressed in the following remarks by Gillett (9): "The transition temperature, at which the type of fracture of a notched-bar specimen of a steel shifts from tough to brittle, is plainly a criterion through which differences not otherwise obvious might be made evident, so low-temperature notched-bar testing might be a useful tool in the constant search for the underlying causes of the 'inherent individuality' of a particular heat of steel, even though that heat might not be destined for low-temperature work." In so far as the authors have been able to ascertain, notched-bar tests of carbon-molybdenum pipe material have not been conducted at lower than room temperature; if such data are available they would be a welcome part of the discussion on this paper. Such an investigation might well be undertaken in order to further this study.

The results of the present investigation have shown that tests at 925 F fail to reveal significant differences among various heats and conditions of steel, in contrast with the marked differences that were observed when testing at room temperature, particularly with the V-notch type of specimen. It may be, as suggested by those that have conducted studies of materials at low temperatures, that even greater differentiation might be possible among heats and conditions of carbon-molybdenum pipe material by means of tests at relatively low temperatures.

Type of Specimen. In order to arrive at a reasonable answer to the question of the correct procedure that should be followed in notched-bar testing of carbon-molybdenum pipe material, frequent reference must be made to the relative merits of the sharp V notch as contrasted with the blunt keyhole or U notch. This phase of the present study found its counterpart in work of other investigators who have commented as follows:

". . . the V-notch type of specimen is likely to be a more sensitive indicator of impact strength than the standard Charpy keyhole specimen" (10).

"The . . . (V) notch is used by some because it gives a larger numerical spread between notch tough and notch brittle materials than is obtained with the more generous radius of the Charpy (keyhole) notch" (7).

"Most commercial specifications are based on values secured from testing Charpy bars with keyhole notch . . . . . this type of notch is not so sensitive to differences in either composition or temperature as the Vee notch . . . . " (11).

The results obtained in the present investigation on carbon-molybdenum pipe material confirm these opinions of other investigators that better discrimination among various qualities of steel is afforded by the sharp V notch than by the blunt keyhole notch or U notch. It is likely that tests made using the keyhole notch or the U notch give a measure of the bend strength under conditions of sudden loading rather than of the true notch toughness of a material.

Heat of Steel. The following comments are probably the most significant that have been found pertaining to the variation that is attributable to differences among heats of steel. Armstrong and Gagnebin (11) stated, " . . . the present state of the art does not permit use of composition, grain size, and heat-treatment as criteria for resistance to impact, which indicates the advisability of subjecting each lot to test . . . "

In a discussion accompanying that paper, Rosenberg mentioned, " . . . impact tests secured on a single heat of steel are more or less peculiar to that individual heat, and will not necessarily be duplicated by another heat of the same kind of steel. Individual heats apparently have what may be termed 'inherent' resistance to impact within certain limits, and this is dependent upon factors not at present recognized . . . "

In the present investigation it is significant that although the chemical composition[10] was virtually the same for all the heats under consideration, and metallographic examination revealed only slight differences in microstructure among the heats in a given condition, the Charpy V-notch test results show marked differences among the average notch-toughness values for various heats; however, these differences are not revealed by either keyhole- or U-notch tests.

Condition of the Steel. The increase in the notch-toughness values as a result of normalizing at either 1650 or 1725 F, which was observed in the room-temperature tests using all three types of Charpy specimen, is consistent with the findings of Crocker and White (12) that normalizing of carbon-molybdenum pipe material improves the notch toughness.

The data shown in (*i*) and (*j*), Table 2, which were incorporated into this investigation from inspection test results on two heats of pipe material, shop-normalized at 1725 F, provide an interesting comparison between the practical aspects of notched-bar testing, as applied to material under consideration for installation, and the technical aspects of notched-bar testing in a laboratory investigation. It is readily apparent that, as judged by the results of Charpy V-notch and keyhole-notch tests on an adequate number of individual specimens, the laboratory-normalized material yielded higher notch-toughness values than the shop-normalized material. Examination of the microstructure reveals that these higher notch-toughness values were accompanied by relatively smaller grain size. These data appear to indicate that, on these two particular heats, the temperature might have been somewhat higher during the shop-normalizing than during the laboratory-normalizing treatment, or that the pipe had been held at normalizing temperature longer during shop-normalizing.

Summary of Discussion

The foregoing observations and discussion comprise the authors' interpretation of the test results that were obtained at

[10] Typical chemical analysis of carbon-molybdenum pipe material used in these tests: C = 0.18, Mo = 0.52, Si = 0.28, Mn = 0.45, S = 0.020, P = 0.017.

room temperature and at 925 F, using various types of specimen from a number of heats of carbon-molybdenum pipe material in various conditions. This discussion has been augmented by frequent references that correlated with the findings in the present investigation.

In so far as the review of the literature is concerned, the present problem on carbon-molybdenum pipe material apparently has not been approached before from the viewpoint taken by the authors, namely, the determination of the influence on the magnitude and uniformity of results of the type of specimen, the heat of the steel, and the condition of the steel. However, this discussion would not be complete without some reference to other possible aspects of the problem that warrant further investigation. Of these, the influence of relatively low temperatures on notch-toughness values of carbon-molybdenum pipe material has already been mentioned. Also, the review of the literature reveals considerable interest in the use of double-width specimens as a source of additional information in debatable cases where tests of standard-width specimens indicate some peculiarity in the particular sample in question.

Riegel and Vaughn (1) mentioned " . . . when we find a heat of steel which is close to the minimum foot-pound value with our single-width specimen, we believe that a more critical examination of the steel is necessary by the use of the intensified notch effect of a specimen similar to that shown but of double the width. If, under this more severe test, the heat of steel gives double the foot-pound values of the single-width specimens, our suspicions on relative sensitivity to brittle cleavage are allayed. If the foot-pound values of the double-width specimens are less than double that of the single-width specimens, the heat is not accepted for the purpose intended."

Inasmuch as such instances occur from time to time in studies of carbon-molybdenum pipe material, it would be well to investigate the influence of double-width specimens on the behavior of various heats in order that some provision for possible tests of double-width specimens might be included in any inspection procedure involving notched-bar tests. Also, some search into the reasons for the inconsistent notch-toughness behavior of carbon-molybdenum pipe material would be in order. Data which might reveal possible relationships between notch-toughness characteristics of this material and microstructure, or steel-melting practice or heat-treating procedure would be a valuable contribution to the art.

Finally, there is the question of correlation of notch-toughness test data and expected behavior in service. While it has been possible in many instances, such as those cited by Riegel and Vaughn (1), for manufacturers to correlate notch-toughness requirements with field performance, and thereby gradually to improve their standards by better control of steel-melting and heat-treating practice, such a correlation, as it applies to carbon-molybdenum pipe material, is still vague. However, it is hoped that if, as those authors point out, wide differences in average notch-toughness values of successive mill heats have been minimized over a period of time, then a similar high standard of steel-melting and heat-treating practice for carbon-molybdenum pipe material might be maintained by continual attention to notch-toughness characteristics of the material.

Conclusions

To summarize the findings under this investigation, it can be concluded that:

1 Charpy V-notch specimens provide a more sensitive indication of differences in carbon-molybdenum pipe material than can be obtained through the use of either the Charpy keyhole- or U-notch specimens.

2 Tests made using the sharp V-notch give a more significant indication of notch toughness than either of the other two types of Charpy notch, inasmuch as the ability of a material to resist propagation of a crack under conditions of sudden loading is accurately revealed by the sharp notch.

3 In cases where the blunt type of notch is sufficiently sensitive for the intended purpose, Charpy keyhole- and U-notch specimens may be used interchangeably for testing carbon-molybdenum pipe material inasmuch as both types of specimen give substantially the same magnitude of average values for any group of specimens and about the same degree of uniformity among individual specimens in any group.

4 An adequate number of carefully selected specimens must be used to insure that the results are representative of the whole sample under consideration. This conclusion is based upon the degree of variation among individual specimens which was encountered with all three types of Charpy specimens. In general, more sharp-notched specimens should be used than blunt-notched specimens.

5 Tests at room temperature show significant differences among heats and conditions of steel, depending in degree upon the type of notch used, whereas tests at 925 F do not reveal such significant differences.

6 Results of notch-toughness tests and metallographic examination of material in the "shop-normalized at 1725 F" condition differed from those obtained on material in the "laboratory-normalized at 1725 F" condition.

Hence the ability of an investigator to determine and evaluate correctly the notch-toughness characteristics of various heats and conditions of carbon-molybdenum pipe material depends upon (*a*) selection of samples from each lot of steel in order to take into account the "inherent" resistance to notched-bar impact that is peculiar to each heat; (*b*) use of a type of notch that will reveal significant differences which may exist among heats and conditions of the steel; (*c*) careful preparation of an adequate number of test specimens to represent the whole sample under consideration; (*d*) proper selection of test conditions, and care in the conduct of the test, to include refinements in technique that will eliminate the testing variables commonly referred to in the literature.

In addition to the physical-strength tests commonly conducted on carbon-molybdenum pipe material at either room temperature or elevated temperatures, the notched-bar test should appeal to producers and consumers, not only because of the significance of the results obtained, but also from the standpoint of economy, simplicity, and expediency.

It can be ably argued by metallurgists that there are very definite influences present in every heat of steel which are directly related to the notch toughness of the material. Therefore it may not be entirely in the realm of speculation to assume that, when the significance of notch-bar testing of carbon-molybdenum pipe material is fully understood, it may be possible to select material of the best quality for high-temperature service on the basis of notched-bar tests.

Discussion

G. F. Comstock.[11] Although we have not used the methods of testing on the type of steel to which this paper is restricted, our general experience with other kinds of steel has led us to agree with the authors in preferring the V notch to the keyhole notch for Charpy tests. Our reasons, however, are different from those of the authors, as we have found that results with the V notch seem to be more consistent so that fewer specimens are required for a reliable conclusion, and accuracy of machining is much more easily secured than with the keyhole notch.

Some strictly comparable results with the two types of notches, obtained in our laboratory from Charpy tests, at 30 deg below zero F, on standard specimens cut from practically the same locations in $^1/_2$-in. plates of commercially rolled low-alloy manganese-copper-phosphorus steel, might be cited to illustrate our experience. Two to four specimens were tested from each location, the results in foot-pounds being as reported in Table 3 of this discussion.

TABLE 3 CHARPY RESULTS ON TEST SPECIMENS

Sample designation	Location in plate	Charpy results, ft-lb at —30 F: V notch	Average	Keyhole notch	Average
4	Center	2.9	3.3	5.1	7.7
		3.6		3.6	
				14.5	
		7.2		26.0	
		7.2		30.4	
4	Near edge	5.1	6.9	26.8	27.8
		8.0		28.2	
		5.1		25.3	
		7.2		25.3	
5	Near edge	3.6	4.7	25.3	20.0
		2.9		4.3	
		2.9		3.6	
7	Center	3.6	3.1	2.9	3.4
		2.9		3.6	
		5.8			
		5.8		34.0	
7	Near edge	5.8	5.4	32.5	24.6
		4.3		7.2	
		2.9		13.7	
8	Near edge	2.2	2.7	18.8	11.6
		2.9		2.2	

The variation in results, leading to doubt as to the value of the averages, or as to the inconvenient necessity for considering all the individual results separately, seems much greater with the keyhole notches. Generally, except for tests at subnormal temperatures, we prefer to use the Izod method, since it is easier to secure concordant check results in that way, and more tests can be made with less machining expense from a limited amount of sample stock.

[11] Metallurgist, The Titanium Alloy Manufacturing Company, Niagara Falls, N. Y.

H. W. Hiemke.[12] This paper appears to be a contribution to the effort currently being made by power-plant engineers to gain a better understanding of toughness and tendencies for embrittlement of carbon-molybdenum steel at power-plant operating temperatures. From an examination of the data, it may be concluded that the materials examined by the authors demonstrated a relatively high degree of notch toughness at room temperature and at 925 F, in both the as-rolled and normalized conditions and for all conditions of test.

The authors quite properly conclude that the V-notch specimen is more sensitive than the U- or keyhole-type of notch. It is the opinion of the writer, however, that this extra sensitivity is obtained by sacrificing reproducibility of results. Also, in order to obtain reliable data with the V-notch type, it is necessary to make a larger number of tests than is the case with the keyhole- or U-type specimen. In this connection, it is desirable to quote the recommendations of the Advisory Committee of the War Metallurgy Committee regarding the advantages of using a Charpy keyhole-type specimen. The reasons for this recommendation were stated as follows:

1 Ease of reproducibility of an accurate radius of curvature of the notch.

2 Extraneous notches caused by drilling the hole are in the most desirable position with a drilled hole.

3 The area back of the notch in the standard Charpy bar is less than the simple beam Izod and a minimum amount of drag and bending occurs in tough specimens thus precluding fictitiously high values.

4 Permits correlation of the data with other results on low temperature impact as most engineering specifications require Charpy keyhole-notched specimens.

It is the opinion of the writer that the reasons advanced by the War Metallurgy Committee in favor of the keyhole-notch type far outweigh the added sensitivity found by the present authors in the use of the V-notch type.

J. L. Holmquist.[13] The authors suggest that the notched-bar impact test may be useful as a correlating device to help establish cause-and-effect relationship between obscure variables not evaluated or even detected by the common tests for chemical composition, tensile properties, and microstructure, and the performance of carbon-molybdenum pipe in high-temperature service.

It is believed to be a generally accepted fact that the notched-bar impact test is sensitive to obscure variables, which may be, for example, very small amounts of nitrogen, oxygen, or hydrogen, the presence or influence of which may not be detected by chemical analysis, tensile tests, or examination of microstructure.

It is to be noted that the notched-bar impact test does not identify such obscure variables, but merely identifies materials which may differ with respect to them although alike in all other respects. The notched-bar impact test can be used as a screening device to single out for the investigator suitable samples on which to pursue his investigations.

The "notch-sensitivity" of a metal depends upon a complex interworking of shear strength, cohesive strength, and the response of each to strain hardening. It is the writer's impression that a full understanding of these phenomena does not exist at present. But the concepts of shear and cohesive strength are more fundamental than notch sensitivity, as measured by the

[12] Senior Materials Engineer, Bureau of Ships, Navy Department, Washington, D. C.

[13] Director of Research, Spang-Chalfant, Division of the National Supply Company, Ambridge, Pa.

notched-bar impact test. A study of the manner in which shear and cohesive strength is influenced by minor constituents or heat-treatment, employing techniques already developed, might be more illuminating than a study of their effect on the notched-bar impact test.

It does not follow that the notched-bar impact tests or shear-cohesive strength studies are the only or necessarily the best means for distinguishing between materials with respect to the presence or absence of obscure variables. Such properties as electrical resistivity, the several magnetic properties, thermoelectric emf, the thermal and stress coefficients of these properties, single electrode potentials, rate of attack by chemical reagents, etc., might provide as good or better screening devices.

It would have added considerable interest to the paper if the authors had given from their experience some examples of differences in high-temperature performance of carbon-molybdenum steels which were considered acceptable for such service by current manufacturing and testing procedures. Only one example has come to the writer's attention. In this case, graphitization occurred adjacent to a weld in a carbon-molybdenum tube. On the other side of the weld, a carbon-molybdenum steel forging was not graphitized, although exposed to the same service conditions for the same length of time.

T. McLean Jasper.[14] The writer wishes to suggest that consideration of the broad subject of testing and correlation with service must be made in connection with notch-impact testing. This has been attempted several times without any marked success. A symposium on "Notched-Bar Impact Test" was presented at the Zurich meeting of the International Association for the Testing of Materials in 1931. The report on such tests covering about 80 pages of carefully considered results on various types of test specimens and on a considerable range of steels together with discussion and summaries should not be overlooked. For the record it is desired to quote from the summary report of Dr. W. Rossenhain, president of Group A, which is attached to the symposium.

"From the reports submitted and the discussion which took place, certain definite conclusions could be gathered:

"1 With one or two dissentients, it was the opinion of those present that the notched-bar impact test is of great practical value as a reception test provided that it is carried out on a test piece of satisfactory type and that the results are interpreted within the limitations which the nature of the test imposes.

"2 It was generally agreed that the results of notched-bar impact tests cannot be used for the quantitative comparison of different types of materials but that they can be used as a test of the quality (satisfactory heat-treatment) of different batches or specimens of similar types of steel. In this sense, the test is to be regarded as little more than qualitative so that only the larger differences between results are important."

While the writer has copied only two of the seven paragraphs in the summary, it is believed that they are sufficient to inject an atmosphere of caution in the use of notched-bar impact values. The experience of the writer in endeavoring to correlate notched-bar impact results with service has been baffling. The test values presented in this paper have not remedied this defect. It is believed that the notched-bar test has been in existence for over 40 years. We are at this time without any "put-your-finger-on-the-spot" correlative values that we may apply in service with a satisfied feeling. It might seem that it would help machinery designers to avoid steels that were most sensitive to sharp corners in designs. Curiously enough notched fatigue specimens do not correlate with the single-blow notched-bar impact.

[14] Engineer, A. O. Smith Corporation, Milwaukee, Wis. Mem. A.S.M.E.

In considering carbon-molybdenum steel and the values presented, the writer would state that the test values are all good. The V notch has a higher average but a greater spread in test-value percentage. This may well be expected since the section area under the V is considerably larger than that under the U or keyhole and also because the V is much harder to machine with the same degree or percentage of precision than the other two.

In saying that the values are all good, it is meant that the values are all above 20 ft-lb and, since no strength and ductility values are available, there is no other comparison to draw. Some of our very expensive high-strength alloy steels cannot meet the values shown nor even a minimum of 20 ft-lb with the Charpy keyhole notch, yet they are successfully used in the services where shock is very severe and where high service stresses are essential for the successful operation of the part.

G. C. Riegel.[15] The authors have taken a rather bold premise concerning the correlation of notch sensitivity of steel and its performance in high-temperature pipe service. After having diligently read the paper, the writer was disappointed in not finding any service data to correlate with the metallurgical investigations of the material. It is presumed that these data will have to await some months or years of application in service.

There remains no question that the more severe the state of stress set up by a notch, the more readily steel can be made to exhibit a brittle behavior. In other words, either the severity of the notch or some other factor such as a change in the geometry of the specimen which increases the state of stress, the influence of temperature, especially a reduction from normal, will bring about a transition of the steel from a tough fracture to a brittle fracture, or failure.

It remains for the technician and the engineer to determine how far from some norm a material may depart, either in its characteristic inheritance, its pretreatment, or application in service (design considered) before one may say this heat of steel is satisfactory or that heat of steel is unsatisfactory.

The pursuit of this plan as proposed by the authors will do much to increase our knowledge and judgment in the manufacture and use of steel.

Authors' Closure

The authors appreciate Mr. Comstock's comments and the supplementary data on a different type of steel, which tend to emphasize the distinction the authors have drawn for C-Mo pipe material between the V notch, as contrasted with the the keyhole or U notch.

Mr. Hiemke has contributed to a broader evaluation of the present problem by bringing to the reader's attention the recommendations of the Advisory Committee of the War Metallurgy Committee. The four points raised are widely recognized and are usually followed in connection with notched-bar testing of most types of steel. With regard to the question of reproducibility of test results, the authors feel that, if a material is reasonably homogeneous or uniform with respect to the factors which influence notch toughness, there is ample evidence that the keyhole and U notch are likely to be more satisfactory than the V notch from the standpoint of reproducibility of test results. However, it seems that the less sensitive blunt notches might be likely to impose a certain "reproducibility of results" on materials which might not be inherently uniform or homogeneous. The findings in the present investigation tend to show this likelihood, inasmuch as it is inconceivable that the great differences in notch-toughness values with the V notches are fictitious or nonexistent if judged by the uniformity of the keyhole-notch results.

[15] Chief Metallurgist, Caterpillar Tractor Company, Peoria, Ill.

When dealing with a coarse-grained C-Mo steel such as is used for high-temperature pipe, and a wide divergence of values for individual specimens in a given group is obtained, investigators cannot afford to overlook the possibility that such variations might be attributable to the absence of uniformity of the factors which influence notch toughness rather than always to deduce that such differences can be accounted for only by "inaccuracies" in the V notch and "lack of reproducibility of results" when using the V notch. Further, the opinion is widely held that scratches or other stress raisers in notches are more likely to affect the magnitude of results when the values are low rather than high; in the present tests, relatively high values were obtained in all cases, so the effect of possible inaccuracies or stress raisers in the V notches should not reasonably be considered as accounting for the variations obtained among individual V-notch specimens.

It should not be inferred that the authors are attempting to depreciate the merits of the keyhole notch for most types of steel, but when it is recalled that the more recent heats of C-Mo pipe material are among the very few coarse-grained types of steel in service, a different aspect of notched-bar testing is introduced that seems to provide an exception to the usual concepts of this test. In this case, test results show that blunt notches do not accurately reveal true relationships among heats and conditions of this steel. The authors have therefore attempted to show by means of these data that the V notch should be used for this particular material if correct evaluation of various heats and conditions of this steel is desired.

This viewpoint is confirmed to some extent by Mr. Holmquist's remarks regarding the ability of notched-bar tests as a "screening device" to identify materials which differ from one another with respect to obscure variables, even though it is acknowledged that the test does not identify those obscure variables. Mr. Holmquist suggests that a study of cohesive strength and shear strength may reveal more explicit information regarding the effect of minor variables in composition or heat-treatment. But since these properties influence notch sensitivity, the notched-bar test might be regarded as a simpler, more practical way of revealing a composite picture of certain differences among batches of material.

Although not usually specified, the notched-bar test has been used by some consumers of C-Mo pipe material as a source of added information and, when low notch-toughness values have been encountered in any particular piece of pipe more comprehensive investigations have been initiated to insure that the pipe will be acceptable. In this way, notched-bar tests have served as a so-called "red flag" in installations of C-Mo pipe, and values for minimum notch toughness have been set, mentally at least, relatively high (about 15 or 20 ft-lb), as compared to those encountered in many low-temperature tests (about 3 to 6 ft-lb).

In commenting on Mr. Jasper's discussion, the test findings are in keeping with point 2 of the Zurich Meeting of the International Association for Testing Materials, on the subject of notched-bar tests, namely, "that they can be used as a test of the quality (satisfactory heat-treatment) of different batches or specimens of similar types of steel. In this sense, the test is to be regarded as little more than qualitative so that only the larger differences between results are important."

The present tests, using the V notch, have revealed large differences among heats and different heat-treated conditions of a single type of steel. Mr. Jasper's word of caution is particularly applicable when making comparisons among various types of steel. Inasmuch as the present tests were limited to a single type of steel and only the test temperature, the heat number, and the condition of this steel were varied, it seems that direct comparison of notched-bar results should be admissible in this case.

The authors wish to reiterate that no attempt was made in this study to correlate, at this time, test results and performance in service. Such a correlation might be possible only after many more years of service data become available. This also applies to Mr. Riegel's comment, for it should be remembered that coarse-grained carbon-molybdenum pipe is a relatively new material, compared with many other types of steel for which test results and service data are abundant.

Firing High-Pressure Furnaces

By E. G. PETERSON,[1] NEW YORK, N. Y.

Developments in the oil-refining industry, particularly in the catalytic-cracking process, have created a need for furnaces capable of carrying high pressures and sustaining high loadings. Direct-fired air heaters are in service which operate at pressures of 45 to 55 psi or higher, with furnace loadings of 500,000 to 2,500,000 Btu per hr per cu ft of volume. The design requirements of such heaters, their details of construction, and operating characteristics are discussed in this paper. The subject is of great importance since the possibility of wide application for this combustion system already exists. One of the most important fields under consideration is that of ship propulsion with power generated by gas turbines and direct-fired air heaters. "Package power" units made up of similar equipment may be used for power generation in small plants.

IT has been fairly common practice for some years to fire boiler or process furnaces under moderate pressures, as, for instance, naval boilers, in which furnace pressures approximate 0.5 psig at high steaming rates. In this same application, heat release in the furnace will reach 250,000 to 300,000 Btu per hr per cu ft of volume. Limited space dictates these operating conditions. In certain industrial processes, furnace pressures have reached 5 psig but, as a rule, the firing is intermittent, occupying a relatively short period in the cycle.

Furnace pressures of 15 to 35 psig and heat liberation in the order of 900,000 Btu per hr per cu ft of furnace volume have been employed in connection with the Velox boiler, as well as in European installations of direct-fired air heaters and gas turbines for power generation. Such installations, however, have been very limited in their number and scope of application.

More recently, in this country, high furnace pressures and furnace loadings have become important in connection with catalytic refining processes in the oil industry. Many direct-fired air heaters are now in service with pressures of 45 to 55 psig or higher, and furnace loadings of 500,000 to 2,500,000 Btu per hr per cu ft of volume. Process requirement and operation of heat-recovery units (gas turbines) fix the system pressure, while economy in pressure-vessel design, rather than space limitation, is responsible for small furnace volume and consequent high rate of heat release per unit volume. In some cases the introduction of high-temperature combustion air (900 to 1000 F) during certain phases of the operation presents a problem in materials and operability. A large volume of relatively cool air, compactness of units consistent with reliability of service at high rates of combustion, and accessibility of parts requiring cleaning or repair demand the careful consideration of the designer of the burner and heater unit.

In the combustion system, Fig. 1, a large amount of compressed air is furnished by a high-efficiency axial compressor. During the process of catalytic cracking, heat is given off and the heated air returned to the inlet of the gas turbine in sufficient quantity to produce all the power required to drive the compressor. On starting up, however, none of this heat is available. Furthermore, the catalyst chambers, ducts, etc., must be brought to operating temperature. Two direct-fired air heaters are provided, one to supply heat to the process chambers, and the other to make up the balance of the energy to be transformed into mechanical power in the gas turbine for operating the compressor.

On starting up, the compressor is run at approximately one-quarter speed by means of a small motor or steam turbine. The air flows to heater No. 1, where its temperature is raised to 900 to 1000 F; the mixture of hot air and combustion gases passes through the catalytic chambers and is reheated in heater No. 2 before entering the gas turbine. The firing rate in heater No. 2 on starting is approximately 50 per cent greater than in No. 1 but, when equilibrium is reached, this burner may be shut off entirely. In some installations, however, heater No. 2 is kept in service continuously to provide additional power output from the gas turbine.

Direct-Fired Air-Heater Designs

The direct-fired air-heater unit, shown in Fig. 1, is one of the earlier designs having a capacity to heat 23,000 cfm of air from approximately 350 F to 900 F. The gas turbine is rated at 3650 hp, 2950 hp being used to compress the air; the additional 700-hp capacity is surplus power which may be used for the operation of the generator.

More recent installations utilize compressors of 40,000 cfm and 60,000 cfm capacity and 55 psi discharge pressure, with gas turbines of 7100 and 9500 hp, respectively, having correspondingly larger air heaters and burners.

Refractory-lined furnaces are largely used. All-metal furnaces have been employed with quite satisfactory results although original cost and maintenance are somewhat higher than the refractory type.

A direct-fired, air-heater burner-and-furnace unit of more recent design, operating at pressures of 3 to 25 psig and firing rates of 10,000,000 to 100,000,000 Btu per hr, is illustrated in Fig. 2. This unit was designed to heat 64,000 cfm of air from 50 to 1250 F outlet temperature, corresponding to a firing rate of 96,000,000 Btu per hr.

While there have been many improvements in the mechanical features of the burner and the heater since the first unit was designed, it is to be noted that the principles worked out for the original unit are employed in the most recent installations. The air stream is divided, and dampers are arranged to control the amount of combustion air to the burner, in order to maintain furnace temperatures sufficiently high to insure complete combustion of the fuel. The additional air to be heated, or "quench" air, passes through the annular space between the furnace and the outer shell and mixes with the hot gases after combustion of the fuel is completed. The burner is exactly the same in so far as mixture of fuels and air is concerned, but it is greatly improved mechanically over the original arrangement.

It is true that experimental units have been set up to operate at furnace loadings up to 10,000,000 Btu per cu ft per hr under conditions of furnace pressures and exit temperatures in excess of those encountered in the commercial applications mentioned, but the tendency in connection with these commercial units has been toward conservative loadings of 250,000 to 750,000 Btu per cu ft per hr, depending upon conditions of operation.

[1] Manager, Air Heater Department, Peabody Engineering Corporation.

Contributed by the Fuels Division and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

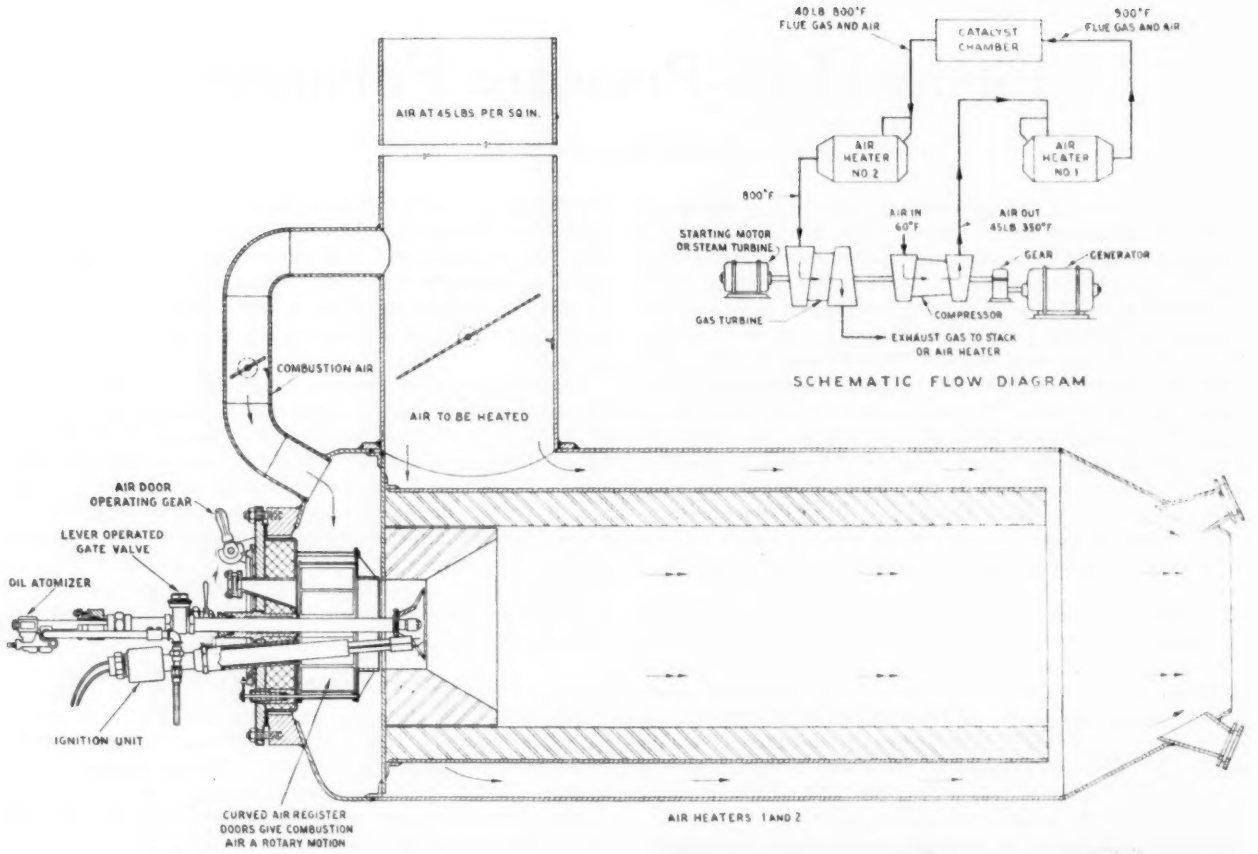

FIG. 1 BURNER ARRANGEMENT

However, in one case, space limitations required a furnace loading of 2,500,000 Btu per cu ft per hr, with 45 psi furnace pressure and 950 F exit temperature. This unit has functioned satisfactorily for several years.

The original burner used in this service is shown in Fig. 3. Only the atomizer was removable with the unit under pressure. The electric igniter was fixed in position, with the result that it was necessary to remove the entire burner in order to replace a cracked porcelain or burned electrode tip. The peephole was rectangular in shape, flared to give a wide vision; however, in bolting the glass between the two rectangular plates, severe mechanical strain could be set up causing rapid failure of the glass when the additional temperature strains were imposed during operation of the unit. The mechanism for the operation of the register louvers consisted of a rotatable ring, mounted on the outside of the register front, carrying pins which engaged in the slots of the cams attached to the driving rods of the louver doors. This necessitated extending individual driving rods through the burner-front plate and fitting them with stuffing boxes to prevent leakage of air from the plenum chamber. Aside from details such as those just enumerated, the general construction features and operating principles of this burner have been retained in later designs.

Fig. 4 illustrates the design of burner now used, subject to modification to fit operating conditions of individual installations. The air doors or louvers, which give the combustion air a rotary motion, are linked together and are operated simultaneously by the master air door whose hinged rod extends through a stuffing box in the register-front plate and is fitted with operating handle and quadrant. The air-register-front plate is designed to meet pressure conditions in accordance with

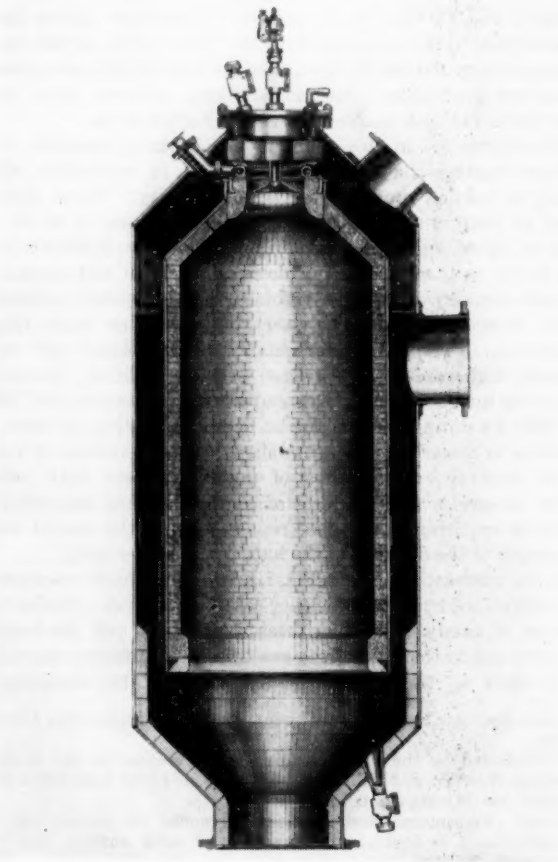

FIG. 2 COMBINED GAS-AND-OIL-FIRED AIR-HEATER UNIT

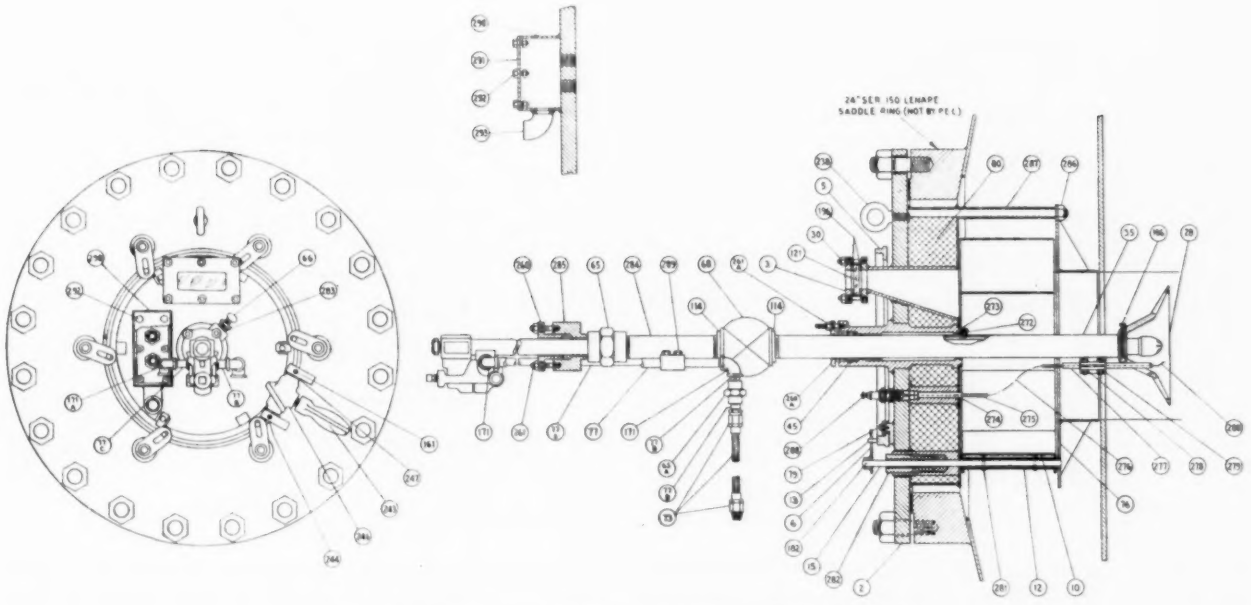

FIG. 3 ORIGINAL DESIGN OIL BURNER FOR HIGH-PRESSURE FIRING

the A.P.I.-A.S.M.E. Code for Unfired Pressure Vessels and is heavily insulated for protection against radiant heat or high-temperature combustion air. The louver doors are of heavy, flanged construction, designed to retain the proper shape under most severe air-temperature conditions. All parts of the burner in contact with highly preheated air are of stainless-steel material, and expansion provision is based upon the type of material and temperature of the combustion air.

The opening through the center of the front plate carries the oil-burner assembly consisting of the diffuser, diffuser pipe, quick-closing valve, union, atomizer stuffing box, atomizer yoke coupling with fittings, and the oil atomizer itself. The position of this assembly with reference to the burner throat may be adjusted with the unit under full pressure. Furthermore, the atomizer may be withdrawn from the assembly under the same condition. The type of atomizer may be either steam-atomizing, as shown, or wide-range mechanical-atomizing; both forms are operating successfully in this service.

Additional openings through the register front plate are provided for the peephole, electric or gas-electric igniter, flame-protection electrode, or other sensitive element, used in connection with the flame-failure shutoff controls. All of these openings are valved so they may be closed against furnace pressure; and, where the adjustment of position or withdrawal of the element is a requirement, stuffing boxes are fitted to prevent leakage of hot gases and possible injury to the operator. The valve in the peephole sleeve protects the glass from radiant heat; the glass is also covered by a wire gauze which assists in distributing heat strain and affords protection against flying glass if breakage from any cause should occur. In some installations, two igniters and flame protectors are used and openings in the register front plate must be provided for the additional unit.

In view of the fact the quick-closing valves are necessarily of steel, in order to conform to general refinery practice, the location of as many as six $2^1/_2$-in. valves on the burner front presents rather a problem when dealing with available commercial valves. In fact, there would not be room for one half that number, so it was found necessary for the company to design and manufacture valves for this special application. The same situation applied to the igniter, and to the small winch which is used for hauling it into position against furnace pressure.

DEVELOPMENT OF SUITABLE BURNERS

The gas burner consists of a tubular ring, correctly positioned to inject the gas fuel into the combustion-air stream, and protected from radiation. The port area is designed to meet operating conditions of capacity, fuel pressure, furnace pressure, fuel-heating value and density, etc. This type of gas burner is stable in operation over a wide range of capacities, pressures, and fuel characteristics.

The development of the burner for this type of service has followed a well-defined pattern. Certain essential standards were set up: (1) The burner must be efficient and capable of producing a flame to fit limited furnace dimensions; (2) it must be operable under all conditions of service; (3) it must provide for the safety of the operator and require a minimum of his time and attention.

High-combustion efficiency is a requirement which has to do not so much with economy in fuel consumption as with the ability to effect complete combustion of the fuel to avoid fouling of turbine blades or passing undesirable combustibles to the process chambers, and to confine the combustion to a relatively small volume without detriment to the furnace lining. This high efficiency is obtained through controlled turbulence resulting from correct shape and disposition of the fuel-distributing elements and baffle surfaces, and the ability to make adjustments from outside the burner with the furnace under pressure.

Under operability, we consider not only mechanical features as selection of materials of construction, allowance for expansion, one-hand control of louvers, etc., but also the fact that the burner must light off with the furnace under pressure and maintain ignition under varied conditions of load. The igniter can be adjusted for correct positioning with respect to the fuel element; adjustable baffle surfaces protect the flame from direct impingement of the air stream until combustion is well established.

Safety and ease in operation have been given careful consideration. The heavy steel register-front plate is adequately insulated against high-temperature combustion air and radiant

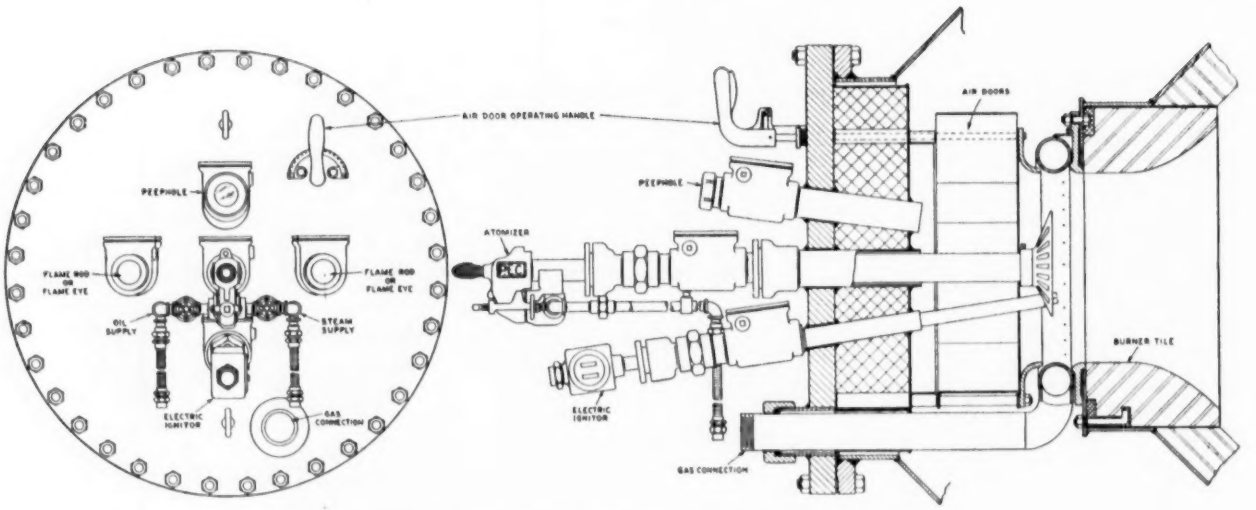

FIG. 4 COMBINED GAS AND OIL BURNER FOR HIGH-PRESSURE FURNACE FIRING

heat; the heat-resisting peephole glass is covered with wire gauze and protected against radiant heat by a quick-closing valve; adjustable or removable elements are positively locked; and flame-protection devices are built into the burner to insure closing of fuel valves in case of flame failure from any cause and to prevent reignition, except as controlled by the operator.

CONTROL AND PROTECTIVE DEVICES

The flame-protective system, Fig. 5, consists essentially of a relay which receives its impulse from a flame-contact rod or electrode when burning gas, or a photoelectric cell when burning oil, and in turn transmits this impulse to solenoid valves directly in the fuel lines or mounted on air-controlled, diaphragm-operated valves in the fuel line. The layout shown covers a dual system, consisting of two relays, two flame rods, two transformers, etc., which operate in parallel. The object of the dual system is to minimize the possibility of delays in starting or shutdowns due to short-circuit or ground in the various elements making up the control system.

In operation on oil fuel, the flame eye will be inserted in one of the flame-rod openings which are so arranged that this element can "see" the oil flame. The oil burner can be operated and adjusted by hand on starting up, by closing the key switch which by-passes the relays and opens the solenoid valves in the oil- and steam-supply lines. During the time the key switch is closed, an alarm sounds to warn the operator that the safety-control device is not in operation. Ignition of the oil flame is obtained on closing the push-button switch and, after the flame is adjusted for stable operation, the key is withdrawn from the key switch and the control takes over. During the time the burner is on oil, the gas-flame electrodes are withdrawn, at least out of the range of the oil flame, for their protection.

When starting up on gas fuel, the two flame electrodes are placed in position and the gas-supply valve in the main line is opened. Closing the push-button switch completes an electrical circuit through the transformers and opens a solenoid valve in the by-pass line to the gas-pilot burner. Ignition of the pilot burner takes place at a low rate which is increased when the pilot flame contacts the electrode. At the same time, the pilot flame is increased in size through the opening of the second valve in the pilot line, and the impulse from the relays is transmitted to the three-way magnetic valves controlling the diaphragm air supply to the main gas valve which opens and permits flow of gas to the main gas ring. When ignition is completed and the push button is released, the by-pass solenoid valve shuts, and both the center pilot burner and the main burner are under control of the relays.

Generally, the control systems are considerably simpler than that shown as they are designed for operation on only one fuel, either gas or oil. On certain gas-fired installations, where oil may be used simply as an emergency fuel, it is not considered essential to have the safety shutoff controls on both fuels. The complication in the system arises from the fact that no one as yet has devised a photoelectric device which will operate on gas fire without a dangerous time lag. It is therefore necessary to use the conductivity of the gas flame rather than radiation to a photoelectric cell which, if it were feasible, would necessitate only a change in filters to operate on either oil or gas flames.

Modifications to this control system are made to suit operating conditions, burner capacities, etc. However, the general features or principles apply to all installations. In any case, the most important consideration is the proper location of the elements which transmit the flame impulse to the relays.

DETAILS OF MODERN HEATER

From the beginning of our connection with this type of work, the essential form and dimensions of the direct-fired air heater have been considered from the viewpoint of the burner designer. To the best of our knowledge, the majority of, if not all, air heaters of this type, whether of our own or other manufacture, have followed the same basic principles developed for the first installation. On first approach to this problem, it was recognized from previous experience with furnace loadings up to 1,000,000 Btu per hr per cu ft of volume, that the high combustion rates involved required a high-efficiency turbulent-type burner, and that such a burner would give its best performance with a limited quantity of excess air through the burner proper. The first step, then, was to divide the air stream so that the quantity of combustion air could be properly controlled and the burner function within its efficient range. The remaining air was diverted to the annular space between the furnace and the outer shell, or allowed to enter the furnace for cooling purposes, outside of the combustion zone. Structurally, the heater shell is designed in accordance with the A.P.I.-A.S.M.E. Code for Unfired Pressure Vessels of materials and workmanship as specified by the Code, with the proper disposition of refractories and insulation to prevent metal parts attaining temperatures beyond those for which they are designed. Air passages must be so

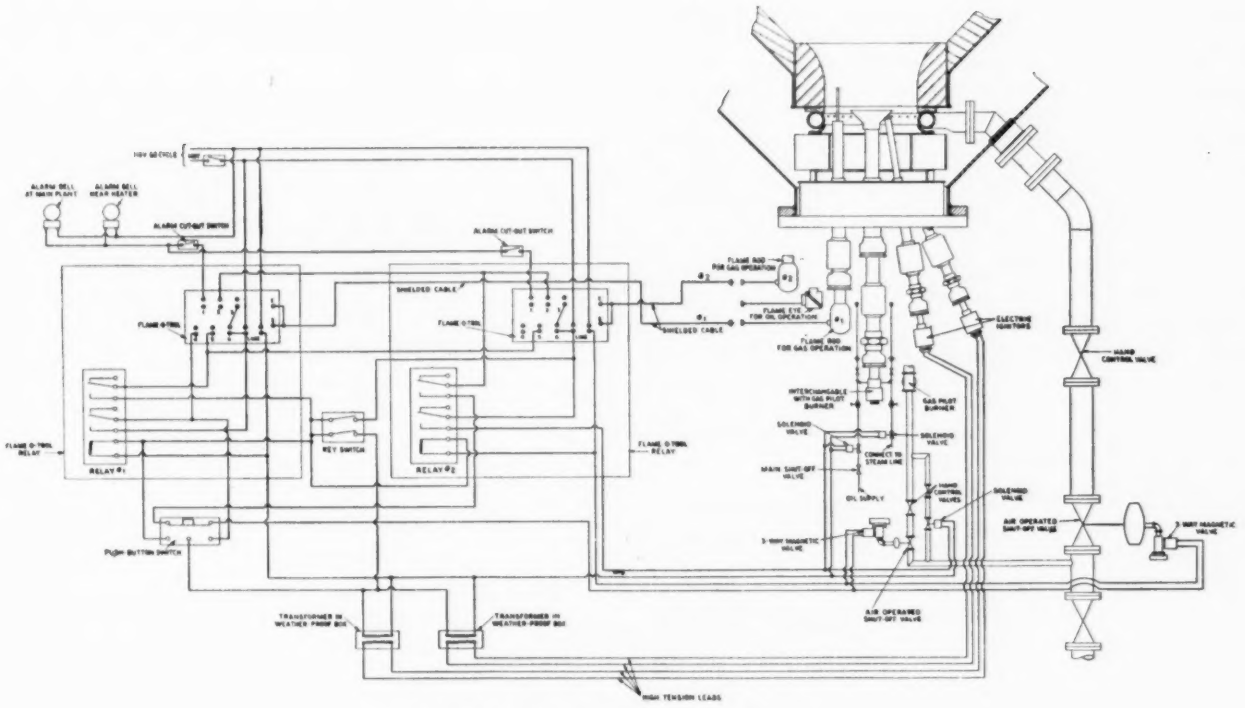

FIG. 5 DUAL-FLAME PROTECTIVE SYSTEM

designed as to keep down pressure loss, and dampers must be easily operated and their controls accessible to the operator, in order to insure that adjustments will be made when required for satisfactory operation.

The flow of heat through the furnace lining and through the outer-shell insulation must be considered in designing the air passages, selecting materials, and applying stiffening to the various members. When units are insulated externally, the thickness of such insulation must be proportioned to the type and thickness of the furnace lining, also to the velocity and quantity of air passing through the annular space between the furnace and outer shell, in order that metal temperatures in the furnace casing and shell are kept within reasonable limits. Convection transfer rates to the cooling air in the annular passage are relatively low, since velocities ordinarily do not exceed 20 fps. However, the area in contact with the air is quite large, as radiation of heat across the passage from the furnace casing to the shell makes the inner surface of the shell effective in the transfer of heat to the cooling air.

Toward the end of the annular passage some insulation should be provided on the inside surface of the shell as the cooling effect of the "quench" air diminishes. The air passage is thus restricted, velocity increased, and a somewhat higher heat-transfer rate obtained for a short distance.

In some cases, insulating firebrick, coated with a special cement to resist sloughing effect of high-velocity air, is used for protection of the shell; it is relatively inexpensive and easy to install. On other units, high-efficiency block-type or castable insulation is employed, requiring a cover of alloy steel for protection against erosion by the air and furnace gases. Where alloy steel is used in this manner, allowance must be made for its higher coefficient of expansion, also for its high temperature compared with the protected shell. Unless provision for this difference in expansion between shell and insulation cover plate is made, buckling of the light cover plate will take place.

When alloy steels are used in the construction of pressure parts of the vessel and are joined to carbon steel, the difference in expansion rate will set up severe strain unless the joint is properly located.

MANY APPLICATIONS POSSIBLE

While we have quite properly confined our discussion to applications in the catalytic refining field, in which we have had experience with upward of 100 installations, there are other applications outside of this field which are gaining in importance and which will demand more thought and consideration on the part of the engineering profession when the present demand on our energies for production of indispensable necessities, such as 100-octane gasoline, begins to abate somewhat. Of these other applications that of ship propulsion by power generated by gas turbines and direct-fired air heaters probably holds the greatest appeal, although we should not lose sight of the fact that there are many problems in other lines which are opening up to consideration. The possibility of applications of direct-fired air heaters to driers, incinerators, etc., and of the development of "package units" for power generation in small plants, requiring a minimum of technical skill for installation, operation, and maintenance, appears to be extensive.

The author realizes that only the high spots of this comparatively new subject have been covered and that he has dealt more in generalities than in specific data. However, the object of this paper has been to acquaint the prospective user of this type of equipment with what he should expect from the designer of the unit rather than to give instruction in the art; also to promote discussion on present applications, whether commercial or experimental, and to induce interest in the future broadening of the uses to which the equipment may be put.

Discussion

A. M. G. MOODY.[3] It would be interesting if the author

[3] Chief Research Engineer, DeLaval Steam Turbine Co., Trenton, N. J. Mem. A.S.M.E.

would add to his already valuable paper some information on the degree to which he has been able to get uniform flow across the exit from the combustion chamber. If the products of combustion are to be used in a turbine, it is imperative that the flow be at a fairly uniform temperature, having no local hot or cold spots. If this condition does not prevail, a smoothing-out section would have to be added, the weight and volume of which would be directly chargeable to the combustion chamber.

Author's Closure

It is recognized that in the refinery installations the volume of duct work connecting the air heater to the vessel in which the heated air is to be used may be many times the volume of the heater itself. Therefore temperature distribution at the heater outlet is not considered of primary importance and no provisions have been made in these installations for obtaining data on this condition.

Where the air heater discharges directly into the inlet of a combustion-gas turbine the distribution of temperature at the heater outlet must be such that local departures from the mean do not exceed 25 F, plus or minus. This has been accomplished satisfactorily by application of positioning control to the individual louvers of the burner air register. Control of the flow of combustion air can be obtained within the relatively small space of the burner air register where the velocity is at a maximum. This construction eliminates the necessity of providing adjustable dampers, vanes, etc., in the larger and less accessible quench air passages toward the hot end of the chamber.

"Temp-turb" Temperature-Control System

By J. R. CAMPBELL,[1] ONTARIO, CALIF.

The "Temp-turb" system of temperature control, described in this paper, consists basically of a means for utilizing the kinetic energy in a flowing fluid in a manner to control the temperature of the fluid. A turbine wheel, the blades of which change their position with temperature changes, has all, or a sample of the flowing fluid, passed through it. Direction of rotation, rate of rotation, and torque output are a function of temperature when fluid-flow rate is constant. Power available from the turbine wheel actuates the valves which determine the fluid temperature.

THE amount of work available from any basic temperature-sensitive element is relatively small and must be substantially amplified by some form of external energy before the response to temperature change can be made to register effectively on the control means. In aircraft, the control means might be an exit flap, such as on an intercooler; a butterfly valve, such as in a heating and ventilating duct; a mixing valve, such as in a heating and ventilating system; shutters or flaps for oil coolers; dump valve for thermal deicing system, etc.

The "Temp-turb" system of temperature control uses the kinetic energy of the flowing fluid being controlled to amplify the work done by the basic temperature-sensitive element. The kinetic energy available in fluid-flow systems in aircraft is generally substantial, and enough energy can be harnessed to operate control means without introducing a harmful pressure drop.

Fig. 1 shows a Temp-turb control unit, as used in the Douglas A-20 for controlling the temperature of air leaving a combustion heater. This air is for cabin heating, windshield defrosting, and turret heating. The Temp-turbs are set to maintain a control point of 200 F ± 15 deg and actually control to within ± 5 deg. As shown in Fig. 2, the control unit is furnished as an integral part of the modulating valve. Operation of the assembly is to allow more air to flow over the heater as temperature tends to increase, and to reduce the air flow as temperature tends to decrease. Heaters in this system are ram-operated.

Operation of Control Unit

Fig. 3 indicates the operation of the rotor or turbine wheel for the type of Temp-turb used on the Douglas A-20. Turbine blades are made of high-activity bimetal 0.005 in. thick and are calibrated to be straight at the control point. Any deviation from the control-point temperature results in a curvature of the turbine blade (the direction of curvature depending upon the direction of the temperature deviation). As the device is a radial-flow turbine, the curvature of the blade imparts a torque to the rotor which is transmitted through a gear reduction to the modulating valve.

After the turbine blades are formed and stabilized (to maintain calibration under all conditions to which control might be subjected), it is not feasible to vary the control point of the unit by varying the form of the blades. Therefore, the angle at which the fluid enters the rotor is varied. Referring to Fig. 1, the inlet guide vanes are mounted as cantilevers at the edge of the inlet nozzle, and their free ends engage a shift ring by means of small pins. Moving the shift ring in either direction from neutral varies the direction of fluid flow over the rotor to either side of pure radial flow. The amount of deviation from pure radial flow is determined by the amount the shift ring is moved. When the flow through the rotor is deviated from radial, the rotor assumes a new temperature-control point. This adjustment allows the control point to be varied about ± 40 F from the normal.

The assembly, shown in Fig. 2, operates on a sample of air which varies from about 5 to 10 per cent of rated flow for a full-open valve. Fig. 4 is a partial cutaway view of the assembly in Fig. 2 and shows the inlet scoop and exhaust outlet from the turbine back to the duct.

Numerous other applications of the Temp-turb principle of temperature control are in the developmental stage; however, the two examples mentioned should provide an adequate picture for an understanding of the system in general.

The work available in any Temp-turb unit is a function of the following:

1 Deviation from the control point.

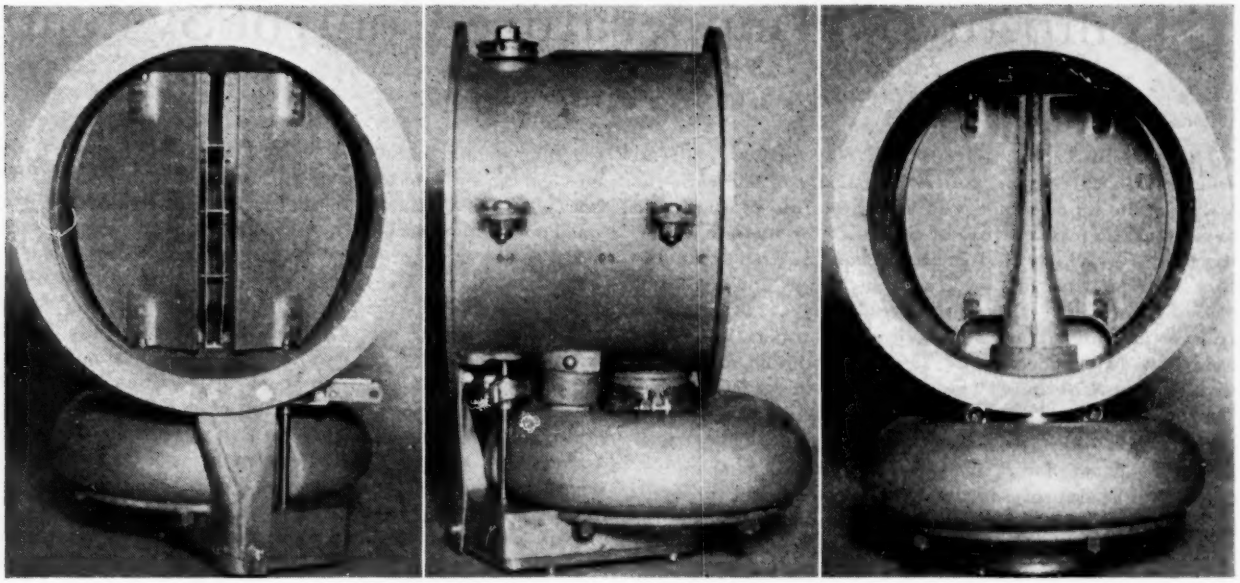

FIG. 2 CONTROL UNIT IS AN INTEGRAL PART OF THE MODULATING VALVE

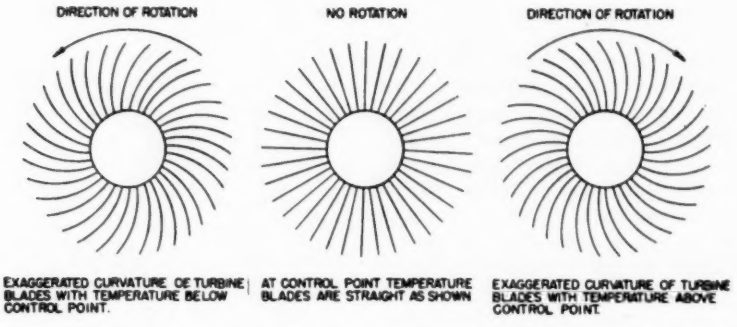

FIG. 3 OPERATION OF TURBINE WHEEL ON TYPICAL "TEMP-TURB" CONTROL UNIT

2 Mass flow of fluid, which for air has to be corrected for

(*a*) Temperature
(*b*) Altitude
} Density

The temperature sensitivity is a function of the following:

1 Massiveness of the basic temperature-sensitive elements.
2 Velocity of the fluid being controlled.
3 Gear ratio between rotor and control valving.
4 Thermal lag of the system.

When designing a Temp-turb unit for a specific application, it is first necessary to determine the following items:

1 Control point.
2 Degree of accuracy to which temperature must be controlled.
3 Maximum work required to operate valving or control means. This may be broken down into the following: (*a*) Maximum torque required. (*b*) Rate at which control means must be moved when operating under maximum-torque conditions.
4 Mass-flow rate of the fluid in system.
5 Allowable pressure drop (drop due to Temp-turb).
6 If system involves flow modulation, what is the minimum flow allowable. In this system, it is always necessary to have a sample of the fluid flowing over the Temp-turb rotor at all times. It is not practical to design for a minimum flow of less than the amount needed for a sample.
7 Allowable space.
8 Allowable weight.
9 Cross-sectional area of ducting or piping in the zone where Temp-turb is to be installed.
10 Whether or not the control point has to be adjustable: (*a*) As a service operation; (*b*) as an "in-use" operation.

PRINCIPAL CHARACTERISTICS OF SYSTEM

General characteristics of the Temp-turb system of temperature control are as follows:

1 Inherently nonhunting: The deflection of the blades, whether made of temperature-sensitive material or actuated by a temperature-sensitive element, is proportional to temperature changes; therefore, the output of the rotor is proportional to temperature changes. A large temperature deviation produces a large corrective force and a large rate of correction. A small deviation produces a small corrective force and a small rate of correction. As temperature error is being corrected, the correcting force and speed (produced by rotor) are reduced in proportion to the error until the control point is reached, at which time corrective force and speed of correction become zero.

Numerous tests under transient conditions have proved that

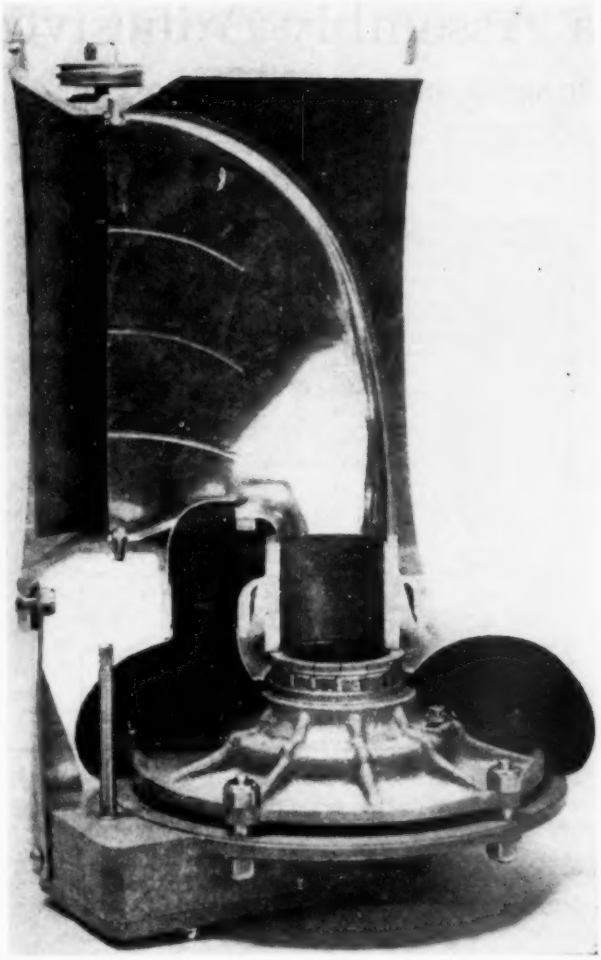

FIG. 4 PARTIAL CUTAWAY VIEW OF TEMP-TURB ASSEMBLY OF FIG. 2

the system is inherently stable. Of course, the thermal balance of the system must be within reasonable limits, and the gear ratio between rotor and control means also must be within reasonable limits.

2 Falling torque characteristics with velocity pressure increases above a certain value: The turbine blades, being operated by resilient thermoelements, are spring-loaded into proper position. This feature allows the blades to be blown into a neutral position under conditions where excessive velocity pressure might result in damaging loads or wear on the mechanism. This factor is of value on high-speed aircraft where ram pressures at times become quite high.

3 Adequate sampling of fluid being controlled: Temperature-sensitive elements have large area exposed to flowing fluid, which is particularly helpful under conditions wherein there is "temperature layering" in the duct. Also, the system is adaptable to special types of sampling scoops.

4 Low thermal lag: Bimetal temperature-sensitive elements are thin and subjected to relatively high-velocity fluid flow, resulting in almost instantaneous response to temperature changes.

5 Not affected by vibration: The torque produced by a vibrating turbine blade is the same as for a nonvibrating blade.

6 Output related to demand on unit: As flow rates increase, causing greater loads on control means, the rotor output increases accordingly.

7 The type of Temp-turb assembly as shown in Fig. 2 has the characteristic of not being affected by radiant heat from a glowing combustion chamber on a combustion heater. The sampling scoop and the location of the Temp-turb control unit make the device respond to air temperature only. This condition is of importance when the control is mounted immediately downstream from the combustion heater.

OPERATING EXPERIENCE

Experience to date indicates no unusual difficulties from a manufacturing standpoint. Any remarks on cost must be predicated on the somewhat limited manufacturing and commercial experience encountered to date. Based upon this experience, it may be said that Temp-turb type controls cost no more than competitive devices.

Concerning service life, Temp-turb controls on test have demonstrated that they have a trouble-free life of greater duration than other forms of controls used for the same operations. It is likely that this is due largely to freedom from complexity. Two units on life test actually worked better after 3000 hr than at the start of the test, due to "wearing-in" of bearings.

The temperature range, over which the Temp-turb principle could be applied, is approximately from —60 F to +600 F. This is on the basis of response and durability of the bimetal temperature-sensitive elements. Greater problems are offered in bearing design at extreme temperatures, and at this time the bearings and their lubrication actually determine the applicable range. On this latter basis, the range is about —60 F to + 350 F.

Fatigue Studies on Urea Assembly Adhesives

By A. G. H. DIETZ[1] and HENRY GRINSFELDER[2]

Assembly adhesives made of "cold-setting," urea-formaldehyde, synthetic resins, are employed in the fabrication of wooden aircraft such as gliders and motor-driven airplanes. Adhesives so used are frequently subjected to vibrating loads which induce alternating stresses in the glue; of these shear, in the plane of the glue, and direct tension, perpendicular to the glue line, are the two which are most likely to bring about failure. It is well known that most materials fail under alternating stresses smaller in magnitude than the static stresses required to cause failure, and synthetic-resin assembly adhesives are no exception. Little has been known quantitatively, however, respecting the behavior of such adhesives under alternating stresses.

In this paper are presented the results of researches into the failures to be expected in glue joints of this kind, particularly the nature of the failure, cycles of stress to failure at various amplitudes and stresses, and the probable "fatigue limit" of such an assembly. Tests were carried out at room temperatures on an assembly adhesive representative of those employed in aircraft fabrication.

Materials and Test Specimens

THE research on "cold-setting," urea-formaldehyde, synthetic resins, as representative of assembly adhesives used in wood aircraft fabrication, was carried out as follows:

Panels. Panels of overlapping 1/8-in. rotary-cut maple veneers were made up, as shown in Figs. 1 and 2. The two outer members *a* overlapped and were glued to the two inner members *b* over a distance approximately 1 1/2 in. The line *b-b* was glued throughout its length, so that the center member behaved as a single piece 1/4 in. thick. Maple was chosen because it is standard shear-block material, is relatively difficult to bond, and is moderately strong.

The panels were prepared according to the formulation: Urea-resin powder, 70 parts; water, 30 parts.

Spreading was by hand brushing and was on both surfaces being bonded. The assembly time ranged from 5 to 25 min, and in all cases the assemblies were closed immediately after spreading and kept closed until the pressure was applied. Bonding was for 16 hr at a temperature of 75 F, and the bonding pressure was 200 psi applied by means of a Black "compressometer."

Two sets of panels were made because difficulties encountered in obtaining satisfactory results with the first set necessitated the fabrication of more material. Panels were numbered as follows:

First	Second
A2	AA1
A3	AA2
A4	AA3
A5	AA4
A6	AA5
A7	AA6

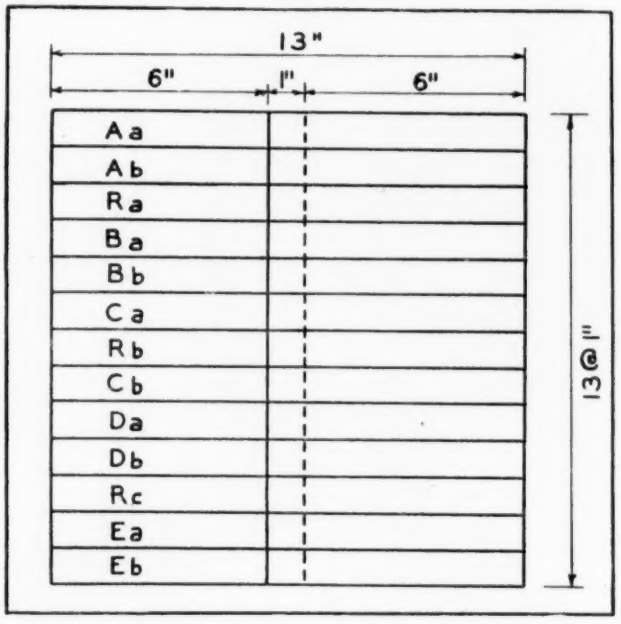

Fig. 1

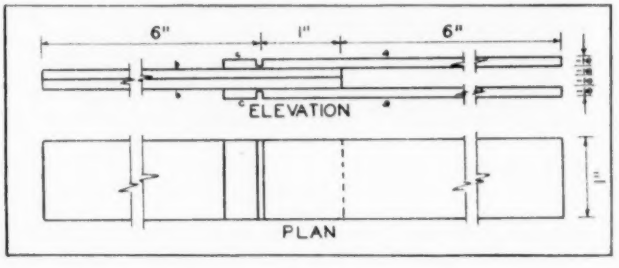

Fig. 2

Specimens. Specimens 1 in. wide were cut from the panels, as shown in Figs. 1 and 2. The overlap was cut to 1 in., as shown in Fig. 2, to provide 2 sq in. of glue line, although a few specimens were cut to 3/4 in. for experimental purposes. In some instances the remaining piece *c* was removed, but in the majority of the tests it was found better to leave it in place.

At the ends of glue lines *a-b*, Fig. 2, beads of glue had squeezed out into the internal corners. In some instances the bead was removed and in some it was notched with a saw, but it was found by test that the glue actually cracked after a few alternations of stress, so that is was unnecessary to pay any particular attention to the fillet caused by glue bead.

Specimens were marked as shown in Fig. 1. Those marked Ra, Rb, and Rc were intended for "modulus-of-rupture" tests, that is, to determine the breaking strength of the assemblages. Specimens Aa, Ba, . . . were intended for vibration, specimens Ab, Bb, . . . for static shear. It was not possible to adhere to this schedule rigidly for the first set of panels because of experimental difficulties to be described, but the specimens were in general so employed in the second set of panels. Moisture content of the material was approximately 9 per cent during the tests.

TEST METHODS

Vibration

Machine. Because of the number of specimens involved and the length of time required for some of the tests, it was necessary to employ a machine which could handle several specimens at one time. The machine is shown in Fig. 3. In this apparatus the

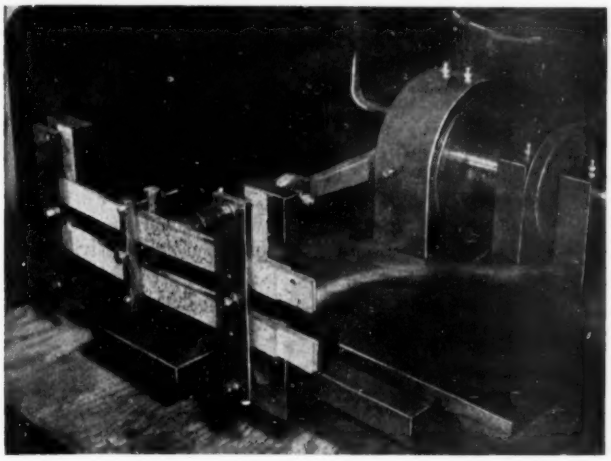

Fig. 3 Vibration Machine With Two Alternating Stress Specimens in Place; End Supports Are Semiclamped

specimens, in groups of two, are held between upright pairs of cold-rolled steel plates which in turn are bolted to a heavy horizontal steel bar fastened to the steel base plate supporting the entire apparatus. The centers of the specimens are forced back and forth by a pusher attached to a driving rod pinned to a connecting rod in turn mounted on an eccentric which forms part of a heavy steel driving wheel. The eccentric can be adjusted to give a throw ranging from zero to $1^1/_2$ in. The driving wheel is mounted in a heavy bronze bearing and is belt-driven by a 1-hp motor. The machine can be operated at various speeds, but in these tests was limited to 1100 to 1300 rpm.

End Supports. Three different methods of supporting the ends of specimens were tried. The first, rigid clamping, as shown in Fig. 4, resulted in fairly frequent fatigue failures in the wood at

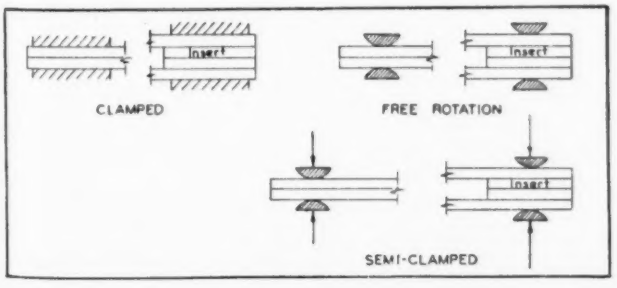

Fig. 4

the supports. Free rotation of the ends, the second method of support, required large deflections at the centers to yield appreciable stresses and caused numerous wood fatigue failures at the center. The end support finally adopted, and the one which yielded generally satisfactory results, consisted of rounded supports, between which the specimens were firmly held by bolts exerting pressure as shown. This allowed a little rotation at the ends, resulting in a semiclamped condition.

Pusher. Four different positions of the pusher were tried, as shown in Fig. 5. Position 2 was first employed, but resulted in fatigue failures in the wood rather than glue-line failures because even the slight compression applied by the pusher to the glue line prevented tensile stresses from building up to the point where

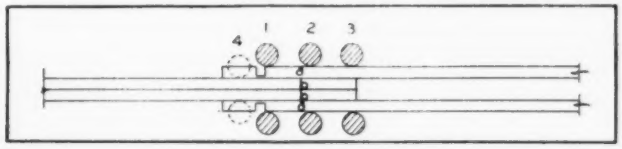

Fig. 5

failure could occur. Such a condition would not generally be found in actual practice. Position 3 was somewhat better, but position 4 resulted in rather quick wood failures. Position 1, finally adopted for the pusher, proved best from all standpoints. It allowed tensile stresses to develop freely. Fairly high percentages of glue-line failures resulted when the combination of pusher in this position was employed, and when saw cuts were held approximately $^1/_{32}$ in. short of glue line *a-b* to avoid local concentrations of stresses which would cause the wood to fail in fatigue. The pusher was not pressed firmly against the wood but was allowed to clear by a few thousandths of an inch or, at most, to come into light contact.

Tests were carried to failure or to 5,000,000 cycles. Two, four, or six specimens were tested at one time, depending upon the amplitude.

Static Shear

Static-shear control specimens were placed in the tension grips of a 10,000-lb Riehle beam-type universal testing machine and pulled apart, as shown diagrammatically in Fig. 6. Under

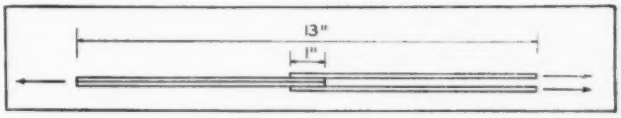

Fig. 6

this load, shear stresses are set up in the glue lines *a-b*, accompanied by some tension perpendicular to the glue line occasioned by the eccentricities in the joints.

Static Bending

Modulus of Rupture. Selected specimens, generally those marked Ra, Rb, Rc, were loaded statically to rupture to determine the breaking strengths and deflections so that the amplitudes to employ in the vibration tests could be decided. As shown diagrammatically in Fig. 7, specimens were supported at the ends

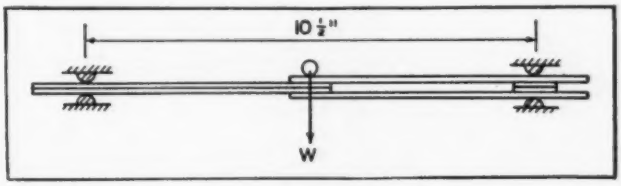

Fig. 7

in the same manner as the vibrated specimens and were loaded with dead weights at the center in the same manner as the vibrated specimens, except that loads were carried to failure. Loads and deflections to failure were both recorded.

Calibration. Each vibration specimen was calibrated by load-

ing in the same manner as the modulus-of-rupture specimens, except that loads were carried only to deflections corresponding to the amplitudes through which the specimens were to be vibrated.

In order to determine the end restraining moments at the supports induced by clamping and semiclamping, a number of specimens were tested twice, once as freely supported simple beams with no end restraint, and again as clamped or semiclamped specimens.

If d_f = deflection at center of a freely supported beam loaded at the center
d_c = deflection at center of a beam completely restrained at its ends and loaded at the center
W = concentrated load at center
L = length of beam
E = modulus of elasticity
I = moment of inertia
M_f = bending moment at center of a freely supported beam loaded at the center
M_c = bending moment at center of a beam completely restrained at its ends and loaded at the center
M_r = restraining moment at ends of a completely restrained beam

$$d_f = \frac{1}{48} \cdot \frac{WL^3}{EI} \quad \ldots\ldots [1]$$

$$d_c = \frac{1}{192} \cdot \frac{WL}{EI} = \frac{1}{4} d_f \quad \ldots\ldots [2]$$

$$M_f = \frac{WL}{4} \quad \ldots\ldots [3]$$

$$M_c = \frac{WL}{8} \quad \ldots\ldots [4]$$

$$M_r = -\frac{WL}{8} \quad \ldots\ldots [5]$$

For semiclamped specimens, the deflections are intermediate between Equations [1] and [2], and the corresponding center moments are intermediate between Equations [3] and [4]. By determining the deflections for Equation [1] and for the semiclamped condition, the center moments for the semiclamped condition can also be determined, and from these the maximum tensile stresses perpendicular to the glue line at the overlap. Shear stresses can be determined from the load, whose magnitude is known as a function of the amplitude (or deflection).

Fig. 8 shows the approximate relationship between the external

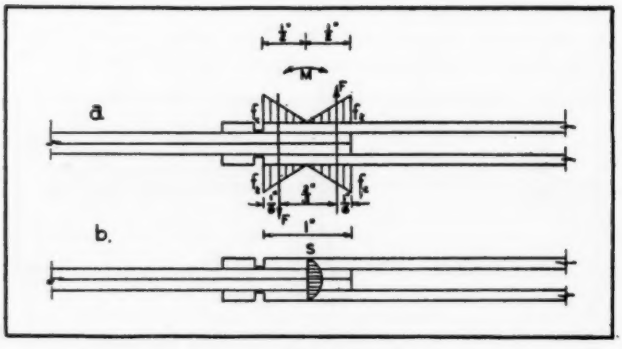

FIG. 8

center bending moment M and the internal resisting moment. With the pusher in position 1 (Fig. 5), tensile and compressive stresses are set up across the glue lines and are approximately triangular in distribution. The varying stresses f have resultants F, acting at the centers of gravity of the triangular stress volumes. The equal and opposite resultants F form a couple $F \times \frac{2}{3}^{\text{in.}}$ which resists the external moment M. The resultant F is equal to

$$F = \frac{2f}{2} \times \frac{1}{2}^{\text{in.}} \times 1^{\text{in.}}, \text{ and } F \times \frac{2}{3}^{\text{in.}} = \frac{f}{3} \quad \ldots\ldots [6]$$

or

$$M = \frac{f}{3} \text{ and } f = 3M \quad \ldots\ldots [7]$$

The actual stress distribution is somewhat different from the simplified diagram, here shown, inasmuch as M varies slightly from one end of the overlap to the other because of shear. This tends to increase f in some portions of the overlap and to decrease it in others. For practical purposes, the stress distribution is closely enough that shown.

Average shear stress in the plane of the glue lines is given by the familiar expression

$$s = \frac{VQ}{bI} \quad \ldots\ldots [8]$$

and is as shown as in Fig. 8(*b*). This is the average condition. It is probable that the true shear stress deviates from this at the ends of the overlap.

TEST RESULTS

General

Test results are summarized in Tables 1 to 3.

Considerable scatter in the results is found, although trends are clearly visible. Marked difficulty was encountered in obtaining satisfactory failures at the glue lines; failure was as apt to occur in the wood as in the glue line. This was particularly true of the vibration specimens.

Static Tests

Static Shear. Table 1 gives the average results of static shear tests for the various panels. In the first set, average strength is 1458 psi, accompanied by 80 per cent average wood failure. In the second set the corresponding figures are 1403 and 90, respectively.

TABLE 1 STATIC SHEAR

Panel	Average load, lb	Average shear stress, psi	Average per cent wood failure
A2	2857	1428	75
A3	2626	1313	83
A4	2842	1422	70
A5	2664	1332	99
A6	2788	1394	90
A7	2960	1458	95
Averages[a]	2916	1458	80
AA1	2864	1432	90
AA2	2851	1425	95
AA3	2929	1465	85
AA4	2700	1350	70
AA5	2706	1353	90
AA6	2792	1396	100
Averages[a]	2807	1403	90

[a] Averages of all individual tests, panel averages weighted in accordance with number of tests from each panel.

The shear-strength averages are less than are found in the standard shear block but are considerably higher than in the standard plywood shear specimens. The shape of the specimen and its general proportions, inducing variable amounts of tension because of eccentric loading, as well as nonuniform shear distribution in the joint, must account for the different values attained.

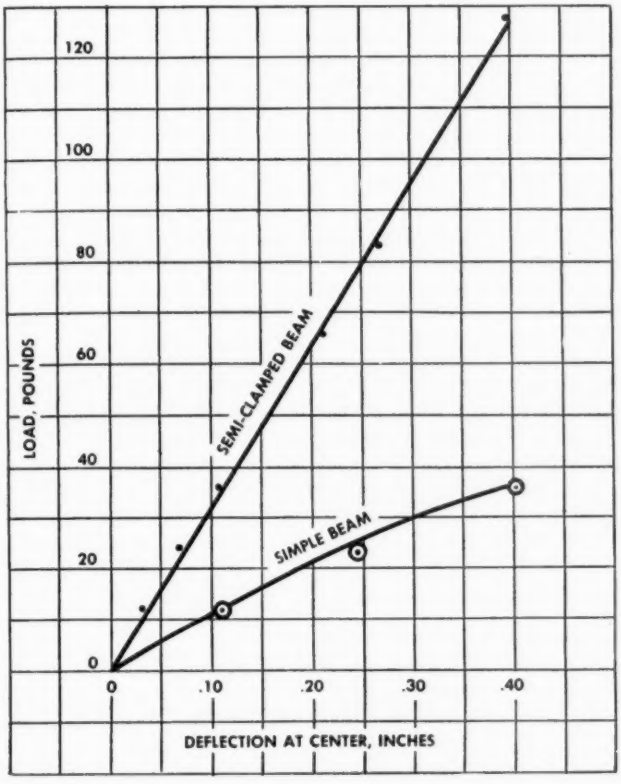

FIG. 9 TYPICAL LOAD-DEFLECTION DIAGRAMS; SIMPLE AND SEMI-CLAMPED BEAMS

Modulus of Rupture. Fig. 9 is a typical set of load-deflection curves for a modulus-of-rupture specimen. The lower curve is for the specimen simply supported, the upper for the semi-clamped end. In general, deflections for the semiclamped condition were approximately one third those for the simple beam, indicating a center moment of approximately $\frac{WL}{7}$. Center moments for the clamped and semiclamped tests ranged from slightly better than $\frac{WL}{6}$ to $\frac{WL}{8}$.

Average values of modulus of rupture for the various panels tested, averages for the two sets of panels, and over-all averages are given in Table 2. Shear stresses were calculated by Equation [8] and maximum tension across the glue line from center moments determined from Equations [6] and [7].

The first set of panels yielded somewhat higher results than the second, but over-all averages and limits were as follows:

Shear: average 190, low 120, high 230 psi
Tension: average 815, low 530, high 1015 psi
Wood failure: average 65, low 45, high 100 per cent

Alternating Stresses. Table 3 summarizes the tests in which glue-line failures occurred under alternating stresses at amplitudes of $^5/_{16}$, $^1/_4$, $^3/_{16}$, $^1/_8$, and $^1/_{16}$ in. Tests in which wood failed in fatigue are not included. Furthermore, the results are for clamped or semiclamped specimens, and for specimens in which failure was complete, except for those which ran to 5,000,000 cycles without failure. The same results are presented graphically on logarithmic paper in Fig. 10. The following appear to be the chief points of interest:

1 Maximum amplitude, $^5/_{16}$ in. induced maximum tensile stresses perpendicular to the glue line approximately two thirds of those found in the modulus-of-rupture tests. Minimum ampli-

tude, 1/16 in. induced tensile stresses approximately one seventh of those found in the modulus-of-rupture tests.

2 Shear stresses were quite low, compared with the static shear tests; the maximum at 5/16 in. amplitude was 5 per cent of the static shears.

3 Failures were primarily tension perpendicular to the glue line and were the kind that would be found in most actual structures.

4 At 1/8-in. amplitude, one specimen ran to better than 5,000,000 cycles. The others failed at approximately 150,000 to 1,000,000 cycles.

5 At 1/16-in. amplitude, all specimens ran to better than 5,000,000 cycles without any signs of failure.

6 When tested in static shear, the unbroken vibrated specimens yielded results which actually averaged a little higher than the static controls. This indicated that at least there was no loss in strength

7 In those vibration specimens which failed during test, lower percentages of wood failure were found than in the modulus-of-rupture controls. No definite trend with respect to numbers of cycles and stress could be discerned.

8 In Fig. 10, the numbers of cycles of stress reversal are plotted against amplitude, shear stress, and maximum tension perpendicular to the glue line. Curves are drawn for the arithmetical averages and for the approximate limits of the scatter bands in the graphs of cycles versus amplitude and cycles versus tension perpendicular to the glue line. Scatter for the shear results is not plotted, inasmuch as shear was a minor factor in causing failure. The curves of amplitude and maximum tension versus cycles to failure flatten to practically zero slope well above the 5,770,000-cycle point.

Conclusions

Conclusions must be drawn with some reservations from these tests, inasmuch as the scatter in the results renders generalizations somewhat difficult. It appears, however, that the following may be said with some assurance with respect to stresses at room temperatures:

1 A joint having the general proportions of those tested, and subjected to vibrations, is as apt to fail in fatigue in the wood as in rupture in the glue line.

2 Inasmuch as the sections tested were quite heavy and spans were short, so that higher shears were induced in the glue lines than would customarily be found, it seems safe to say that failures in glue lines of this type will occur primarily because of tension perpendicular to the glue line (and the grain of the wood) rather than by shear in the glue line.

3 If maximum tensile stresses perpendicular to the glue lines of these adhesives are kept below 120 psi, there should be no failures. As a matter of fact, extrapolation of the observed curves indicates that it is highly probable that stresses can be 150 to 160 psi, that is, 20 per cent of the "modulus of rupture," or static ultimate stresses. If stresses reach 200 psi, failure may be expected to occur at 5,000,000 cycles or less, and as the stresses go still higher, the number of cycles to failure becomes rapidly smaller, with highly variable results. The "fatigue limit," if that term may be employed here, appears to be 20 per cent of the ultimate.

The foregoing conclusions are based upon tests made at room temperature upon specimens at approximately 9 per cent moisture content.

Application of these results depends upon the ability to determine stresses in vibrating structures, by analysis or test. Wherever members cross each other, bending moments are apt to set up tensile stresses perpendicular to the glue line and the grain of the wood. Such stresses may be uniformly distributed or may vary from maximum to minimum approximately as in the tests here described. In such instances, the dimensions of the overlapping parts should be large enough to keep the tensile stresses from exceeding 20 per cent of the tensile strength of the wood perpendicular to the grain. For species such as maple and birch, alternating tensile stresses of 125 to 150 psi may be employed, for other species such as spruce or mahogany, the stresses will be less.

Acknowledgments

Acknowledgments are due particularly to John Barry, Research Assistant, who carried out the experimental work, and to Prof. W. M. Murray, of the Department of Mechanical Engineering at the Massachusetts Institute of Technology, who was instrumental in the design of the testing apparatus. The laboratory staff of the Resinous Products and Chemical Company made the test material.

Heat and Vapor Transfer in the Dehydration of Prunes

By R. L. PERRY,[1] DAVIS, CALIF.

Quality of prunes is known to be influenced by the temperature and relative humidity of the dehydrator air, and by the time required for drying, long exposures to high temperatures at high humidities resulting in excessive caramelization and cooked taste. To determine the actual temperatures of prunes during dehydration, readings were made by thermocouples inserted at different points in prunes for three test runs at about 166 F, and relative humidities of 15, 27, and 43 per cent. To permit adapting the data obtained to commercial dehydrators, surface thermal conductances were computed. The vapor conductance at the surface was estimated from the thermal conductance, by employing the heat-mass transfer analogy. From the vapor conductance and the evaporation rate, the difference in vapor concentration required to move vapor from the prune surface to the air stream was calculated. Moisture movement within the prune was investigated by cutting the flesh of samples, removed after 3, 6, 10, and 16 hr drying, into two parts, that near the surface, and that near the pit.

Nomenclature

The following nomenclature is used in this paper:

A = area of prune surface, sq ft
A_d = area of prune surface, per pound of dry matter, sq ft per lb
B = drying coefficient, slope of free-moisture line on semi-logarithmic paper, 1/hr
c = unit heat capacity, Btu/lb F
c_d = heat capacity of prune, per pound of dry matter, Btu/lb F
C = moisture concentration, lb per cu ft
D = diameter, ft
e = base of Naperian logarithms, 2.7183
E = equilibrium-moisture ratio, pounds of moisture per pound of dry matter
f = unit surface thermal conductance, Btu/hr ft² F
f' = unit surface vapor conductance, lb/hr ft² (lb/ft³) or ft/hr
F = free-moisture ratio, pounds of free moisture per pound of dry matter. ($F = M - E$)
H = relative humidity, per cent
k = thermal conductivity, Btu/hr ft² (F/ft)
k' = moisture conductivity within prune, lb/hr ft² (lb/ft⁴) or ft²/hr
M = total-moisture ratio, pounds of moisture per pound of dry matter
n = exponent of Prandtl modulus in forced-convection equations
N = prune count, number of dried prunes, of 0.2 moisture ratio, per lb
q_c = convective- and radiant-heat-exchange rate, between prune and its surroundings, Btu per hr
q_s = sensible-heat-gain rate of prune, Btu per hr
q_v = heat rate in evaporation, Btu per hr
r = latent heat of evaporation of water, Btu per lb
R = radius, ft
t = temperature, F
V = air velocity in free cross section of tunnel, fpm
w = evaporation rate, lb per hr
W = weight of prunes
α = diffusivity of water vapor through air, ft²/hr
γ = weight density, lb per cu ft
θ = time, hr
μ = weight viscosity, lb/hr ft

Subscripts:

i, for prune-air interface
0, for outside
∞, for remote air stream
1, initial

Dimensionless moduli:

fD/k = Nusselt modulus for convective heat transfer at a fluid boundary
$f'D/\alpha$ = Nusselt modulus for convective mass transfer at a fluid boundary
$c\mu/k$ = Prandtl modulus of fluid properties for convective heat transfer
$\mu/\alpha\gamma$ = Prandtl modulus of fluid properties for convective mass transfer
$k'\theta/R^2$ = Fourier modulus for mass conduction in solids
$f'R/k'$ = Biot modulus for mass transfer at a solid-fluid interface

Introduction

In this paper, data on the temperature and moisture distribution in prunes during dehydration are presented. Surface conductances for heat and vapor are computed from the data, and the vapor concentration and relative humidity at the prune surface are found. The deviation of moisture distribution within the prune from that which would occur with constant moisture diffusivity is disclosed.

Studies by Moses, Cruess, et al (1)[2] fixed the over-all limiting dehydrator conditions of temperature and humidity for production of prunes of high quality. Although it was known that prolonged high air temperature and high humidity gave a dark, caramelized, low-grade prune, the actual prune temperatures during drying were not observed. In order to extend the results of their dehydration tests made at constant air temperature and humidity to commercial practice, where counterflow, parallel-flow, center-exhaust, end-exhaust, and cross-flow dehydrators are used, the prune temperature itself was needed.

The empirical equations developed by Guillou (2) led to the first marked advance in prune-dehydrator design technique since

the work of Christie and Ridley (3), but they left several questions unanswered. No explanation was available for the observation that variations in relative humidity did not influence drying rate unless the relative humidity exceeded 35 per cent. This was contrary to the observation that in some other materials the drying rate is proportional to wet-bulb depression. Another unanswered question was why the equilibrium-moisture content, determined by plotting drying rate against moisture ratio, differed from that observed by Guillou (4), Table 2, on prunes held in atmospheres of different humidities until constant weights were reached.

The investigations reported herein were planned to throw more light on the answers to these questions. No previous attempts to measure either temperature or moisture in fruit-drying dehydration had been noted in the literature.

The Dehydration Process

When a fresh prune is placed in a high-temperature air stream of a moisture concentration lower than that which represents equilibrium with the prune flesh at the air temperature, heat is transferred by convection and radiation to the prune surface; thus

$$q_c = fA(t_\infty - t_i) \quad [1]$$

At first this heat results principally in a rise in temperature

$$q_s = cW \frac{\partial t}{\partial \theta} \quad [2]$$

in which t represents the average temperature of the prune, the interior being warmed by conduction from the surface. However, as the surface layers rise in temperature, the vapor concentration at the surface rises. When it exceeds that in the adjacent air stream, vapor escapes through the resistance offered by the adjacent air-vapor mixture

$$w = f'A(C_i - C_\infty) \quad [3]$$

The vaporization absorbs heat

$$q_v = wr \quad [4]$$

or, combining Equations [3] and [4]

$$q_v = rf'A(C_i - C_\infty) \quad [5]$$

(An additional quantity of heat is necessary to warm the vapor from the temperature at which it escapes from the prune to that which it attains in the air stream. This is a minor item which can be neglected, especially since only part of it has to pass through the resistance of the adjacent air-vapor mixture.) The heat available from convection and radiation is utilized in temperature rise and evaporation

$$q_c = q_s + q_v \quad [6]$$

As the temperature rises, the heat available from convection and radiation decreases, but the evaporation rate increases, so that there is soon little heat available for further temperature rise. The prune temperature is then, combining Equations [1] and [5] and noting that q_s is negligible in Equation [6]

$$t_i = t_\infty - \frac{f'r}{f}(C_i - C_\infty) \quad [7]$$

Equation [7] is of limited utility because of inability to establish the value of the surface-moisture concentration C_i, except indirectly from test data. The surface concentration is related to the moisture ratio of the prune flesh, and to the temperature, but varies with the drying history of the prune. It is evident, of course, that as vapor escapes from the surface, a moisture-concentration gradient is established within the prune, so that moisture moves to the surface, but not rapidly enough to maintain the initial concentration. The evaporation rate thus decreases gradually, and the temperature approaches more closely that of the air. Even with the help of the data at hand, however, the formulation of an ideal system, which would describe adequately the dehydration of a prune, has not been realized. The continually changing balance between vapor and heat transfer which determines the drying rate and the prune temperature is not yet mathematically predictable, and reference must still be made to empirical relations such as are presented herewith.

Test Apparatus and Procedure

Two groups of tests were conducted. In the first group, simultaneous observations of weight of sample and of temperature at prune surface and prune pit were made during constant-condition dehydration runs. The initial and final dimensions, volume, and density were noted, and the final moisture content measured. In the second group, several prunes were removed at successive drying times, and the flesh was dissected into two sections, that near the skin and that near the pit, for moisture-content determination. Subsequently, the dried skin was planimetered to find its area, in order to learn the area and thickness of the segments which had been removed.

Temperature-Distribution Tests. In each run of the first group,

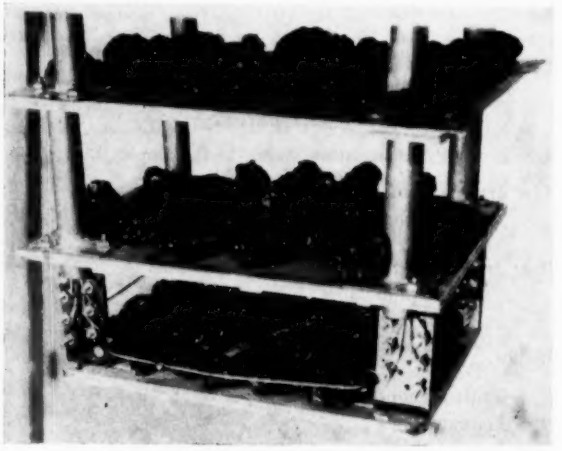

Fig. 1 Test Tray of Prunes, at End of Run

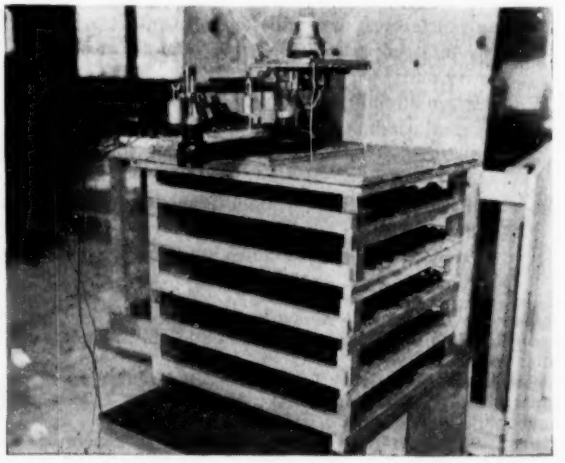

Fig. 2 Test Tray, Surrounded by Guard Trays

temperatures at three points in each of five prunes were taken by means of No. 36 gage copper-constantan thermocouples, read with a Leeds & Northrup No. 8662 portable semiprecision potentiometer. One thermocouple was inserted just under the skin at the top of each prune, the junction being so close to the surface that it could be seen through the translucent skin, and the leads continuing just under the skin for about $^{5}/_{8}$ in., to minimize conduction errors. One thermocouple was placed next to the pit. In three of the five prunes, the third point was just beneath the skin on the side which was to lie on the tray, while in the other two, the third point was just under the skin at the side.

These five test prunes were placed among twenty others of similar size and maturity on a tray of $^{1}/_{4}$-in. plywood, which could be weighed as drying proceeded, the thermocouple extension leads serving as suspensions from the scales. This tray, Fig. 1, was hung in the center of a larger guard tray which was included in the center of a stack of five, Fig. 2, placed in the dehydrator tunnel, 17 in. square in cross section. Only the lower tray in Fig. 1 was weighed, the two above it being access hatches which fitted into the two upper guard trays. Although the suspending leads were sheltered from the air stream by the tubular shields noticeable in Fig. 1, and the tray was restrained laterally by bridles, it was found necessary to close the air-control damper while weighing was being done.

Four runs were made, each at about 166 F air temperature, and at an air velocity of 600 fpm, in the free cross section of the tunnel. It was found during the first run that the thermostat was in need of repair, having a range of 7 F, so that, although the periodic heat exchange with the prune was of some interest, the data were of little direct value. Subsequent runs were made with manual control, an auxiliary heater being adjusted with a variac. General data for these runs are given in Table 1.

TABLE 1 GENERAL DATA ON PRUNE TEMPERATURE TESTS

Run number	2	3	4
Average air temperature, deg F	169	166.5	166
Average wet-bulb temperature, deg F	122	134	105
Average relative humidity, per cent	27	43	15
Tray loading, lb per sq ft	3.98	3.90	3.94
Duration of run, hr	16.1	18	17.2[a]
Final-moisture content,[b] 20 prunes per cent	20.3	21.0	19.3
Average weight, lb:			
Initial, 5 temp test prunes	0.0500	0.0511	0.0519
Initial, 20 additional prunes	0.0502	0.0485	0.0488
Final, 5 temp test prunes	0.0163	0.0168	0.0186
Final, 20 additional prunes	0.0169	0.0170	0.0168
Moisture ratio, pounds of moisture per pound of dry matter:			
Initial, average of 25 prunes	2.76	2.67	2.58
Final, average of 25 prunes	0.26	0.27	0.24
Average volume, cu ft:			
Initial, 5 temp test prunes	0.000713	0.000728	0.000757

[a] Tunnel air damper inadvertently shut at 1 hr, opened at 1.58 hr.
[b] Wet basis.

After completing each run, the final moisture content of the twenty companion prunes was determined with the electric-resistance moisture tester of the Dried Fruit Association. The thermocouples were examined to discover if they had inadvertently been misplaced in completing the lead connections or in installing trays in the tunnel. In general the top and side thermocouples influenced the wrinkling in such a way that the junction was on a ridge, as shown in prune *B*, Fig. 3, with the following exceptions:

Run 2, prune 3: Top thermocouple in a ridge, but not at apex, being about $^{1}/_{16}$ in. or $^{1}/_{3}$ of ridge height below apex, see *A*, Fig. 4.

Run 3, prune 4: Top thermocouple in valley, as *B*, Fig. 4.
Run 4, prune 2: Top thermocouple in valley, as *B*, Fig. 4.
Run 4, prune 2: Side thermocouple near ridge at edge of bottom, as *C*, Fig. 4.
Run 4, prune 5: Side thermocouple in double ridge, as *D*, Fig. 4.

As the prunes softened with rise in temperature and loss of moisture, the bottom began to flatten, so that at about 2 hr of drying, the flat spot was about $^{1}/_{4}$ as long and as wide as the prune. Wrinkling was just discernible at this time. After 6 to 8 hr, the flat spot was about $^{2}/_{3}$ as long and as wide as the prune.

FIG. 3 DRIED PRUNES CONTAINING THERMOCOUPLES

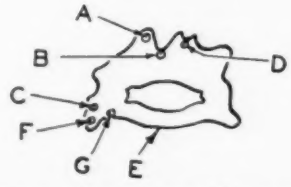

FIG. 4 CROSS SECTION OF DRIED PRUNES SHOWING THERMOCOUPLE LOCATIONS

As the end of drying was approached, the bottom shrank up toward the pit, Fig. 3, prunes *A* and *C*, so that it was cupped with a slight convexity at the middle, Fig. 4, *E*. The bottom junction was usually found just under the pit, in the bulge, with the following exceptions:

Run 3, prune 1: Bottom thermocouple at ridge at edge of bottom, as *F*, Fig. 4.
Run 3, prune 5: Bottom thermocouple near ridge at edge of bottom, as *G*, Fig. 4.

Moisture-Distribution Tests. Two runs were made for measuring moisture distribution, each at 166 F and 105 F wet-bulb temperature. In these runs, four lots of similar prunes were weighed and placed on the trays for drying. After 3 hours, samples from the first lot were removed, weighed, and the skin, with an adhering adjacent layer of flesh, was sliced off for a moisture determination. The flesh adhering to the pit was also removed, and moisture determinations were made on it and on the pit. A similar procedure was followed at 6, 10, and 16 hr. In the second run, the slices from the top, sides, and bottom of the outer layer were kept separate. Some loss, from 6 per cent in the 3-hr sample, to 2 per cent in the 16-hr sample, occurred in the dissecting, and this was allotted to the inner and outer layers on a proportional-weight basis.

The moisture determinations were made by drying to constant weight in an atmospheric oven at 65 C (149 F), for want of a vacuum oven. After the moisture was found, the skin sections of the second run were soaked, the flesh removed, and the skin was dried in small pieces for the purpose of measuring its area with a planimeter. This procedure permitted estimating the average thickness of the top, bottom, and side slices of the second run.

Test Results

Temperature Distribution. The temperatures of the prunes rose rapidly in the first half hour, until within about 20 F of the air temperature, as shown in Fig. 5. They then rose more slowly, until at the end of drying, the surface temperatures were only 2 to 3 deg below air temperature. Because of trouble in controlling the air temperature precisely (there was a periodic fluctuation of 1 to 2 deg in air temperature even with a steady heat input, noticeable in the air-temperature curve in Fig. 6) and of the rapidity with which the prunes tended to respond to a change in air temperature, the data were first plotted as broken lines from point to point, Fig. 6. From such preliminary graphs, smoothed curves were sketched by eye, with consideration of any air-temperature changes which were occurring simultaneously. The air temperature, the mean of the prune surface, and of the prune-center temperatures, and the weight of the 25 prunes are shown for Runs 2, 3, and 4, in Figs. 7, 8, and 9, respectively. The maximum and minimum prune temperatures are also shown in these figures, the curves overlapping at some points as one prune rose above or fell below the others.

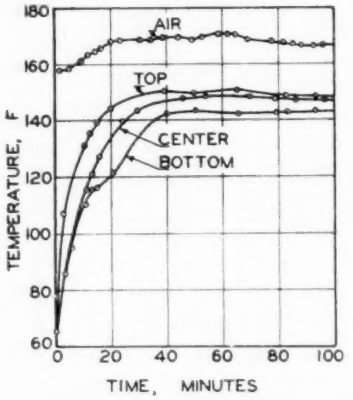

Fig. 5 Temperatures of Prune During Initial Warming; Run 2, Prune 5

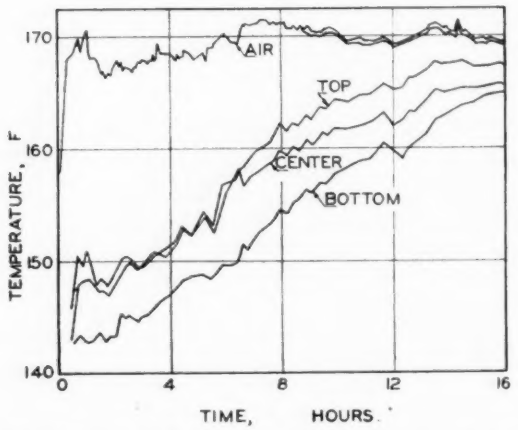

Fig. 6 Graph of Original Temperature Data; Run 2

The considerable variations in temperatures of prunes in the same runs are illustrated in Figs. 10, 11, and 12. Thus in Run 2, Fig. 10, center temperatures of two prunes differed as much as 13 F at one time, nearly as much as the difference of the mean of the five prunes from the air temperature. In Run 3, Fig. 11, however, there was much less variation. That the peculiar dip in the curve for the coldest prune at 12½ hr in Run 4, Fig. 9, is not an error is substantiated by the additional curves for this run, Fig. 12, where it can be seen that the temperature of several, but not all, of the points dropped temporarily at this time. The drop at 13½ hr was obviously due to a drop in air temperature. No explanation is available for this peculiar behavior, except possibly sticking and subsequent loosening from

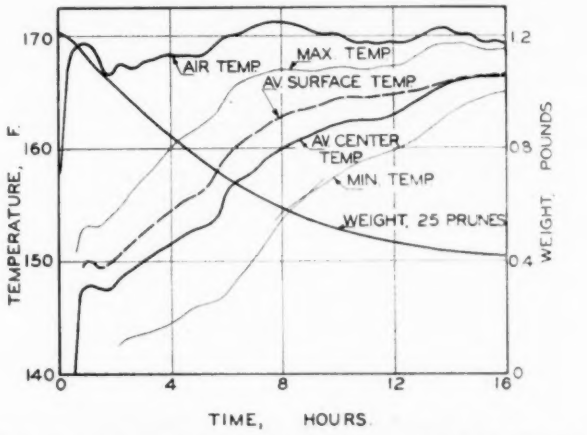

Fig. 7 Weight of 25 Prunes, Air Temperature, and Average Temperature of Prune Surface and Prune Center; Run 2

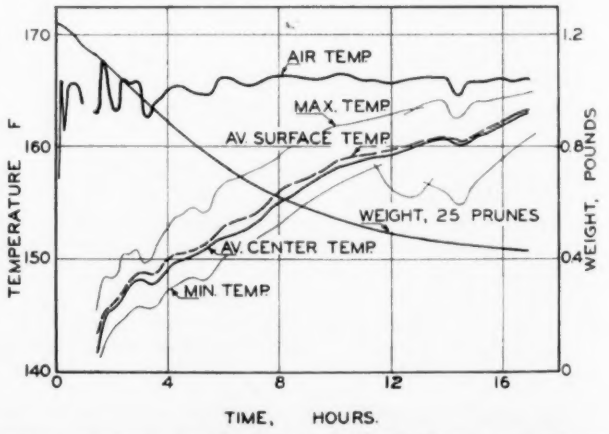

Fig. 9 Weight of 25 Prunes, Air Temperature, and Average Temperature of Prune Surface and Prune Center; Run 4

the tray caused by shrinking. This would permit part of the prune to dry slowly for a time, and then evaporate rapidly when it loosened, giving a temporary depression for a limited area.

The mean difference between the top-, side-, or bottom-surface temperature and the center temperature, was computed by giving the side point 4 times the weight accorded the top and bottom

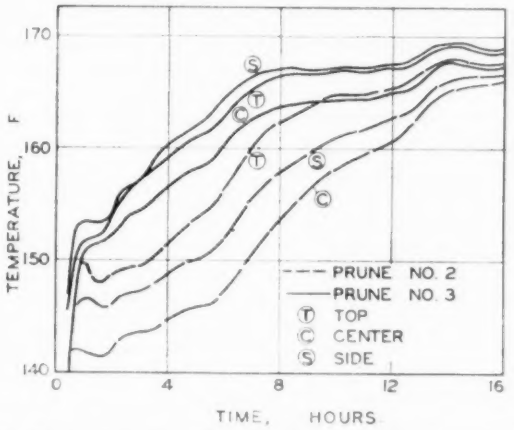

FIG. 10 TEMPERATURES OF TOP, SIDE, AND CENTER; PRUNES NOS. 2 AND 3, RUN 2

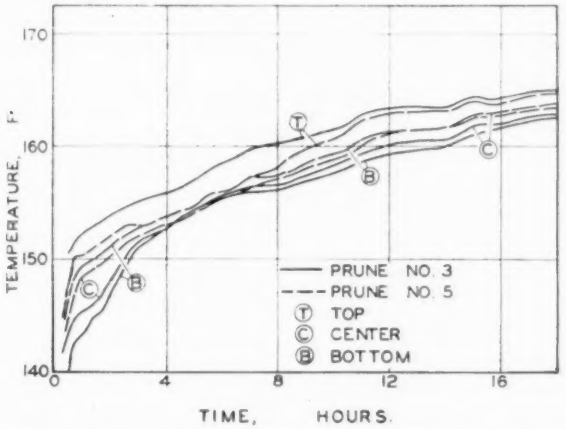

FIG. 11 TEMPERATURES OF TOP, CENTER, AND BOTTOM; PRUNES NOS. 3 AND 5, RUN 3

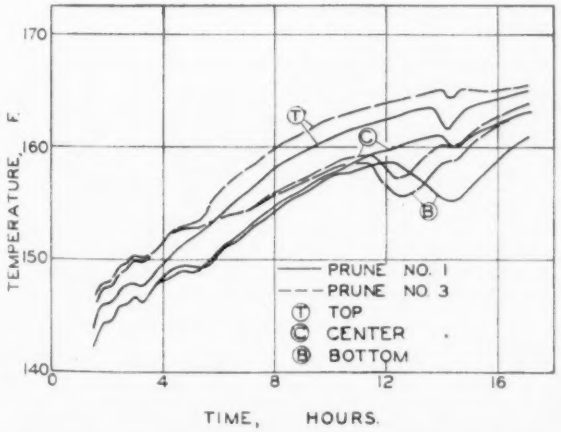

FIG. 12 TEMPERATURES OF TOP, CENTER, AND BOTTOM; PRUNES NOS. 1 AND 3, RUN 4

points, because the arrangement of the prunes on the tray suggests that about these proportions of its surface have similar exposures. Unfortunately, this was not realized when the tests were planned, so that the points were not placed in these proportions. From the mean center temperature of the five prunes, and the mean surface-to-center difference, the mean surface temperature was found. From the surface temperature and the

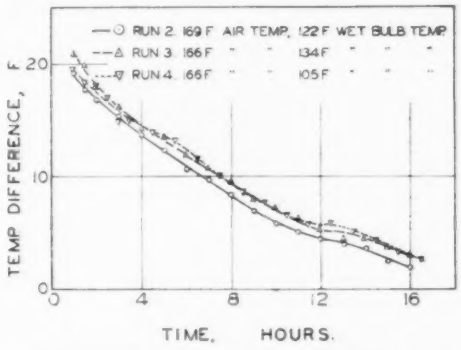

FIG. 13 DIFFERENCE BETWEEN AIR AND PRUNE AVERAGE SURFACE TEMPERATURE

air temperature, the differences between the air and the prune-surface temperatures were obtained, as shown in Fig. 13.

Evaporation Rate. The evaporation rate is indicated by graphs of free-moisture ratio (pounds of free moisture per pound of dry matter), plotted against time on semilogarithmic coordinates, Figs. 14, 15, and 16. The free-moisture ratios were calculated from the prune-weight data, the final-moisture content, and the equilibrium-moisture data, Table 2. The points on these curves did not fall on a single straight line, the slope becoming greater in the middle of the drying period and falling off at the end. For each straight section, the moisture ratio is

$$F = F_1 e^{-B\theta} \quad [8]$$

and the evaporation rate $$\frac{dF}{d\theta} = -BF_1 e^{-B\theta} = -BF \quad [9]$$

TABLE 2 EQUILIBRIUM-MOISTURE RATIOS FOR FRENCH PRUNES AT 150 F (4)

Relative humidity, per cent	Moisture ratio: Pounds moisture / Pounds dry matter
18	0.044
28	0.052
62	0.34
74	0.63
81	1.05
95	1.75

Heat Transfer. The rate of heat transfer to the prune was taken to be the sum of the sensible- and latent-heat rates. The sensible-heat rate per pound of dry matter is the product of the rate of temperature rise and the heat capacity per pound of dry matter. The unit heat capacity of cellulose and levulose being about 0.3 Btu/lb F, the heat capacity per pound of dry matter is

$$c_d = 0.3 + 1.0M \quad [10]$$

The latent-heat rate per pound of dry matter was taken to be the latent heat of water at the temperature of the surface, multiplied by the evaporation rate per pound of dry matter. This calculation neglects the heats of solution of dissolved components, which are not known, but which are probably small. Except during the first half hour, when the rate of temperature rise is high, and the rate of evaporation low or possibly negative, the sensible-heat rate is less than 1 per cent of the latent-heat rate.

In order to compute the unit surface conductances, it was first

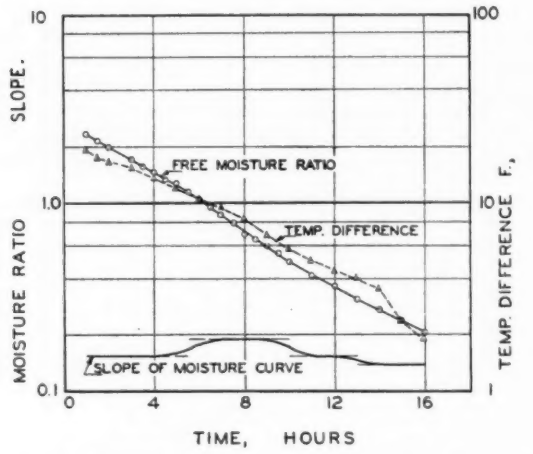

FIG. 14 FREE-MOISTURE RATIO AND TEMPERATURE DIFFERENCE; RUN 2

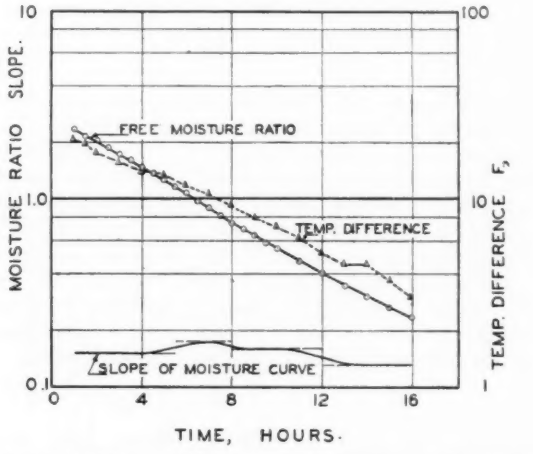

FIG. 15 FREE-MOISTURE RATIO AND TEMPERATURE DIFFERENCE; RUN 3

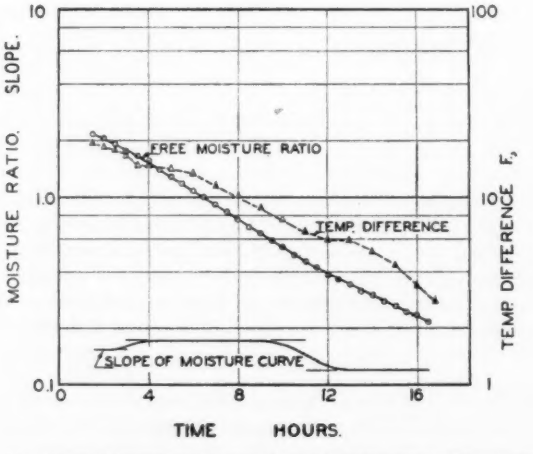

FIG. 16 FREE-MOISTURE RATIO AND TEMPERATURE DIFFERENCE; RUN 4

necessary to find the surface area of the prunes. The initial surface area was taken to be that of a spheroid with a major axis that of the prune, and a minor axis the mean of the two minor axes, which were nearly equal. The final surface area was found from the area data of the dried samples in the second group of tests. The 3, 6, 10 and 16-hr samples were found to have a dried-skin area of 70, 67, 74, and 62 per cent, respectively, of the initial spheroid surface, averaging 68 per cent. Lineal shrinkages of strips cut in two directions around a prune were 78 and 82 per cent, representing an area shrinkage of 64 per cent, but the figure of 68 per cent from the second group of tests was thought to be more reliable. In order to establish the surface area as a function of the moisture ratio, an additional point was obtained from the observation that the prunes were beginning to wrinkle at about 2-hr drying time, when the moisture ratio was about 2.05. At this time, the moisture loss has been primarily from the outer layers, and the volume shrinkage has corresponded to the skin-area shrinkage so that wrinkling has not occurred. After this, the skin does not dry or shrink as rapidly as the prune does, so that wrinkling results.

The relation between prune volume and moisture ratio was found by plotting average density, as found from the initial and final volume and weight data, against moisture content on a wet basis, giving nearly a straight line, Fig. 17. To facilitate calculations, this was converted to density as a function of moisture ratio, and is given with prune-volume and surface-area data in Fig. 18. The volume at a moisture ratio of 2.05 was then used to fix the surface area of the spheroid at this moisture ratio, wrinkling just having started as previously noted. The surface area-moisture ratio curve in Fig. 18 is strictly valid only for the dehydrator conditions of the tests. In counterflow, and other dehydrator arrangements, where the temperature and humidity change from point to point, the relation between the moisture

content of the surface and interior will vary, and the surface area-moisture ratio curves will differ somewhat.

With the surface-area, temperature-difference, and heat-rate data in hand, the unit surface thermal conductances were calculated, both on a prune-surface area and a dry-weight basis, and are given in Figs. 19 and 20. The conductance on a surface-area basis is the conventional conductance, but that on a dry-weight basis is more readily usable and avoids the uncertainty of the actual prune-surface area. The conductance at first increases as drying proceeds, remains nearly constant for a time, drops appreciably near the end of drying, and then seems to rise again. The final drop and rise are puzzling, but were observed in all three runs.

Vapor Conductance and Concentration. In order to find the difference in vapor concentration at the prune surface and in the air stream, the unit surface vapor conductance is required. This is obtained from the observed thermal conductance, using the heat-mass-transfer analogy. According to Boelter, Cherry, and Johnson (5), the Nusselt modulus for mass transfer ($f'D/\alpha$) can be predicted from the Nusselt modulus for heat transfer (fD/k), and the Prandtl moduli for mass and heat transfer, ($\mu/\alpha\gamma$ and $c\mu/k$), as follows

$$\left(\frac{f'D/\alpha}{fD/k}\right) = \left(\frac{\mu/\alpha\gamma}{c\mu/k}\right)^n \quad \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

where n is the experimentally determined exponent of the Prandtl modulus for the analogous heat-transfer system. McAdams (6) recommends a value of 0.3 for n for fluids flowing normal to tubes and banks of tubes. Canceling in Equation [11], and using 0.3 for n

$$f'/\alpha = f/k(k/c\gamma\alpha)^{0.3} \quad \ldots\ldots\ldots\ldots\ldots\ldots [12]$$

At 166 F, the value of k for dry air (International Critical Tables) is 0.0156 Btu/ft hr F, and from Hilpert's data, reported

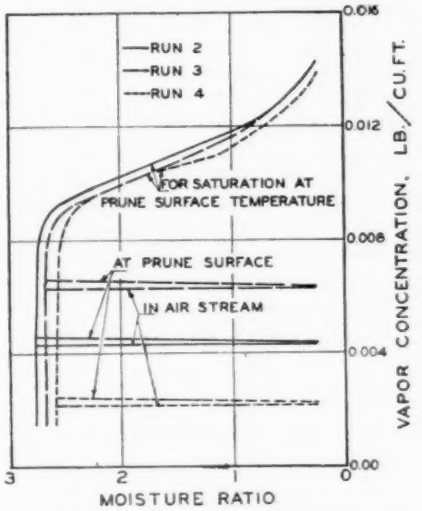

FIG. 21 VAPOR CONCENTRATION AT PRUNE SURFACE

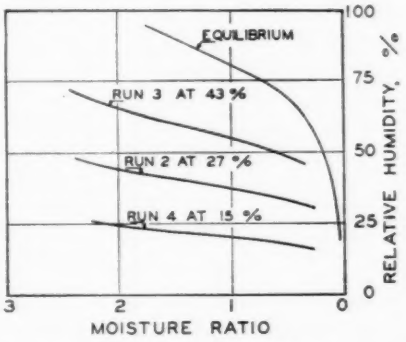

FIG. 22 RELATIVE HUMIDITY AT PRUNE SURFACE

by Boelter, Cherry, and Johnson (5), α is 1.28 sq ft per hr. The density of dry air at this temperature is 0.063 lb per cu ft and the unit heat capacity is 0.24 Btu/lb F. Substitution of these values in Equation [12] gives, for the conditions of these tests

$$f' = 77f \quad \ldots\ldots\ldots\ldots\ldots\ldots [13]$$

The air-vapor mixture adjacent to the prune has an appreciable humidity and a temperature below 166 F, particularly at early stages of drying, but corrections for temperature and humidity will not change the constant of 77 by more than 1 per cent. As shown in Equation [3], the vapor-concentration difference depends upon the evaporation rate and the surface conductance. Rearranging Equation [3], and introducing the equivalent of f' from Equation [13]

$$C_i - C_\infty = 0.013\, w/fA \quad \ldots\ldots\ldots\ldots\ldots\ldots [14]$$

It was more convenient to use, instead of the evaporation rate w, the rate per pound of dry matter from Equation [9], $-BF$, and the surface area per pound of dry matter, A_d, which gave

$$C_i - C_\infty = -0.013BF/fA_d \quad \ldots\ldots\ldots\ldots\ldots\ldots [15]$$

Vapor-concentration differences and vapor concentrations at the prune-air interface are given in Fig. 21. The vapor concentrations for saturation at the prune-surface temperatures, needed in finding the relative humidity at the prune-air interface, are also shown. These curves are based on a uniform air temperature of 166 F, using the data in Fig. 13, to give prune-surface temperatures, and adding the vapor-concentration differences to

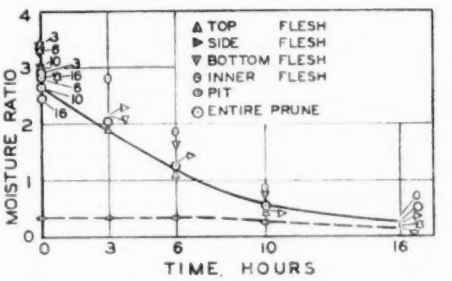

FIG. 23 MOISTURE RATIOS OF SUBDIVISIONS OF PRUNE FLESH

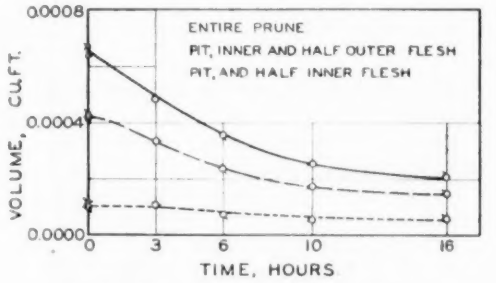

FIG. 24 PRUNE VOLUME DURING DRYING

the average vapor concentration for each run. This was done to avoid distraction by insignificant fluctuations which would result from plotting the data directly with its short-time irregularities in air temperature and humidity. The relative humidities at the prune-air interface, calculated from vapor concentration and vapor concentration for saturation, from Fig. 21, are given in Fig. 22.

Moisture Distribution. The first moisture-distribution test was of limited value because the depth of cut was not evaluated. The second run yielded the data in Table 3, upon which Fig. 23 is based. In comparing the moisture concentrations in top, side, and bottom slices, variations in depth of cut, noted in Table 3, must be borne in mind.

To determine the depth of cut, the volume and surface area of each section was needed, the weight of dry matter and moisture content being known. The area was given directly by planimetering the dried skin, as previously described. The density of the flesh, used in finding the volume, was obtained by subtracting weight and volume values for the pit from those for the whole prune, yielding separate density data for flesh and pit, given in Figs. 17 and 18.

The sets of original data for the 3, 6, 10, and 16-hr observations were necessarily on different lots of similar prunes, which as can be seen in Table 3 varied in initial dimensions and moisture content. In order to estimate what the condition of each sample would have been at the other times, the time-volume curves in Fig. 24 were prepared.

DISCUSSION OF RESULTS

Drying rates in these tests were a little slower than those indicated by Guillou's Equation [2] for drying in hardware cloth racks

$$B = 0.2(t/165)^{4}(V/600)^{0.2}\frac{(100-H)}{60}(N/50)^{0.67}\ldots[16]$$

The mean drying coefficients for a change of moisture ratio from 2 to 0.2 lb per lb were 93, 87, and 99 per cent, respectively, of the prediction of equation for Runs 2, 3, and 4 of the first group, and 93 per cent of the predicted value for the 16-hr sample of the second group.

Temperature of Drying Prunes. Temperature differences be-

tween air and prune were nearly the same for all three runs, Fig. 13, even though the wet-bulb depressions were 32.5, 47, and 61 deg for Runs 3, 2, and 4, respectively. This result is in accordance with the fact that the drying rate is not appreciably affected by changes in relative humidity of the dehydrator air below 35 per cent. The temperature difference depends primarily upon the drying rate and the surface conductance; thus, if the drying rates and surface conductances are the same, temperature differences will also be the same.

It does not seem worth while to develop an equation giving prune temperatures directly, because, in the usual commercial dehydrator, constant drying conditions do not occur. The air-to-prune temperature difference can be estimated from the drying rate and surface conductance. Then the prune temperature can be obtained by subtracting the temperature difference from the air temperature. The surface thermal conductance per pound of dry matter can be given roughly for these runs as

$$fA_d = 10 + 4M \quad \ldots\ldots\ldots\ldots\ldots\ldots [17]$$

At the start of drying, this can be expected to vary with the 0.8 power of the air velocity, the flow pattern being that in a channel, while near the end of drying it may vary with the 0.6 power, flow being around irregular shapes on the tray surface. It will be proportional to the prune count to the $^2/_3$ power, since it is expressed on a unit-weight basis, for which the surface is proportional to the $^2/_3$ power of the number of prunes per pound. It will be a little higher for tray loadings of less than 4 lb per sq ft, but will be materially reduced by heavier loadings which can be obtained only by piling prunes, obstructing air access to prune surface.

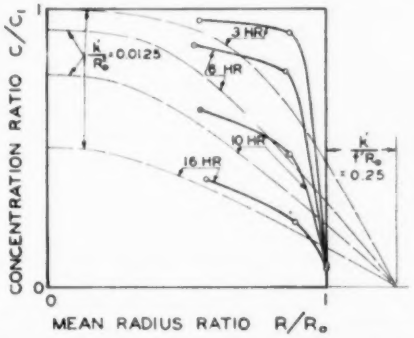

FIG. 25 MOISTURE DISTRIBUTION DURING DRYING

Vapor Concentration and Relative Humidity. The vapor-concentration difference between the prune surface and the air stream is small, so that it has a minor influence upon vapor concentration at the surface. The relative humidity at the prune surface is dependent primarily upon the vapor concentration in the air stream and the surface temperature of the prune. The evaporation rate is not greatly influenced by the relative humidity of the air stream until the relative humidity at the prune surface rises high enough to raise the equilibrium-moisture ratio appreciably. As shown in Table 2, the equilibrium-moisture content does not rise rapidly with relative humidity until humidities of over 50 per cent are reached. The free-moisture ratio (total- minus equilibrium-moisture ratio) was not greatly influenced by raising the air-stream relative humidity from 15 to 27 per cent, Fig. 22, but the further rise to 43 per cent reduced the free-moisture ratio materially at the start of drying.

As the end of drying is approached, the relative humidity at the prune surface drops because the prune-surface temperature approaches that of the air. A low relative humidity is important here if a low final-moisture ratio is required.

Moisture Distribution. A simple, but inadequate, ideal system with which to compare the moisture-distribution data, is that of a homogeneous sphere which dries without shrinking, with a constant moisture conductivity and a constant surface vapor conductance. The moisture distribution for this sphere can be found directly from its thermal analog. Assuming k'/R_0^2 to be constant at 0.0125 (1/hr) and $k'/f'R_0$ to be 0.25, the moisture-concentration ratios are given by the dashed curves in Fig. 25, using values for temperature distribution in a sphere from McAdams (6) or Boelter et al (5). These constants were arbitrarily selected to approximate the actual distribution at 16 hr.

From the volumetric data of Table 3, the mean radius with respect to volume was computed for the outer surface, outer layer of flesh, and inner layer of flesh, for each of the time intervals (viz., 0–3 hr, 3–6 hr, 6–10 hr, and 10–16 hr) of the moisture-distribution run. The free moisture concentration in pounds per cubic foot was then expressed as a fraction of the initial free moisture concentration, and plotted against the mean radius ratio in Fig. 25. The surface concentration was taken to be that in equilibrium with the prune-surface air-vapor mixture, at the relative-humidity values in Fig. 22. The departure of all the surface points, and the internal points at times other than 16 hr, from the ideal system is marked. The comparison is of course considerably qualified by the fact that the observed points are placed at the mean radius ratios of the sphere which was changing in volume with time. The result is similar to that noted for a slab of soap by Hougen, McCauley and Marshall (7).

The concentration gradients, represented by the observed points, indicate that the moisture conductivity within the prune decreases as the flesh becomes drier. As long as the thickness of the layer of decreased conductivity is not too great, the resistance is not greatly increased because the path is short and the cross section, nearly that of the prune surface, is large. Near the end of drying, however, the distance that moisture must travel through low-conductivity material is greater, and the path near the center is of smaller cross-sectional area, so that the drying rate tends to drop off. If prunes are to be dried only to 20 per cent moisture (16.7 per cent on a wet basis), the departure from a logarithmic curve is not pronounced, but for low terminal-moisture contents, a reduced drying rate can be expected.

SUMMARY AND CONCLUSIONS

1 The temperature difference, air stream to prune surface, dropped from 20 F at the end of the first hour, to 3 F at the end of drying, for prunes drying from a moisture content of 2.7 to 0.27 lb per lb of dry matter in 16 hr.

2 The unit surface thermal conductance rose from 7 Btu/hr ft² F at the start of drying to 8 at intermediate stages, and then dropped to 6, at an over-all air velocity of 600 fpm, measured in the free tunnel cross section.

3 Changes of air-stream relative humidity do not appreciably influence drying rates of prunes if the relative humidity is less than 35 per cent because:

(*a*) The equilibrium moisture content - relative humidity curve does not rise rapidly until relative humidities over 50 per cent are reached.

(*b*) The concentration difference between the prune surface and the air stream is small. The moisture conductivity of prune flesh is low, compared with the surface conductance, so that most of the resistance is within the prune.

(*c*) The prune-surface-temperature depression is only a fraction of the wet-bulb depression, so that the vapor concentration required for saturation at the prune-surface temperature is much higher than it would be at the wet-bulb temperature.

4 The moisture distribution within a prune during drying indicates a decrease in moisture conductivity with decrease in

moisture content, so that the differential equation for diffusion for a system with constant properties (the Poisson-Fourier equation) is not applicable.

5 Although the drying rate is nearly proportional to the free-moisture ratio in the usual drying range (down to 0.2 lb of moisture per lb of dry matter), it decreases for lower moisture contents, because of the decrease in moisture conductivity of prune flesh. Extrapolation of the evaporation rate moisture content curve beyond the usual drying range thus intersects the moisture-content axis at an abnormally high value which does not coincide with observed equilibrium-moisture-content values. This is of commercial importance only where very low final-moisture contents are required.

ACKNOWLEDGMENTS

The author wishes to thank Coby Lorenzen, Jr., for preparing and installing the thermocouples in the prunes; B. D. Moses, Rene Guillou, and Coby Lorenzen, Jr., who helped in conducting the tests; and L. M. K. Boelter who gave stimulating suggestions on technique and on the analysis of results.

A New Approach to the Problem of Conditioning Water for Steam Generation

By R. E. HALL,[1] PITTSBURGH, PA.

Modern boilers, because of their high operating pressures and ratings, and their high rates of heat adsorption, intensify the problems associated with the continuous operation which is of such critical importance in our vast productive program. For instance, actual consumption of the boiler tubes by the high-pressure boiler water must be continuously guarded against. Destructive boiler scale such as that composed of sodium silicate, sodium-aluminum and sodium-iron silicates, sodium sulphate and sodium phosphate, must not be permitted to form. The boilers must not fill up with sludge, and the turbines must be kept free of deposits on their intricate blading. Suspecting that sodium for a number of reasons is of destructive influence in the boiler water, the author has initiated building boiler waters on a potassium basis, with affirmative results that are set forth in this paper.

Starting with substitution in the boiler water of potassium for the universal sodium equilibrium, the author has been led to give consideration to the problems of "hide-out" of boiler-water salts, corrosion by the bonded oxygen of the boiler water, silica in boiler and turbine, equilibria developed in the superheater in any carry-over of boiler water, and under certain conditions, protection from embrittlement. In systematizing the results which must ensue from the complex network of interrelations of temperature, pressure, and concentration, under these conditions, he makes use of the conceptions of the concentrating-film boiler water, generalizes the temperature-pressure-concentration relations in the form of a Δt function, and points out how the relationship of incongruent solubility between water and the silicates must be controlled.

Introduction

SOME years ago, introduction of equilibrium-wise thinking into boiler-water chemistry brought into use maintenance of the phosphate equilibrium in the boiler water as the final step in its conditioning for elimination of the alkaline earth-metal scales. Inasmuch as engineers were demanding larger boiler units, higher pressures, higher ratings, and higher rates of heat absorption, but, particularly in the industrial field, felt well-nigh frustrated by the drastic restrictions (1)[2] on feedwater deemed necessary therefor, this innovation was timely in removing these restrictions, and thus contributing to the progress achieved in attainment of the objectives sought.

Scarcely were the alkaline earth-metal scales under control, however, when new difficulties arose in the form of siliceous deposits comprising silica and sodium silicate, sodium-aluminum and sodium-iron silicates. The phosphate equilibrium was not designed to, nor could it, prevent their formation. At about the same time, another phenomenon, the hiding-out of boiler-water salts in the boilers of high pressure and high rating, became well recognized. Purer water for the boiler was conceived to be an answer to this problem, but the purer boiler waters which resulted brought to light a problem of their own, namely, furrowing and channeling of tubes, with development of large amounts of magnetic iron oxide, and final failure; or, development of large quantities of magnetic iron-oxide sludge without channeling or furrowing in evidence at any special point. Since these cases of special corrosion have been attributed to dissolved oxygen entering the boiler in the feedwater, tremendous effort and expense have been brought to bear on removal of the last vestige of dissolved oxygen from the feedwater, but without remedying the condition. As a last straw, as boiler-water alkalinities have been lowered almost to the vanishing point in another move to combat such corrosion, there has arisen an epidemic of silica deposition in the lower pressure stages of turbines, not amenable to steam-washing, but requiring caustic-washing (26) or complete shutdown of the unit for cleaning. Elimination of the silica content in the boiler water would seem to be the obvious move to make; but soft boiler deposits, relatively high in magnesium content, and not removable by blowdown, then become another cause of irritation and distress.

Faced with deficiencies of circulation in hard-worked tubes that might very well function as planned if these other problems were solved, the engineers have come to the point of bluntly questioning the chemists whether further progress in conditioning boiler waters is possible.

Inauguration of Potassium Equilibrium in Boiler Water

During the summer of 1942, with the end in view of attempting to break the deadlock which existed relative to solving these different problems, we inaugurated the drastic change of maintaining the boiler water on a potassium equilibrium, in place of the sodium equilibrium which has characterized boiler waters from the beginning of steam generation. As illustrated in Table 1, boiler deposits in the evaporative sections, before the advent of phosphate equilibrium in the boiler water, consisted mainly of calcium and magnesium salts with variety provided at times by silica, sodium silicate, and magnetic oxide of iron. After the advent of phosphate equilibrium, the deposits as illustrated in Table 2, while containing minor amounts of calcium

Contributed by the Joint Research Committee on Boiler Feedwater Studies and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Note: Space does not permit publication as an appendix of the tabulated data which have been used, but a complete set of these tables is on file at the Engineering Societies Library, 29 West 39th Street, New York, N. Y., for reference. The original data are available in the references of the Bibliography.

Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

and magnesium salts, were dominated instead by sodium salts, i.e., sodium silicate, sodium-aluminum silicate, sodium-iron silicate, sodium phosphate, and sodium sulphate, along therewith, silica and magnetic oxide of iron.

It was decided to get rid of sodium in the boiler water and to substitute potassium therefor. Potassium and sodium are chemical equivalents, but are not always peers chemically, as is well illustrated by the simple examples of hard and soft soaps, and such differences as make potassium silicate a preferred binder in special flux coatings for welding rods, and a more successful vehicle than sodium silicate for pigments in some decorative paints (39). The problem to be studied was whether the substitution of potassium for sodium might demonstrate a difference at the temperatures and pressures of the boiler-water cycle which would eliminate alkali-metal deposits.

Messrs. L. E. Hankison and M. D. Baker of the West Penn Power Company expressed willingness that this experiment be put into practice at the Springdale Station of the company. It was Hankison, who at the same station had previously carried on the experimental work in practical operation for the phosphate equilibrium (2).

From the time it started, this work has continued at Springdale and, because results are remarkably definite, will continue. Meanwhile, in the early spring of 1943, with the results at Springdale as a background, we brought the system of potassium equilibrium to the attention of the engineers in a few plants which had specific problems to which the system pertained.

Fundamental Phenomena of the Boiler-Water Cycle

The troublesome problems, which have been noted, existed in mild form in the older lower-pressure boilers, but were considerably minimized by low ratings and by scale formation. The cleaner boilers that have resulted from phosphate-equilibrium treatment, along with higher pressures, temperatures, ratings, and higher rates of heat absorption, have magnified these trouble-making factors seriously.

Why?

To answer that question, we must bring clearly into focus what happens as the dilute over-all boiler water traverses those surfaces where steam is generated, where the boiler tubes are exposed on the heated side to furnace temperatures of 2000 to 2500 F, where they must rapidly absorb the furnace heats both of radiation and convection, and must transfer this heat to the water they contain at a rate such that their external surfaces will remain at 800 to 900 F, or thereabouts. In the boiler-tube raceway, unimpeded flow of boiler water and formation of myriad steam bubbles therefrom interest us most.

Whatever may be the mechanism by which the steam bubbles form, Fig. 1 will serve to illustrate, conventionally, a transient state of affairs with billions of recurrences. What happens on the tube surface *A* under the steam bubble? Partridge (3) a

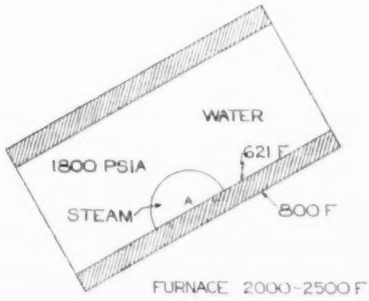

Fig. 1 Transient State of Affairs With Billions of Recurrences

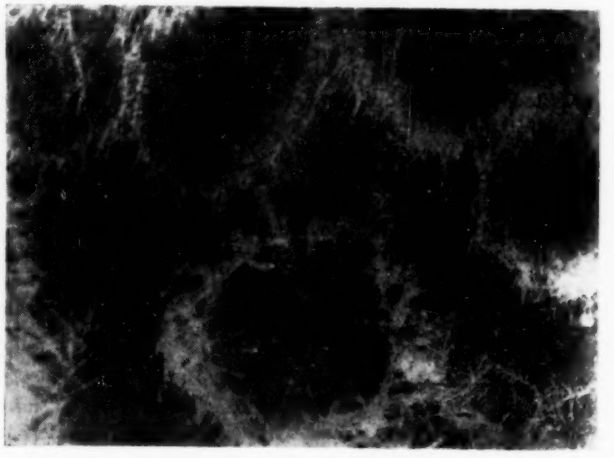

Fig. 2 Mechanism of Formation of Calcium-Sulphate Scale

number of years ago initiated the move to answer that question when he photographed the process of calcium-sulphate scale formation, as shown in Fig. 2. In explanation, he stated: "Due to the great increase in resistance to heat flow of the gas film over the resistance of the liquid film, the metal surface tended to overheat locally, in the area within the interface." Along therewith, the film of boiler water covering the surface under the bubble concentrated or evaporated, and deposited its content of calcium sulphate in the form of scale at the periphery of the contact of the bubble with the tube surface.

May we assume therefore that wherever a steam bubble forms, or where the more severe conditions of steam-blanketing,

or film-boiling, as noted by Davidson and Associates (4, 5) occur, the film of boiler water on the surface will evaporate to dryness,[3] or so concentrate as to deposit its salt in solid form? To answer that question, let us consider the experiment illustrated in Fig. 3. In the flask, with its vapor-containing wall carefully insulated against loss of heat, a dilute solution of calcium chloride is boiling, at atmospheric pressure, freely discharging its steam to atmosphere through the side arm of the flask. The boiling temperature t_l, of the solution equals t_v, the temperature of the carefully heat-insulated vapor, which, however, issuing from the side arm immediately drops in temperature to 212 F. The difference between the temperature t_v of the steam in the flask and the temperature $t\mathrm{H_2O}$ of steam developed by pure water boiling at the same pressure is Δt. Concentration of the solution, constantly increasing because of loss of steam through the side arm, finally reaches 70.6 per cent or 0.28 mol fraction[4] which, at atmospheric pressure or 14.7 psia, is saturation concentration. The equal temperatures of solution and vapor, t_l and t_v, have likewise increased with the increasing concentration, and at saturation are designated t_s, and Δt becomes Δt_s. For the condition of saturation, t_s = 326 F, $t\mathrm{H_2O}$ = 212, and the steam in the flask is superheated 114 deg ($\Delta t_s = t_s - t\mathrm{H_2O}$). The initial concentration of the calcium chloride, whether a few parts per million, or a few per cent, is a matter of indifference. If the pressure is fixed at 14.7 psia, and heat is supplied at the requisite level, the conditions for saturation as noted will eventually obtain. With continuation of boiling and discharge of steam, t_s and Δt_s will not increase, but instead, separation of solid salt will begin and continue until only solid calcium chloride remains. On the other hand, if the heat level is not sufficient to raise Δt to Δt_s, boiling will cease and equilibrium will obtain at the maximum Δt corresponding to the heat level in question, saturation never being reached unless the heat level is increased to raise Δt to Δt_s.

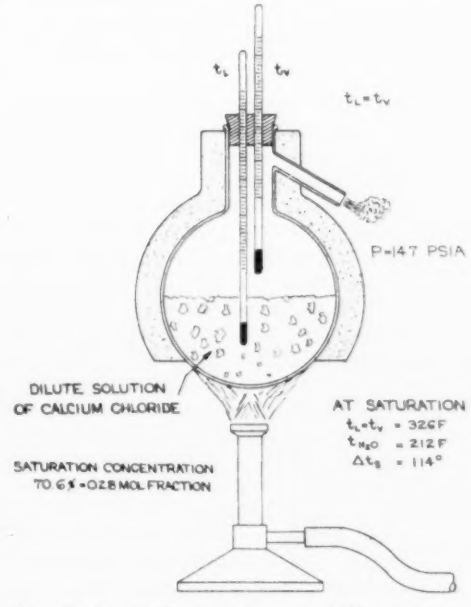

FIG. 3 SIMPLE ILLUSTRATION OF Δt FUNCTION

In the experiment, pressure is fixed at atmospheric, and if the flask contained pure water, boiling would occur at 212 F ($t\mathrm{H_2O}$). With solution in the flask, however, boiling does not occur at 212 F, a fact which signifies that the vapor pressure of the solution is less than that of pure water. In general, at any temperature t, decrease in vapor pressure of any solution becomes greater as its concentration increases, and thus is a function of the concentration of the solution, or equally, of the number of solute molecules in the solution. It was Raoult who pointed out that in dilute solutions of nonelectrolytes, the function is closely that of strict proportionality (A, II).[5]

When the temperature of a solution of any given concentration is increased, its vapor pressure is thereby increased. In the experiment, with pressure fixed at atmospheric, when the temperature t_l of the solution was raised sufficiently above 212 F, the increment of temperature (Δt) over 212 F sufficed to increase the vapor pressure of the solution to atmospheric, and boiling then occurred. As evaporation proceeded, and concentration of the solution accordingly increased, the increment of temperature Δt over 212 F, required to occasion boiling, likewise increased. The relationship thus established for pressure of 14.7 psia and $t\mathrm{H_2O}$ = 212 F, is applicable as well to all boiler pressures and the corresponding boiling temperatures or $t\mathrm{H_2O}$ values. It is thus obvious that Δt is a function of the concentration of the solution or, equally, of the number of solute molecules in the solution.

In the light of these conclusions, let us examine what happens to a film of boiler water on surface A, Fig. 1, if the temperature of the surface becomes heated above boiler-water temperature, 621 F, by an amount Δt. Pressure is fixed at 1800 psia. As the film begins to boil and concentrate at this fixed pressure, because of increased temperature Δt, its vapor pressure must attempt to decrease because its number of solute molecules is increasing. This attempt, however, is offset or compensated by the tendency of the vapor pressure of the solution to increase with rise in temperature. Meanwhile concentration of the film proceeds in its effort to establish the relationship among the different forces which represents equilibrium for the particular Δt value assumed. As concentration thus proceeds, some components of the solution may reach saturation, and be deposited, while others, more soluble, carry on the work of building the concentration to the degree required for equilibrium. If the Δt assumed happens to be greater than the Δt_s of saturation concentration of all components in the solution, evaporation to complete dryness must occur. This is what happened in the development of scale illustrated in Fig. 2, since calcium sulphate at saturation has a low value of Δt_s. But if the Δt_s value of some components at saturation is greater than the Δt assumed, they will remain dissolved and merely increase in concentration by the amount necessary to establish equilibrium.

These considerations illustrate the distinction between the customary conditions obtaining in measurements of vapor-pressure lowering and boiling-point rise, and those which obtain at the steam-water interfaces in a boiler. In the first, temperature and concentration are usually the independent variables with vapor pressure the dependent variable; in the second, vapor pressure and concentration are independent variables, temperature the dependent variable. But in the boiler, pressure, fixed by the boiler, and temperature, established by the degree of overheating Δt at a surface such as A, Fig. 1, are the independent variables, and the concentration of the concentrating-film boiler water is the dependent variable. Its value is commonly expressed as a mol fraction, and frequently indicated by X_2.

We shall designate as the Δt function relations of this type, occurring at the steam-water interfaces of the boiler-water and

[3] W. Otte has assumed evaporation to dryness in all cases (49), (50).

[4] The mol fraction of any constituent in any solution is the number of mols of that constituent divided by the total number of mols in the solution.

[5] References to the Appendix are thus indicated throughout the paper. See footnote on page 457.

steam cycle. Whenever we shall refer to the Δt function, we shall thereby signify the equilibrium that will be reached or approached on the basis of the variables pressure, temperature, and concentration, operating in accordance with the rules heretofore set down. Under the dynamic conditions that exist at a surface such as A, Fig. 1, or even areas where steam-blanketing or film-boiling exists, any well-defined equilibrium for any certain set of conditions may not be reached because of insufficiency of time. The film on surface A will continually struggle to establish equilibrium, however, and in so doing will at all times follow the pattern laid down by the principles of the Δt function.

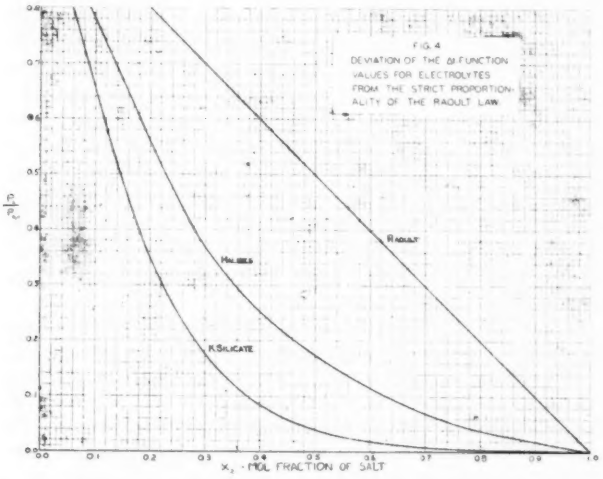

FIG. 4 DEVIATION OF THE Δt-FUNCTION VALUES FOR ELECTROLYTES FROM STRICT PROPORTIONALITY OF THE RAOULT LAW

This will be illustrated by examples. In the experiment, Fig. 3, if sodium chloride, potassium chloride, or sodium sulphate, respectively, were used in place of calcium chloride, the results would be as follows (A, III, 4, 5, 19; IV, 3, 4, 12):

Pressure = 14.7 psia	Saturation concentration X_2 = mol fraction	t_s deg F	Δt_s deg
Sodium chloride	0.109	228	16
Potassium chloride	0.123	227.5	15.5
Sodium sulphate	0.051	217.1	5.1

If the pressure were 1800 psia, as in Fig. 1, on the surface A under the steam bubble, the results would be thus:

Pressure = 1800 psia	Saturation concentration X_2 = mol fraction	t_s deg F	Δt_s deg
Sodium chloride	0.190	692	71
Potassium chloride	0.292	745	124
Sodium sulphate	0.0095	625	4

This means that if the solution of potassium chloride were evaporating on the surface A, Fig. 1, the overheating of that surface on the inner side of the tube to produce saturation in the solution would necessarily be 124 deg. For the sodium-chloride solution, overheating to the extent of 71 deg, and for that of sodium sulphate, only 4 deg, would produce saturation. If for instance the overheating at A were 35 deg, the solution of neither potassium nor sodium chloride would attain saturation, but that of sodium sulphate would evaporate to dryness.

In the generally strong solutions of electrolytes which result from the concentration of boiler water, the curves plotted on the basis of the Δt function variables provide a valuable guide in the study of these solutions. Fig. 4 illustrates the deviation of the halides (sodium and potassium chloride, bromide, and iodide) (6) and of the potassium silicates (7) in saturated solution, from the strict proportionality of Raoult's law. (P_s and P_{h_2o} are, respectively, the vapor pressures of the saturated solution and of pure water at t_s). Later sections will develop the use of these curves.

Suppose that the solution had contained two species of molecules, for instance, sodium sulphate and sodium chloride: According to the Δt function, the value of Δt is a function of the number of solute molecules present, and largely independent of their kind. Thus, in this mixture, both the sodium chloride and the sodium sulphate will each exert its influence toward increasing Δt, hence with less concentration of either one for a given Δt than if either were in solo solution. At the pressure of 1800 psia under consideration, the data of Schroeder, Gabriel, and Partridge (8), (A, VII, 2) show that with increasing concentration of sodium chloride, no marked increase occurs in the solubility of sodium sulphate. Hence if a solution containing these two components evaporated on surface A, Fig. 1, overheating of the surface of somewhat more than 4 deg, depending upon their relative concentrations, would cause saturation concentration of the sodium sulphate, and it would begin to precipitate as solid phase on the surface, while the sodium chloride would remain in solution and keep on concentrating, requiring a considerably higher temperature to effect its saturation. If in place of sodium sulphate, very soluble sodium or potassium nitrate (A, III, 10, 11; IV, 9) were the other component of the solution, the degree of overheating of the surface A which would be necessary in order to cause saturation concentration of either component would be largely increased over what it would be for either one. The significance of this is that once sufficient data have been acquired in relation to the Δt-function properties of the boiler-water salts, it will be possible to predetermine for any value of Δt, whether a boiler water upon concentration will finally become saturated with respect to one or all components, and by appropriate adjustment of their relative concentrations, to impose on the solution the desired condition of these components as Δt is reached.

Thus, in Fig. 1, we can readily picture what will happen at the surface A, if the boiler water contains constituents of limited solubility like sodium sulphate along with some caustic soda. As the temperature at A rises by some amount Δt, the film of boiler water must concentrate in accordance with its Δt-function value. Sodium sulphate will precipitate, and the caustic will concentrate. Deposition of sodium sulphate or attack of the surface by the concentrated caustic, either or both, will create resistance to the flow of boiler water. If, however, we condition the boiler water so that quite soluble salts are present to concentrate along with the caustic, then since the attainment of Δt rests mainly upon the number of molecules in solution, and not largely on their species, neither the caustic nor the soluble salts will concentrate excessively in developing the equilibrium corresponding to the rise in temperature Δt on the tube surface. By this preclusion of development in the boiler tubes of impediments to flow, maximum flow of boiler water is assured. Therewith the probability of steam-blanketing or film-boiling conditions is lessened, and the life span of the bubble, Fig. 1, and also the Δt value of the A surface are kept at a minimum.

Thus from this careful examination of events contingent upon bubble formation, or more broadly, occurring at interfaces of boiler water and steam, there evolves a pattern for molding them to the best advantage of boiler operation. Cognizance must be taken of the fact that in any boiler, there are in reality two different boiler waters to consider, namely, the dilute over-all and the concentrating-film boiler waters. In the boiler, wherever the dilute over-all boiler water governs conditions, we need consider only its isobaric-isothermal properties; but where concentration occurs, as in the concentrating-film boiler water under

the steam bubbles which are forming, or at points of steam-blanketing or film-boiling, we must give heed to its isobaric-polythermal properties as it concentrates in accordance with the Δt function. When any carry-over of the dilute boiler water enters the superheater, it is subjected to isobaric-polythermal conditions, and it will concentrate therein in accordance with the pressure and temperature relations which obtain. The concentrated magma thus formed upon passing into the turbine meets the falling pressure and temperature which characterize conditions therein, and we must consider its properties in relation to the polybaric-polythermal conditions to which it is subjected. In Table 3, these facts are briefly summarized.

TABLE 3 PRESSURE-TEMPERATURE RELATIONS AFFECTING BOILER WATER AND CARRY-OVER

		Isobaric isothermal	
		Over-all boiler water	
		Isobaric polythermal	Polybaric polythermal
A	*Boiler:* boiler water	Concentrating-film	*Turbine:* Gradual dilution of concentrated carry-over
B	*Superheater:*	Highly concentrated boiler-water carry-over	

Particularly, Table 3 emphasizes the need of a systematized procedure to take cognizance of the changes occurring in the isobaric-polythermal regions of the boiler or superheater, and the polybaric-polythermal region of the turbine, in addition to that which has been generally applied to the dilute over-all boiler water. Such systematic procedure means so balancing the proportional relationship and character of the components in the dilute over-all boiler water, which can be readily established as desired and checked by analysis, that changes of concentration occurring at interfaces of boiler water and vapor in accordance with the Δt function cannot result in development of high causticity, or in the separation of water-insoluble components, especially those siliceous in nature.

In order to arrive at the features which must be embodied in this inclusive procedure, we shall now subject the problems enumerated in the introduction, and, incidentally, factors relating to protection from caustic embrittlement also, to examination in the light of the potassium equilibrium and the application of the Δt function.

The Problems of Hide-Out of Boiler-Water Salts

The boiler-water salts which have been mainly recognized as guilty of hide-out are sodium sulphate and sodium phosphate. Some recent data, however, in which the silica concentration was followed closely, have shown that sodium silicate is equally guilty with the phosphate and sulphate.

In the range of boiler-water temperatures the solubilities of sodium phosphate and sodium sulphate (A, III, 13, 19) decrease rapidly with temperature increase. The fact that sodium silicate joins with the sodium sulphate and phosphate as a hide-out salt ties in well with the very limited solubility data on sodium silicate which are available (A, III, 15) and which show it to have a decreasing solubility curve in the range of boiler-water temperature. From the customary thinking in terms of retrograde solubility alone, however, it is difficult to see how hide-out would occur, since the sulphate and phosphate solubilities are a couple of thousand parts per million or more at operating pressures well above those in which hide-out has been characteristic. Neither is it likely that the double salts of sodium sulphate and sodium phosphate, which were recognized and discussed by Schroeder, Berk, and Gabriel (9), (A, VII, 7), are the reason for the hide-out of these two salts, as the solubilities of these double salts are appreciable.

In the illustration of overheating of surface *A*, Fig. 1, we must remember that Δt_s governs the number of molecules necessary for saturation and hence deposition, and that the apparently considerable solubility of sodium sulphate as viewed from the standpoint of parts per million shrinks to a relatively insignificant value when expressed as mol fraction. Reference to the values of Δt_s for sodium sulphate (A, IV, 12), over the range of boiler temperatures, discloses a maximum of 8 deg only and at the temperature of 600 F, of no more than 4. This means that if the water surface of a boiler tube is heated only a very few degrees above boiler-water temperature, where rapid evaporation is occurring or where there is a tendency to film-boiling or steam-blanketing, sodium sulphate will precipitate readily enough. Low Δt_s values are a characteristic of salts whose saturation concentration is given by small value of the mol fraction or, in other words, by a relatively small number of molecules in the solution. Thus sodium carbonate (A, IV, 2) is similar to sodium sulphate, its maximum Δt_s being 10 deg.

Sodium carbonate does not appear as one of the hide-out salts, presumably because of its ready decomposition into caustic soda, and because so little of it is present in the boiler waters at even medium boiler pressure. Reference to the solubility tables of sodium phosphate and sodium silicate discloses that their saturation concentrations are given by extremely small mol fractions, so that while their vapor pressures are unknown, and therefore likewise their values for Δt_s, yet doubtless these are very small and probably lower than Δt_s for sodium sulphate.

The question might be raised if the increased solubility of sodium sulphate in the presence of caustic soda at higher temperatures and pressures as found by Schroeder, Gabriel, and Partridge (8), (A, VII, 1), would not tend to minimize the hide-out tendency of sodium sulphate by considerably increasing its Δt_s value. While no values are available for the vapor pressure of such solutions, the mol fraction of sodium sulphate at saturation concentration is small even with its increased solubility in the caustic-soda solution, and the inference therefore is that deposition of sodium sulphate would occur with relatively low Δt_s. According to the work of Schroeder, Berk, and Gabriel (9), (A, VII, 7, 8), caustic soda has little influence on the solubility of sodium phosphate, and hence on the value of Δt_s, at which deposition would occur.

Plainly, the elimination of hide-out demands that the components in the boiler water shall be of much higher Δt_s than that characteristic of sodium sulphate. This viewpoint is supported by the high values of Δt_s for sodium hydroxide and sodium chloride (A, IV, 3, 5), since neither of these salts is guilty of hide-out propensities.

At one of the stations on which we initiated potassium-equilibrium conditioning during the spring of 1943, but while sodium-conditioning was still in effect, measurements on hide-out had shown the conditions to be as bad as, and probably worse than, any we had previously experienced. Both the sulphate and the phosphate skyrocketed when boiler load was reduced. With potassium-equilibrium treatment well established, successive tests have shown complete absence of sulphate hide-out, and elimination of all but the barest trace of phosphate hide-out. Why should this be the case? So little is known of the solubility of potassium phosphate (A, III, 14), that no help in answering this question is to be gotten from it. The solubility of potassium sulphate (A, III, 20) is of low mol fraction, however, about double that of sodium sulphate. Thus while the vapor pressure of saturated potassium-sulphate solutions at the temperature in question (625 F) is unknown, the Δt_s value is doubtless a little higher than that of sodium sulphate. But unless small differences in Δt_s values are of very critical influence in the occurrence or nonoccurrence of hide-out, it seems improbable that the only slightly larger Δt_s of potassium sulphate in itself could have been the major reason for its disappearance in this case. Comparison of potassium chloride and sodium chloride A, III, 4, 5; IV,

3, 4), for example, at boiler pressure of 1400 psia (Table 5) shows that saturation concentration for the former occurs at mol fraction of 0.274, and Δt_s of 104 deg; for the latter, at mol fraction of 0.182, and Δt_s of 65 deg. These values, while favoring potassium chloride, are high enough in either case to dispel any thought of their activity in hide-out. For either potassium metasicilate or disilicate (A, III, 17, 18; IV, 10, 11), Δt_s is extremely high, and the solubilities likewise are high, in very decided contrast to sodium silicate. What we consider to be the most feasible reason for disappearance of the hide-out is our establishment in the boiler water of an environment of soluble salts, which, together with the gain from the higher Δt_s value of potassium sulphate and perhaps phosphate, effected the result.

While all the data that we would like to have for their bearing on this problem of hide-out are not of record, yet enough are available to make it feasible to conclude that elimination of hide-out requires a Δt_s value for dissolved components in the boiler water which, as concentration occurs at any steam-water interface, is considerably greater than that of sodium sulphate. With sodium equilibrium maintained in the boiler water, this means that the concentrations of salts with low Δt_s value such as sodium sulphate, phosphate, and silicate must be carefully controlled and held as low as possible. On the basis of very limited observation, it appears that the substitution in the boiler water of potassium equilibrium for the customary sodium equilibrium increases markedly the permissible tolerance of sulphates, phosphates, and silicates. Because the methods used in obtaining the solubility data for potassium sulphate are not beyond question, and because solubility data on potassium phosphate are lacking, we are engaged at the present time in the determination of their solubilities at boiler-water temperatures. As more data of the kind become available, it will be possible to bring the details of this problem into sharper focus.

The Problem of Magnesium Deposits

An excellent example of this problem is a seaboard plant in which condenser leakage of salt water supplies magnesium to the boiler without simultaneously supplying sufficient silica to combine with it as serpentine or other magnesium silicate. A soft deposit, definitely characterized by magnesium phosphate, or at times, hydroxide, develops in the boiler. Though not forming hard scale, it clings to the surfaces and resists removal by blowdown. A similar condition may arise with the use as feedwater of a natural or treated water containing excess of magnesium over silica.

Magnesium silicate, which is the most, or at least one of the

c Saturation pressure less than boiler pressure.
d Concentration of the unsaturated solution.

most insoluble of the silicates, forms in the boiler water as a sludge which remains dispersed therein and is removed from the boiler by blowdown. Very likely its high insolubility plays a major role in this, resulting in its complete precipitation in the body of the dilute over-all boiler water, and thus its avoidance of taking any part in the reactions which characterize the concentrating-film boiler water.

The fact stands out that if any magnesium is to gain entry into the boiler water, provision should be made therein of sufficient silica to insure its combination with the magnesium as one of the magnesium silicates, thus avoiding magnesium phosphate or hydroxide.

Add silica for the purpose if necessary? Yes, why not? To be sure, the finger of suspicion has been leveled at silica universally, and its constant companion, sodium, has remained unsuspected and been accepted as a matter of course. The case is one of mistaken identity, and the truth is that if the influence of sodium over silica is replaced by that of potassium—if the boiler water is maintained on the potassium equilibrium—silica, in the amount required, can be accepted safely as a member of the boiler-water salts, and be of real use. The logic of this conclusion is foreshadowed by the diametrically opposite solubility properties of the sodium and potassium silicates in the range of boiler-water temperatures (A, III, 15, 16, 17, 18), as demonstrated by the curves in Fig. 5, the former being of the same retrograde type as sodium sulphate and phosphate, and the latter being of the type of sodium and potassium chloride. As regards relationships in the turbine, further facts will develop as we proceed.

The Iron-Oxide Sludge Problem: Corrosion by the Bonded Oxygen of the Boiler Water

In any plant, with the excellent deaeration characteristic of present-day operation, dissolved oxygen entering the boiler in the feedwater is of the order of a millionth of a per cent, while the oxygen it contains, bonded to hydrogen, constitutes 88.9

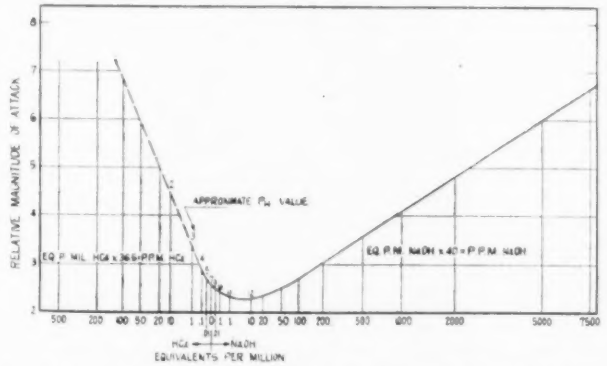

Fig. 6 Attack on Steel at 590 F by Water of Varying Degrees of Acidity and Alkalinity

per cent of its weight. If this bonded oxygen is in some way unleashed in quantity, the possibilities of damage to the boiler are better imagined than experienced. The pertinent questions are: May the bonded oxygen be readily unleashed, and if so, what measures may be taken to prevent it?

In answering the first question, we may well start with the curve in Fig. 6, developed by Partridge (10) on the basis of data obtained by Berl and van Taack (11). As demonstrated by the curve, susceptibility of boiler steel to dissolution in the contacting water increases with increase either of acidity or alkalinity. In conformity with the teaching of this curve, the over-all boiler water is in general held in the pH range of 8.3 to 12, the former being that naturally assumed by water boiled in an iron vessel (12). In this pH range the steel is only slightly susceptible to dissolution by the boiler water. Inasmuch as boiler waters are thus maintained alkaline, we shall confine our attention to the alkali side of the curve. Increasing of alkali concentration results in greater relative magnitude of attack on the steel, a result in conformity with the reaction involved

$$FeO + 2HONa = Fe(ONa)_2 + H_2O \quad [1]$$

Thereby the steel surface is deprived of its protective film of iron oxide and renews it by reacting with water thus

$$Fe + H_2O = FeO + H_2 \quad [2]$$

or, finally, probably, in the boiler with formation of magnetic oxide, Fe_3O_4 (10, 28). Simply, then, as recorded in Reaction [2], the bonded oxygen of the boiler water is unleashed from its hydrogen and combines with the boiler steel, thus providing the protective film so necessary therefor, and preventing or greatly retarding any further release of bonded oxygen, so long as the film remains intact. It is the entry of Reaction [1], and more specifically, the degree of alkali concentration in the reaction, which, in the end, destroys the film, and thereupon, with infinite recurrence of both Reactions [1] and [2], takes its toll of the boiler metal. It is the bonded oxygen of the boiler water which, uniting with the boiler steel, gives rise to the heavy deposits or sludges of magnetic iron oxide, sometimes with destructive furrowing and channeling, or more localized severe pitting; sometimes with merely general action on the surfaces as attested by the magnetic-oxide deposits.

Briefly, the problem of preventing this action involves the features of having alkalinity as required in the over-all boiler water, but at the same time making provision that in the concentrating-film boiler water, the concentration of alkali will be sufficiently restricted to nullify Reaction [1].

To get some idea of the alkali concentration at which Reaction [1] is sufficiently rapid to be damaging, Kaufman and Marcy in our laboratory, rotated 5 per cent solutions of caustic soda and potassium hydroxide in bombs of boiler-steel construction at approximately 470 F for a number of hours [see also (32)]. The solutions put into the bombs were clear and free of precipitate. In case the bombs were not pickled before the experiment, the solutions removed were heavily contaminated with iron-oxide sludge, presumably developed from the iron-oxide coating of the bomb walls by the mechanism of Reaction [1]. When sodium sulphite was added in sufficient quantity to account for any dissolved oxygen, similar results ensued. However, if the bombs were pickled just prior to the experiment, thus largely removing their iron-oxide coating, with or without sodium sulphite, very little iron-oxide sludge was apparent in the solution after a number of hours at the elevated temperature of the experiment. In other words, while the 5 per cent concentration of caustic was sufficient to carry through Reaction [1] with considerable speed, Reaction [2] was too sluggish to be damaging under the conditions and in the duration of the experiment. Longer duration would doubtless have occasioned formation of the iron-oxide sludge in larger amount, without segregation of the attack in any one spot. We believe these conditions parallel those in boilers which, on inspection, are found with considerable magnetic-oxide sludge distributed pretty well throughout the boiler, usually with some marked accumulation in drums or headers, but without evidence of intensified attack in any particular areas.

Are there, however, factors in the boiler which will speed up Reaction [2]? Further experiments by Kaufman and Marcy tested the effect of increasing the caustic concentration. At the same temperature previously noted, they found a 10 per cent caustic solution to attack the surface of the bomb very little in-

deed, if it was pickled prior to the experiment; when a 20 per cent solution of caustic was used, the attack, while not heavy, nevertheless was considerable, as indicated by the amount of magnetic-oxide sludge produced. In a parallel experiment with 10 per cent caustic solution, but with the surface of the bomb not pickled prior to the experiment, the attack produced a heavy sludge of magnetic oxide. As illustrated in Fig. 6, Berl and van Taack at 590 F similarly found magnitude of attack to increase with increased caustic concentration. Thus one very decided

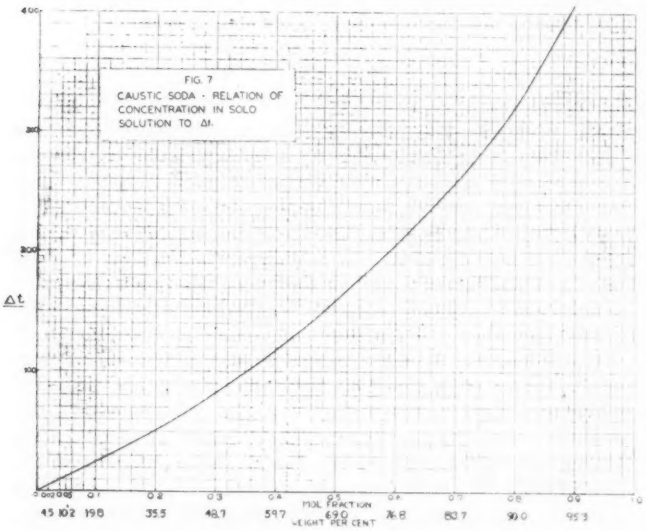

FIG. 7 CAUSTIC-SODA RELATION OF CONCENTRATION IN SOLO SOLUTION TO Δt

factor in speeding up Reaction [2] (and Reaction [1] as well) is an increase in caustic concentration. Another factor is increase of temperature, not illustrated by the foregoing experiments at fixed temperature, but undoubtedly of big influence (29).

With these factors in mind, let us consider what may happen in the concentrating-film boiler water, as formed for example on surface *A*, Fig. 1, under the steam bubble, where simultaneous increase both of temperature and concentration is brought to bear on a restricted area. Fig. 7 (A, V, VI) shows the result. If Δt is only 5 deg, a solo solution of caustic soda will attain concentration of approximately 4.5 per cent at equilibrium; if 50 deg, the caustic concentration will rise to 35.5 per cent; and to greater concentration if Δt is larger. At any steam-water interface, therefore, such as *A*, Fig. 1, and more markedly wherever steam-blanketing or film-boiling may occur, the factors of temperature and caustic concentration, increasing in unison, exercise on a restricted area their combined power of acceleration on both Reactions [1] and [2].[6]

[6] For illustrations of bonded-oxygen corrosion, see reference (10), both items. We believe Fig. 7(*a*) is an apt illustration of this type of corrosion, but with special circumstances leading to its development. As evident from the illustration, discrete pieces of deposit have been randomly stacked. Composed mainly of calcium phosphate and a little calcium carbonate, silica negligible, they were almost certainly formed in a part of the boiler remote from the evaporative section where they were found, and were transported in the circulating boiler water until an eddy or backwater resulted in their being gathered together as shown. Their relation to bonded-oxygen corrosion lies in their being firmly cemented together by a matrix of magnetic oxide of iron (little copper is present). The eddy or backwater indicates interruption of maximum boiler-water flow, a condition which favors steam-blanketing or film-boiling. The further impetus given to this condition by the overburden of stacked pieces of deposit quite evidently resulted in a concentrating-film boiler water of sufficient concentration to accelerate Reactions [1] and [2], and thus provide the magnetic-oxide matrix.

However vicious may be the attack on the boiler metal by the combined power of these two factors, it is made still more devastating by another factor. As shown by the vapor-pressure data of solutions of caustic soda (A, III, 6; IV, 5; V; VI), and the specific illustration of 1400 psia and 1000 F of Table 5, the concentrating-film boiler water will never go to dryness if it contains caustic soda (or, for that matter, caustic potash). On the contrary, the solution of caustic, instead of shriveling with increasing Δt on the surface, will spread instead in accord with its well-recognized characteristic of so doing (34), and thus broaden the area of attack. At the same time, the attack according to Reaction [2] by the water, held in liquid form frequently well above critical temperature of 705 F, will be maximum since the contacted surface cannot build a protective oxide covering because of the rapid dissolution thereof, according to Reaction [1] by the high caustic concentration of the contacting concentrating-film boiler water.

All factors considered, it is not surprising that attack on the metal is very rapid and devastating. Results thereof have been described by Drewry (30) and others (10, 31).

At such surfaces, concentration of caustic to the degree at which embrittlement readily occurs requires only a moderate value of Δt.

How, then, shall required alkalinity be provided in the over-all boiler water, and yet be adequately restricted in concentration in the concentrating-film boiler water?

One method consists in providing in the over-all boiler water a ratio of potassium or sodium chloride to alkalinity, such that as

FIG. 7(*a*) CORROSION BY BONDED OXYGEN

concentration in accordance with the Δt function occurs as required by the Δt of any steam-blanketed surface, the alkalinity will remain of small amount and innocuous. For instance, if the boiler water contains 1 molecule of alkalinity and 4 molecules of potassium chloride, then the concentration of caustic that will result will be only one fifth of what it would be if the potassium chloride were not present. In Reaction [2], the intensity factor of liquid water in contact with the metal surface will remain, but opposing this, by strict limitation of the caustic concentration, Reaction [1] can be held in check, and the iron-oxide film on the metal, not being dissolved off so rapidly, has the chance to be protective to the metal, at least in considerable degree. It is an

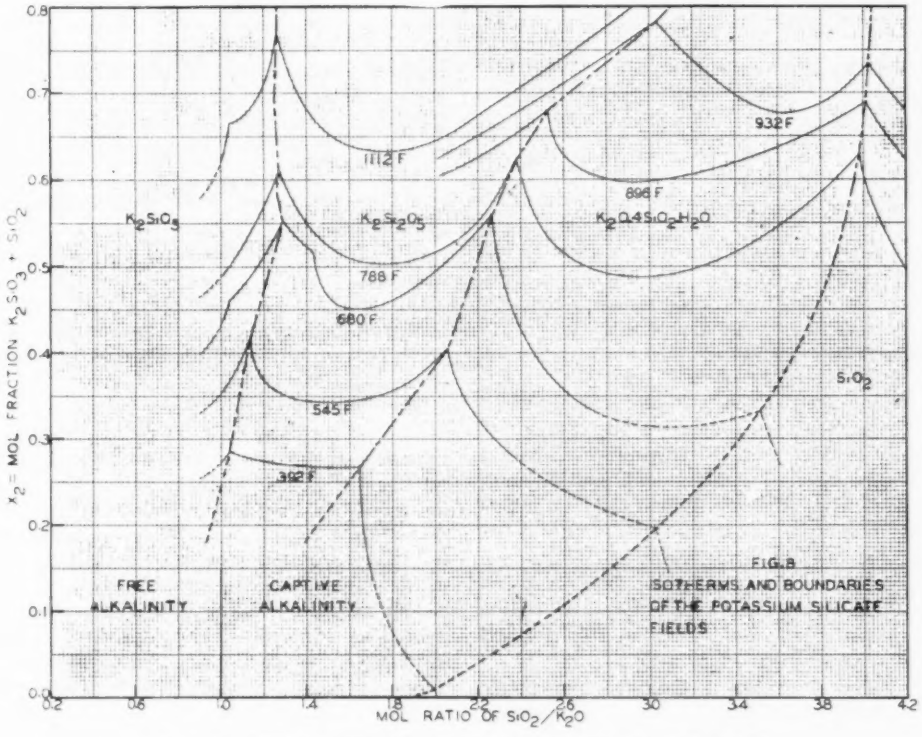

FIG. 8

FIG. 8 ISOTHERMS AND BOUNDARIES OF POTASSIUM-SILICATE FIELDS

interesting point that as a boiler water is purer, so is it more aggressive in the development of iron-oxide sludge, unless its alkalinity is practically nil. Further, it is evident that sodium sulphate can be only slightly effective in preventing concentration of alkalinity, because sodium sulphate reaches saturation concentration at very low value of Δt, thereupon merely precipitating, and leaving it up to the caustic molecule to provide a great share of the concentration demanded by Δt, the very thing that must be avoided.

Another method of approach is to have all boiler-water alkalinity that of hydrolysis (13, 35), so that when the over-all boiler water, concentrating at a surface, becomes concentrating-film boiler water, the hydrolytic alkalinity will return to the parent molecule and not accumulate excessively. The alkalinity of hydrolysis we term "captive alkalinity," as opposed to free alkalinity, which will concentrate highly at a surface. Such captive alkalinity in the boiler water can be given by the hydrolysis of the phosphates and, of especial interest to us, by that of di- and metasilicates. The hydrolysis of the phosphates is not of so much value for this use, because they, or at least the sodium phosphate, follow sodium sulphate in their solubility relationships. On the other hand, the potassium di- and metasilicates are very soluble, keep on increasing in solubility with temperature increase and therefore are particularly valuable in control of the boiler-water alkalinity in the form of captive alkalinity. At the present time, to take care of this problem of magnetic-oxide sludge, we are using the potassium-chloride method at one plant; at another, a combination of potassium chloride and captive alkalinity, supplied by potassium silicate; and the same also at a third plant in which the potassium silicate is of value not only for captive alkalinity but to provide the silicate in the boiler water to prevent soft magnesium deposits.

In some cases, efforts to eliminate corrosion by bonded oxygen have followed the course of maintaining extremely low alkalinities in the boiler water. In this case, Reaction [1] is made negligible, and the concentrating-film boiler water may most likely evaporate to dryness, changing the concentration of H_2O in Reaction [2] from that of liquid water when caustic maintains the film liquid, to the value corresponding to the density of steam at the temperature of the surface in question. The method is effective, but not infallible, if Δt is sufficiently large, as proved by a number of instances (36, 31, 25). In any event, however, the method provides optimum conditions for silica deposition in boiler and turbine, as will become apparent in the sections which follow.

The Problem of Silica in the Boiler

There are only two possible methods of procedure relative to silica, namely, remove it, or else live with it and make it behave. In fact, silica is a component in boiler waters that must be reckoned with whether or not steps are taken for its removal, since whatever may be left after treatment for its removal accumulates in the boiler water, and in lesser or greater degree the silica problem holds sway. But, as previously noted, it has virtue in combining with magnesium, and thus preventing the soft but troublesome high-magnesium boiler deposits. As shown in Fig. 5, both sodium metasilicate and disilicate (A, III, 15, 16) in the boiler-water temperature range show retrograde solubility, that is, decrease of solubility with temperature increase, and must therefore be classed in the group of salts such as sodium sulphate, carbonate, and phosphate, and hence at surprisingly low value of Δt in the Δt-function, reach saturation and deposition on evaporative surfaces. On the other hand, both potassium metasilicate and disilicate (A, III, 17, 18) show increasing solubility with temperature increase through the whole range to their melting point. In this respect, therefore, they may be classed with the group of materials, such as sodium chloride, potassium chloride, and sodium and potassium hydroxides, which behave similarly. In contrast to the sodium silicate, their Δt_s values (A, IV, 10, 11) are extremely high, and thus wherever a concentrating-film boiler

water develops, they will aid in the prevention of deposition rather than abet it.

Table 4 comprises a comparison of Δt_s of saturated solutions of potassium metasilicate and sodium sulphate, values for the latter being used, since the solubility of sodium sulphate and sodium metasilicate are similar in type, and since no vapor-pressure values for sodium-silicate solutions are available. For example, at 621 F, potassium metasilicate has a saturation concentration of 0.40 mol fraction or 85 per cent, the vapor pressure of the solution is 79.4 psia, water at this pressure boiling at 311 F. Thus Δt_s has the surprisingly high value of 310 deg. On the other hand, sodium sulphate and undoubtedly sodium silicate practically to the same extent at 617 F, or approximately the same temperature, has a saturation concentration of 0.012 mol fraction or 8.7 per cent, the vapor pressure of the solution is 1710 psia, and water at this pressure boils at 614 F. Thus Δt_s in the latter case is only 3 deg. What this means in the concentrating-film boiler water is clearly evident from the previous discussion of the Δt function: The potassium metasilicate will not hide out, and will not be scale-forming, while the sodium silicate will hide out, and will be scale-forming. Or stated in a different way, in the 1800-psia tube, illustrated in Fig. 1, potassium silicate can never reach saturation in the concentrating-film boiler water at surface A, since the vapor pressure of its solution at saturation never attains that pressure; while with sodium sulphate and sodium silicate, Δt of not over 3 deg brings about saturation.

Fig. 8 illustrates further properties of the potassium silicate that emphasize the value of maintaining the boiler on potassium equilibrium, thus avoiding the sodium silicates. The concentration as mol fraction is plotted as ordinate, and the abscissa is the mol ratio of SiO_2/K_2O. This brings out a fact concerning the silicates that does not pertain to other boiler-water salts. If, for instance, one started with a pure solution of potassium hydroxide, the ratio SiO_2/K_2O would be zero. If silica is now added, it dissolves, and the amount of silica added may be such that the mol ratio of SiO_2/K_2O becomes 0.6, 1.6, 2.0, or more, or any intermediate figure. Let us consider what happens to a solution of silica and potassium hydroxide with varying ratio of SiO_2/K_2O, and let us choose the isotherm of 680 F, which is one of those chosen by Morey (7) in the experiments in which he obtained the data plotted in this figure. With a ratio SiO_2/K_2O of 1.0, and concentration to saturation, the solid product that precipitates is potassium metasilicate. As the ratio SiO_2/K_2O is increased, and becomes almost 1.3, the solid product that precipitates is no longer potassium metasilicate, but potassium disilicate. Continuing along the 680 F isotherm, with silica concentration increasing until the ratio SiO_2/K_2O is a little greater than 2.2, the saturated solutions precipitate potassium disilicate as solid phase. Beyond this point, the solid phase becomes tetrasilicate ($K_2O \cdot 4SiO_2 \cdot H_2O$). Finally, only when the ratio SiO_2/K_2O is somewhat more than 3.4, is the field reached in which silica precipitates. Following the 392 F in place of the 680 F isotherm, we find that at a ratio SiO_2/K_2O of 2, the dotted line separating the field of silica from the field of potassium tetrasilicate intersects the experimental isotherm of 392 F, at practically zero concentration. Therefore if the boiler water contains silica and potassium hydroxide in the mol ratio of 2, and the operating pressure is 225 psia, corresponding to 392 F, precipitation of potassium tetrasilicate and silica might readily occur in the concentrating-film boiler water. But, if the ratio SiO_2/K_2O under that condition were 1.6 or lower, then this precipitation would not occur, and at the pressures above 225 psia, and at ratios of silica to alkali in the range of 2 or less there is practically no possibility of deposition of silica or the potassium-silicate compounds in the concentrating-film boiler water for any values of the Δt function within the range of reason. The interesting point is, that the higher the operating pressure of the boiler, the more certainly this is the fact.

Now contrast with this what happens in the case of sodium silicate. The exact data are not known, as they are being worked upon by Morey (14, 15) at the present time. But one can gain an idea of what they will be by reference to Fig. 5, depicting the enormous contrast in the solubilities of the sodium and the potassium silicates. As regards stability, also, the potassium silicates have the advantage (16), since, as far as known, no tetrasilicate of sodium comparable to the tetrasilicate of potassium exists, and any decomposition of sodium disilicate results directly in deposition of silica. The relationship of incongruent solubility (27) between water and the silicates, signifying their decomposition by water, may occur in the boiler as well as in the turbine, but will be discussed as a part of the role of silica in the turbine.

Our observations under actual operating conditions of the boilers at Springdale, and of test experiments carried out in bombs, agree fully with the conclusions which are reached by study of this diagram.

But, the question may arise, this is true for the potassium silicates as compared with the sodium silicates, but what of the potassium-aluminum silicates and the potassium-iron silicates as compared with the sodium-aluminum silicates and the sodium-iron silicates? Inasmuch as only very limited (33) experimental data are available, so far as we know, dealing with solubilities of the alkali-aluminum silicates, we must revert for our conclusions to our observations in operating boilers. In the Springdale boilers, in the generating tubes, where hard, flinty deposits of sodium-aluminum silicate, mixed with silica, magnetic iron oxide, and copper, prevailed during the maintenance of sodium equilibrium in these boilers, in spite of everything that we could do, with advent of the use of potassium equilibrium and the appropriate relationship between silica and alkali in the boiler water, these deposits have completely disappeared and the tube surfaces are clean. Very likely, the vastly different solubility of the potassium silicate as contrasted with the sodium silicate is the influential factor in producing this result.

Application of the Δt Function to the Isobaric-Polythermal Conditions in the Superheater

Thus far, in our discussion of the concentrating-film boiler water, and the conclusions that follow from application thereto of the Δt function, we have directed our attention mainly to problems involving the low Δt_s values of substances like sodium sulphate, sodium phosphate, and sodium silicate. But where conditions of steam-blanketing or film-boiling are severe, Δt of the tube surface may be quite high, as indicated by finding a spheroidized condition of cementite in, or even decarburization of, the metal when metallographic examination is made. In the superheater, too, any boiler water which carries over in the steam must concentrate and come to equilibrium therewith at a value of Δt equal to the superheat of the steam. Conditions are more severe, but the principles are the same as those illustrated in the experiment, Fig. 3. It will be sufficient for our purposes to consider the temperature range from 212 to 1400 F, and, therefore, maximum Δt of 1188 deg. This involves consideration of solutions well above the critical temperature of water.

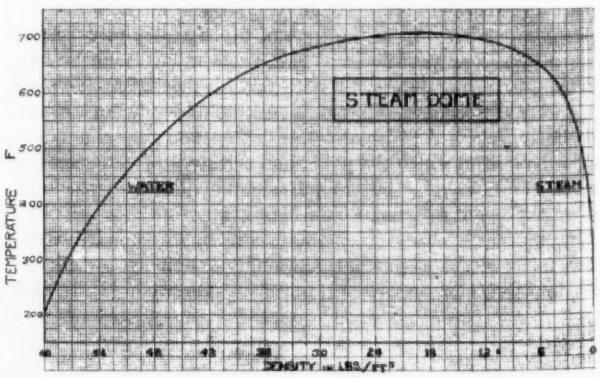

Fig. 9 The Steam Dome

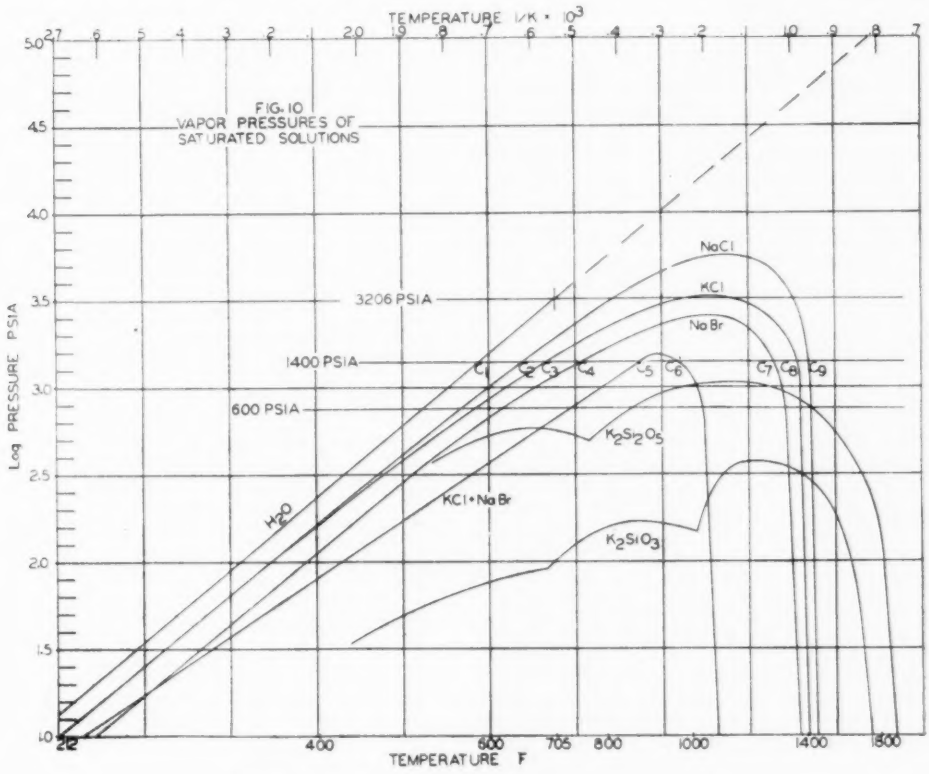

FIG. 10 VAPOR PRESSURES OF SATURATED SOLUTIONS

What is the significance of critical temperature of water in relation to solutions? Morey (14), calling attention to the steam dome as illustrated in Fig. 9, points out that the densities of water and steam gradually approach each other and become equal at critical temperature without discontinuity. Increase in density of steam is very rapid as critical temperature is approached. At and just below critical temperature, the steam dome is almost flat. He states:

"There is no discontinuous change at the critical temperature of water, and there is no reason to expect a change in the solvent power of water at critical temperature when the liquid and vapor phases merge continuously into each other.

"The critical temperature of water is a characteristic of pure water only. When a binary system consisting of water and a soluble compound such as potassium disilicate is considered, the critical temperature of water is without significance. A solution of salt in water raises the boiling point, that is, decreases the vapor pressure, and if the salt is sufficiently soluble, the vapor pressure of the saturated solution at the critical temperature of water is far less than the vapor pressure of pure water."

Fig. 10 shows the relationship for a few salts (A, III, IV) of vapor pressure to temperature of saturated solutions, the data for these curves being taken from papers by Morey (7) and Keevil (6), and from the International Critical Tables (17). These curves, representing the vapor pressure of saturated solutions at ascending temperatures, evidence no break at the critical point of water and show the course that such salt solutions would take in the concentrating-film boiler water or in the superheater, in their endeavor to reach equilibrium on the basis of the Δt function at any value of Δt under consideration.

Table 5 shows what happens when such solutions of one dissolved component or in one case of mixed components (potassium chloride and sodium bromide) are carried over in the steam of a boiler operating at 1400 psia and are raised in temperature to 1000 F in passing through the superheater. The data are obtained as follows:

The isobar of 1400 psia, Fig. 10, intersects the vapor-pressure curve of water at C_1, then successively on their ascending branches, those of NaCl at C_2, KCl at C_3, etc.; and on their descending branches, NaCl at C_5, KCl at C_6, etc. The isobar does not intersect the curves of $K_2Si_2O_5$ or K_2SiO_3, or those of NaOH or KOH, which are not shown because they lie below 10 psia, the base line of the diagram. To illustrate the significance of an intersection, let us consider C_3 of KCl. The temperature corresponding to C_3 is 691 F, which is the saturation temperature for a solution of KCl with vapor pressure of 1400 psia. The saturation concentration of 61 per cent is obtained from the solubility curve of KCl (see solubility data, A, III, 5). The difference of the temperatures corresponding, respectively, to C_3 and C_1, 691 and 587 F, or 104 deg is Δt_s. Since saturation occurs at 691 F, and 1400 psia, and since the temperature in the superheater rises to 1000 F, pressure remaining unchanged, the solution must evaporate to dryness, in a manner similar to the solution of calcium chloride, illustrated in Fig. 3.

The Δt_s values corresponding to the other intersections C_2, C_4, and C_5 also lying on the ascending branches of the curves, are less than the superheat, 413 deg, hence the solutions to which they correspond must evaporate to dryness. The huge difference that may exist between solo solutions and mixtures is well illustrated by the Δt_s values of only 104 and 166 deg, respectively, for KCl and NaBr, while that of their mixture is 287 deg, or more than the sum of their separate Δt_s values. Inasmuch as the 1400-psia isobar does not intersect the vapor-pressure curves of solutions of the potassium silicates, nor of those of caustic soda and caustic potash, these solutions will not attain saturation under the conditions we have assumed, and the salts will remain

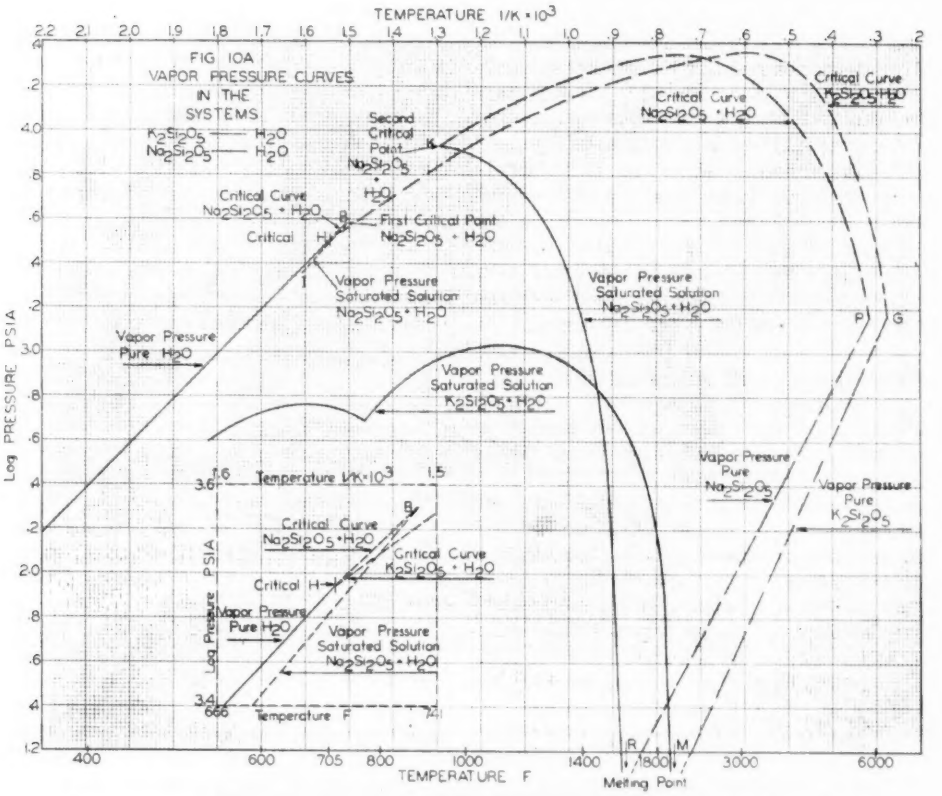

FIG. 10(*a*) VAPOR-PRESSURE CURVES IN THE SYSTEMS $NaSiO_5$-H_2O AND $K_2Si_2O_5$-H_2O

in solution even as they pass from the superheater at the full temperature of 1000 F.

The intersections of the 1400-psia isobar with the descending branches of the various saturation curves shown, occur well above the superheat temperature of 1000 F, except in the case of the mixture KCl + NaBr. In that case, the saturation curve reaches its maximum vapor-pressure value at approximately 914 F and, thereafter, as its equilibrium vapor pressure becomes lower with increasing temperature (also increasing concentration), intersects the 1400-psia isobar at C_6, 970 F, and at 1000 F lies well below it. This means that at 970 F, the potassium chloride and sodium bromide must redissolve, and at 1000 F, will pass from the superheater in solution. If the superheat temperature was a little above 1400 F, all solo salts noted in Fig. 10 would redissolve and pass from the superheater in solution. In case of mixtures, evaporation to dryness might never occur, but if it did, redissolution would be almost certain to occur, and very likely at temperatures considerably lower than 1400 F. The mixture of potassium chloride and sodium bromide is the only one on which data are available at present. On the descending, as well as on the ascending branch of its saturation curve, its marked difference in values from those of the saturated solo-solution curves of its components emphasizes the need of data of this sort for mixtures of salts which will be representative of those characterizing boiler waters. Experimental technique is extremely difficult, but Partridge and Kaufman of our laboratories are drawing plans for the work.

The vapor-pressure curves of saturated solutions thus far discussed, and presented in Fig. 10, are of salts whose solubilities continuously increase with rise of temperature. The descending branch of each of the vapor-pressure curves is approaching closely to the melting temperature of the dry salt as it intersects the base line (pressure = 10 psia) and attains that temperature somewhat below at a pressure which is the vapor pressure of the pure salt, and a concentration of 100 per cent dry salt.[7]

If, now, the temperature of the melted salt is raised, the pressure created by the pure vapor of the salt increases. In the case of potassium silicate, Fig. 10(*a*), this follows a line such as *MG*,[8] originating at the melting point and attaining critical state at *G* (assuming no decomposition of salt or vapor), just as water attains its critical state at *H*. The line connecting *G* and *H*, and representing the lowest vapor pressures of critical conditions for mixtures of water and potassium disilicate, is known as their critical, or plait-point curve. The critical curves of sodium chloride and potassium chloride for a short distance beyond *H* have been determined by Schröer (A, VIII). The significant point about this curve is that throughout its length, it lies well above the vapor-pressure curve of saturated solutions of potassium disilicate, no intersection of the saturation vapor-pressure curve and of the plait-point curve occurring. This is a general property of the plait-point curves of substances whose solubilities increase with increasing temperature in both branches of the saturation vapor-pressure curve. Between the saturation vapor-pressure curve and the plait-point curve of any substance lie the vapor-pressure curves of its unsaturated solutions, critical state

[7] The melting point under these conditions will be very slightly different from the melting point usually cited in the handbooks, a value obtained under ordinary atmospheric conditions.

[8] The broken-line curves *MG*, *RP*, *GH* and the two segments *PK* and *BH* are hypothetical only, definite points not having been established. *K* has been tentatively fixed by Morey. Definite location of *B* is not established other than that it lies slightly above the critical temperature of water. One point of *BI* has been established by Morey (private communication) at 662 F, but the general form of these curves of decreasing solubility along the ascending branch has been established by the data on Na_2CO_3 and Na_2SO_4 (A, III, 2, 19). The incongruent solubility relationship of $Na_2Si_2O_5$ probably begins shortly below *I*.

of the solutions occurring at their points of tangency to the plait-point curve (40). At or above the critical point of the solution, there is no discontinuity of solubility, the substance dissolved in the water remaining in solution in the gaseous phase, and solubility increasing with both temperature and pressure, but especially the latter (41, 20, 42).

Now let us consider the salts whose solubilities are retrograde in the range of boiler-water temperatures. In keeping with their low solubilities, their Δt_s values are low, and at 1400 psia (Table 5), evaporation to dryness will occur almost immediately upon entry into the superheater. The question of moment to anyone interested in boiler waters is: Will this same condition continue, as temperature is increased well above 705 F in the superheater, or will changes occur resulting eventually in a descending branch of the vapor-pressure curve, and therefore greater solubility?

In regard to critical characteristics, the data on sodium disilicate by Morey and Ingerson (14, 15) are alone available. Line IB represents the saturation vapor-pressure curve of sodium disilicate. It passes close to the critical point of water H and, slightly beyond at B intersects the critical or plait-point curve joining H with P, the critical point of sodium disilicate, and passes through points B and K, but with a break in the curve over the interval BK. Beginning at point B, the intersection with the critical curve, the sodium disilicate exists only in solid form, or dissolved in the fluid (gaseous) phase; the coexistence of liquid and vapor is impossible.

Morey and Ingerson (21) state: "When the critical curve is intersected in one point by the solubility curve (as at B), it must also be intersected in a second point."

In searching for this second point, they (15) started with sodium disilicate at its melting point just below R, Fig. 10(a), and by controlling as desired the pressure of steam with which they surrounded it, found vapor pressure to increase with falling temperature along the line RK. Finally near K (8500–8700 psia, 932 F), the second point of intersection of the saturation vapor-pressure curve with the critical curve has been located tentatively. From K, the descending branch of the vapor-pressure curve extends unbroken through R to the melting point of the salt, saturation concentration being high and increasing with temperature increase.

The break BK between the first and second intersections of the saturation vapor-pressure curve and the critical or plait-point curve is a little-explored region, of which Morey (14) states:

"Numerous experiments have been made at temperatures ranging from 375 to 500 C (707 to 932 F) and at pressures up to 16,500 psia and with mixtures ranging in composition from sodium metasilicate to the eutectic between sodium disilicate and quartz. These studies are not complete, but they all indicate that under the conditions of experiment the percentage of sodium oxide and silica in the vapor becomes large. Some results as yet unconfirmed indicate over 50 per cent by weight of solid material in solution in the vapor.

"The conditions of these experiments are more drastic than those encountered in steam boilers and superheaters, but, nevertheless, the very considerable power of steam under these more drastic conditions to transport ordinarily nonvolatile components will be paralleled by a smaller transport power per unit of steam at the lower pressures."

For the theory of these relationships, in the temperature range above critical for water, which characterize the salts of retrograde solubility, the reader is referred particularly to Morey and Ingerson (21) and to Schröer (20).

The very great difference in behavior in the region above 705 F of sodium disilicate, representative of the inorganic salts, with retrograde solubilities approaching zero at the critical temperature of water from those of steadily increasing solubility is apparent from Fig. 10(a). While no data on the former are available, other than those of Morey and Ingerson on sodium disilicate, it seems practically certain that they, like it, must have a descending branch to their saturation vapor-pressure curves, and along that branch must increase in solubility with rising temperature.[9] The physical characteristics of such solutions, for instance fluidity, are unknown. Where the curves of mixtures of salts, some with retrograde and some with continuously increasing solubilities, as boiler-water salts, would lie on the diagram, and whether their temperatures on the descending branches of the curves would be low enough to be significant as regards conditions in the superheater, we can only surmise until pertinent data have been obtained.

Once the essential data are available to establish Δt-function curves, such as those in Figs. 4, 10, and 10(a), for boiler-water compositions, an analysis of the dilute over-all boiler water, expressed in mol fractions of the components, will make feasible estimation of concentrations and of the condition of the components in the concentrating-film boiler water, or of carry-over in the superheater at different values of Δt, and likewise at any point in the turbine of which the temperature and pressure are known. We may illustrate the principle by the following example:

In Keevil's (6) work, from which the data of the KCl-NaBr mixture were obtained, the concentration of the saturated solutions was not measured. Kaufman and Morris in our laboratory made a saturated solution by agitating water with solid KCl and NaBr and found the boiling point at atmospheric pressure to be 245 F, the composition of the solution being expressed by 0.044 mol fraction of KCl, 0.029 of KBr, and 0.117 of NaBr, a total of 0.19 mol fraction or 56.4 per cent. At intersection C_s, Fig. 10, P_s = 1400 psia or boiler pressure; t_s = 874 F; and P_{H_2O}, the vapor pressure of pure water at t_s, read from the extension beyond critical of the H_2O vapor-pressure curve (hypothetical, but of use in the calculations) is 8040 psia. The ratio P_s/P_{H_2O} = 0.174. Now, let us assume, in the absence of data on mixtures, that the deviation curve of the Halides, Fig. 4, applies to their mixtures as well as to their solo solutions; this may or may not be true but is as near the truth as we can get until more data are available. The value of 0.174 on the ordinate P_s/P_{H_2O} corresponds to X_2 = 0.5 mol fraction on the abscissa. The evalua-

[9] The data of Goranson on albite, $NaAlSi_3O_8$, and orthoclase, $KAlSi_3O_8$, indicate that the complex silicates, such as analcite, $NaAlSi_2O_6.2H_2O$, and leucite, $KAlSi_2O_6$, belong in this class (44, 45).

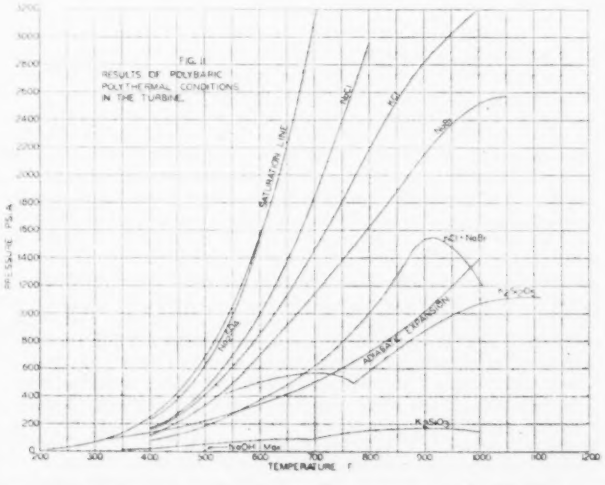

FIG. 11 RESULTS OF POLYBARIC-POLYTHERMAL CONDITIONS IN TURBINE

tion of mol fraction into per cent involves uncertainty because of lack of knowledge of the relative proportions of K, Na, Cl, and Br in the saturated solution at 874 F. However, as the solubility curves of the salts involved are similar in form and in so far as we know do not form double salts, we shall assume that their proportionate concentrations at 874 F, and 1400 psia, remain essentially what Kaufman and Morris found them at 245 F and 14.7 psia. On that basis, the molar concentration of the saturated solution at 874 F is estimated to be 0.116 of KCl, 0.076 of KBr, 0.308 of NaBr, 0.500 H_2O, which correspond to 14.8 per cent KCl, 15.5 per cent KBr, and 54.3 per cent NaBr, a total of 84.6 per cent. The outside limits of variation would be represented by 80.6 per cent if the solution contained only KCl, and 85.2 per cent, if only NaBr. When data become available to obviate the uncertainties involved in the assumptions necessarily made in this case, the method will give a clear picture of the condition of any salts transported as carry-over in the steam, if the temperature and pressure of the latter are known.

Returning to Fig. 10, we note that for a superheat temperature of 850 F, and a boiler pressure of 600 psia, only potassium metasilicate and the alkalies lie below the isobar, and would leave the superheater in solution.[10]

Presumably in a great majority of cases any carry-over of boiler water in the steam, attaining even a semblance of equilibrium at the temperature of the superheater, has become a magma (that is, a thin paste of solution with precipitated salts dispersed therein) by the time it enters the turbine. Once their Δt-function properties are known, it will be possible to prescribe and maintain in the over-all boiler water, proportional relationships among its components which, as concentration occurs, will result in magmas of least disadvantage both to superheater and turbine.

Role of Silica in the Turbine

The magmas, as they leave the superheater, are the product of equilibrium corresponding to its high temperature and boiler pressure. As they enter the turbine and experience lowering of temperature and pressure, they must change in seeking to maintain equilibrium under the new conditions. What happens to the magmas[11] of solo solutions, and of the one known mixture of potassium chloride and sodium bromide, is shown in Fig. 11, developed by Kaufman, for pressure of 1400 psia and total temperature of 1000 F. An ideal adiabatic expansion curve has been used for purposes of illustration, but the conclusions drawn will hold equally well for operating conditions. All curves falling within the area bounded by the saturation line and the adiabatic expansion curve represent undissolved or solid condition of the different substances concerned in this example; all curves falling below the adiabatic expansion curve represent a dissolved condition of the respective substances. Thus at all pressures and temperatures, potassium metasilicate and potassium or sodium hydroxide enter the turbine and continue on through in dissolved form. Sodium sulphate, chloride, and bromide, and potassium chloride, enter in solid form, and remain thus until the region of condensation or close thereto is reached, finally dissolving. The sodium di- and metasilicates, because of low solubility and consequent small Δt, values like sodium sulphate, almost certainly enter and remain in solid form until the lower-temperature region of the turbine is reached. Apparently potassium disilicate enters the turbine under consideration in dissolved form, begins crystallizing at about 730 F and 560 psia, and then at 536 F enters the region of its incongruent solubility relationship with any moisture, a relationship discussed fully later. The mixture of potassium chloride and sodium bromide enters in solution, then saturates and crystallizes at 984 F and 1330 psia, but redissolves at about 563 F and 300 psia, where its saturation curve crosses the adiabatic expansion curve, considerably above the region of condensation.[12]

With the establishment of Δt-function curves for boiler-water salt mixtures, it will be possible to relate the composition and condition of magmas entering the turbine to their tendency for adherence (47, 48), and hold this minimum by establishing appropriate relationships in the dilute over-all boiler water. However, because of certain intrinsic properties of the silicates, enough is already known to point the way toward rendering them least obnoxious in any carry-over.

In the turbine, above the temperature range approximately 500 F, silica found in any deposition is probably combined in the form of sodium silicate, and thus is water-soluble at the temperatures usual in washing turbines; below the 500 F range, it is uncombined and insoluble, usually being in the form of quartz down to perhaps 250 F, and in the amorphous form thereafter. This quite signal temperature boundary between sodium silicate on the high, and uncombined silica on the low side, leads to the conclusion that there must be definite chemical characteristics of the silicates which cause this condition to exist. What are these characteristics?

In studying the silicates to answer this question, we must perforce use the potassium salts as our examples, as sufficient data on the sodium salts are not of record. One conclusion, however, may be inferred, i.e., that the sodium silicates, because of their retrograde solubility, and consequent very small Δt, value, will at least equally, and perhaps more strongly, exemplify the characteristics brought out than will the potassium salts.

Morey (14, 27) states: "A large number of compounds become decomposed by, and are incongruently soluble in, water at elevated temperatures." In a solution in which the ratio of silica to potash is that of the disilicate ($2SiO_2$:$1K_2O$) and the temperature is lowered to below 536 F, "the disilicate becomes decom-

[10] As pointed out by Hall (43), the passage of superheated steam over solid sodium chloride in determinations of its solubility in the steam may result in dissolving the sodium chloride with formation of a strong solution, thus largely changing the conditions of the experiment. In Spillner's (18) work, for example, with total steam temperature of 765 F, below 2600 psia (183 kg per cm²) the sodium chloride would remain solid as long as it retained its purity; at 2600 psia, and 765 F, it would dissolve to form a solution of 0.214 mol fraction or 47 per cent, the solution becoming more dilute over the remaining range of experimental pressure terminating at 3980 psia (280 kg per cm²). In his experiments on potassium chloride, dissolution of pure solid salt would occur at 1930 psia (135 kg per cm²) and 765 F, the solution formed having a concentration of 0.302 mol fraction or 64.2 per cent, and dilution occurring with increased pressure. In Straub's (19) experiments at 1540 psia, the sodium chloride would be dissolved up to the temperature 667 F, and solid above that temperature; at 2200 psia, it would be dissolved up to 732 F, and solid above. It is apparent from the curve of KCl + NaBr (Fig. 10) that, if the sodium chloride should collect any impurity from its surroundings during the experiment, the maximum temperature at which it would remain in dissolved form at the pressure level of the experiment would be higher than for the pure salt.

[11] Perhaps better in this case, "equilibrium products" since the example deals only with solo solutions, and one mixture of two components only.

[12] What would happen in the case of a mixture such as that of sodium sulphate and sodium hydroxide? At high temperatures of the superheater, the solubility of sodium sulphate in sodium-hydroxide solutions is probably quite high (the data of Schroeder et al. (8) lead to this conclusion). With temperature falling rapidly in the turbine, solid sodium sulphate would almost certainly form in the magma. In this connection, it is notable that sodium sulphate readily crystallizes as deposit in high-pressure turbines (43). Sodium silicate in the magma would probably duplicate the performance of sodium sulphate (43). In the latter case, the separation of sodium silicate may result in a remanent magma with higher $Si:O_2/Na_2O$ ratio. Silica enrichment of this type has played a large part in the differentiation of molten magmas in nature, with granite, which is high in silica, forming in the latter stages (46).

posed by water, and crystallizes only from solutions which contain an excess of potassium oxide. If a solution containing potash and silica in the disilicate ratio is cooled and crystallized below 536 F, the compound separating is not potassium disilicate but potassium tetrasilicate ($K_2O.4SiO_2.H_2O$), and below this temperature potassium disilicate is incongruently soluble in water.... Potassium tetrasilicate becomes decomposed by water at temperatures below 680 F, with quartz becoming the stable phase."

In the light of these facts, we can visualize the chain of events started by the exceptional property of the disilicate of crystallizing from solution in the turbine beginning at about 730 F, as just noted, (Fig. 11). Farther on as the crystals thus formed redissolve at lower temperatures, it seems probable that the relationship of incongruent solubility between water and disilicate develops, with formation of tetrasilicate, which in turn and by the same mechanism splits off silica. The high solubility and high Δt, value of potassium metasilicate insure its presence in solution throughout the turbine, and by excess of alkali over silica development of the incongruent solubility relationship with water is avoided. The disilicate of sodium, with retrograde solubility curve and small Δt, value, is very likely to be already crystallized in the magmas entering the turbine from the superheater, but as a region of lower temperature is reached, at which its solubility is higher, decomposition by water presumably proceeds, thus directly forming silica without the interposition of any tetrasilicate. The course of sodium metasilicate in the turbine is probably similar, but more easily controlled than that of the disilicate.

Also significant is the abrupt ending of the solubility curves of potassium disilicate and metasilicate in Fig. 5, the cause thereof being the beginning at the temperature indicated of their incongruent solubility relationship with water, as evidenced by their decomposition thereby.

One may also read the story from the curves in Fig. 8. Starting for instance with a solution in which the ratio of SiO_2/K_2O is 2 (that of the disilicate), we find that the vertical co-ordinate representing this ratio crosses the saturation isotherm of 1112 F at 0.645 mol fraction, and well within the field of stability of $K_2Si_2O_5$, so that any crystals separating from solution will be potassium disilicate, which has high solubility. Following the same co-ordinate downward, we find it crossing the saturation isotherm of 680 F at 0.495 mol fraction, and still well within the field of disilicate stability. But a little lower, at a mol fraction value of 0.385, this co-ordinate crosses the boundary line separating the field of potassium-disilicate stability from that of potassium tetrasilicate. From that point on, down to the very small mol fraction or solubility value of the intersection of this co-ordinate with the 392 F saturation isotherm, any crystals separating will be potassium tetrasilicate, which in this temperature range has the property of decomposition by water with formation of silica. Thus, a ratio of silica to alkali of even a little less than 2 (Fig. 8), normally as one of its inherent properties, splits off silica in the lower temperature region of the turbine. As the ratio of silica to alkali increases, the effect becomes more pronounced.

How are these conclusions affected, if Spillner's work (18) on solvent action of steam is finally found correct? While there has been considerable discussion of the vaporization of boiler-water salts with the steam, and their transport in this form into the turbine, the point is not settled. Straub (19) has been working on it and has made an excellent report. Morey's work (14) indicates that any volatilization of the sodium silicates into the steam will occur as salts and not as silica, if the $SiO_2/(alkali)$ ratio in the boiler water is appropriately controlled by the boiler-water alkalinity. In any event, in the turbine, condensation from vapor phase to solid phase or solution must precede deposition as solid phase. As any silicates thus condense from the vapor phase, they will follow immediately the course of reaction just described, and will likewise equally respond to conditions directed toward controlling the course of reaction.

For the application of these facts to the control of silica deposition in the turbine, we can reduce them to the formula of appropriately controlling the ratio $SiO_2/(alkali)$ in the over-all boiler water, thus obviating conditions favoring any development of the relationship of incongruent solubility between water and the silicates in the turbine, and also thereby establishing conditions unfavorable to any separation of insoluble silica, and in fact favorable to the dissolution of silica already deposited.

With these facts in mind, it is not surprising that there has been an epidemic of silica deposition in turbines. Every step taken in the direction of very low alkalinities in the boiler water, usually as an aid in combating the ravages of corrosion by the bonded oxygen thereof, raised the ratio of SiO_2/Na_2O in the over-all boiler water, and thus abetted the certainty and extent of a relation of incongruent solubility between any silicate, and any moisture or any solution developing in the lower-temperature range of the turbine. Very likely boiler waters have been made too pure. The absence of other soluble salts to exercise their influence in the Δt function of the concentrating-film boiler water, thus restraining an otherwise exaggerated rise in caustic concentration, has led to the necessity of so far decreasing boiler-water alkalinity that the $SiO_2/(alkali)$ ratio has risen to values highly favorable to silica deposition in the turbine. It should be noted that it is not the absolute value of the silica in the boiler water, but the value of the ratio of silica to alkali that is the governing factor. Quite evidently, the practical answer in operation is to build the dilute over-all boiler water to meet the requirements, as expressed both by the Δt function and by the $SiO_2/(alkali)$ ratio, and so to maintain it.

Protection From Embrittlement in the Light of the Δt Function

If caustic embrittlement is caused by strong caustic-alkali solutions, resulting from strongly concentrating boiler water at vapor-water interfaces, application of the Δt function to the problem of protection therefrom leads to significant results. If the evaporation necessary to concentrate the boiler water to high causticity occurs at boiler pressures or thereabouts, and at a surface such as A, Fig. 1, subject to higher temperature than corresponds to the steam pressure, concentration of the boiler water will proceed according to the Δt relationship, and the rapid increase of caustic concentration with increase of Δt, unless restrained by other suitable salts in the boiler water, is illustrated by the curve in Fig. 7.

The type of embrittlement (25) produced by reaction of the boiler water on a tube surface such as A, Fig. 1, is illustrated in Fig. 13, in which the damage resulted, we believe, from a concentrating-film boiler water due to relatively large Δt value. Under such conditions of boiler pressure and Δt values, any protective action of sulphate must be that of scale formation or plugging action, since its solubility is of such small mol fraction even with its increment of solubility in caustic solution, that its aid in deterring concentration of caustic to meet the Δt requirement is negligible for all practical purposes, unless perchance Δt is enough so that the temperature environment is that corresponding to the descending branch of the vapor-pressure curve of sodium sulphate, or its mixtures with caustic soda and other salts (see sodium disilicate, Fig. 10(a), and the discussion concerning it). The usual absence of spheroidization of the cementite in embrittled metal disputes the existence of the necessary temperature, unless the descending branch of the curve is shifted to much lower temperature by reason of the mixture of salts. Sodium phosphate, as used by Schroeder and Berk (24) and by Whirl

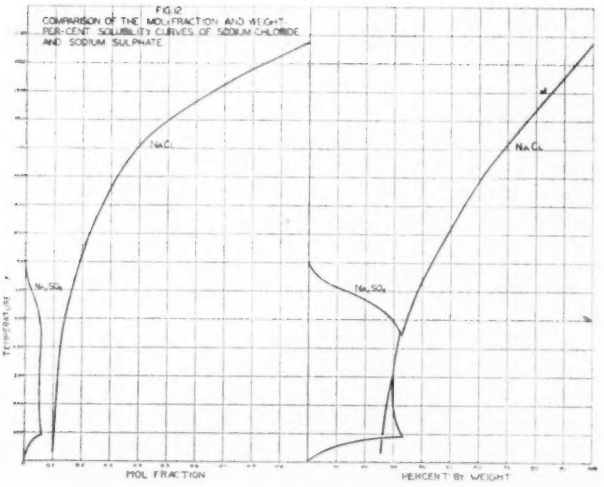

FIG. 12 COMPARISON OF MOL-FRACTION AND PER-CENT-BY-WEIGHT SOLUBILITY CURVES OF SODIUM CHLORIDE AND SODIUM SULPHATE

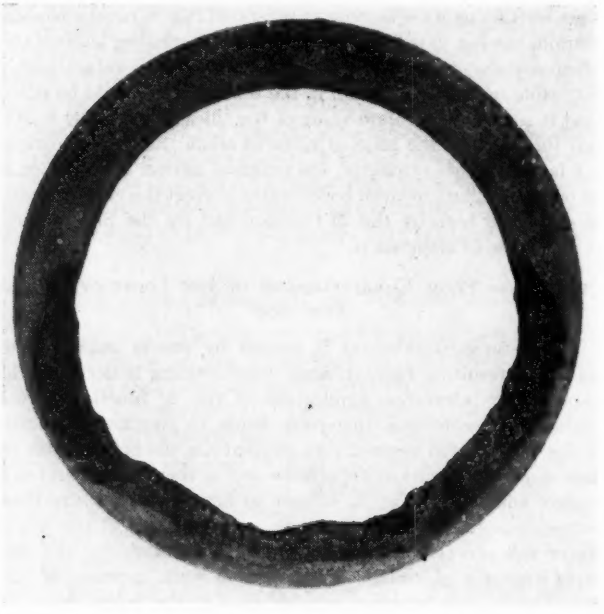

FIG. 13 EMBRITTLEMENT DUE TO Δt-FUNCTION CONDITIONS ON A GENERATING TUBE SURFACE

and Purcell (13), holds any concentration of alkalinity in check, because purposely the over-all boiler-water alkalinity is of captive type based on sodium phosphate.

On the other hand, sodium or potassium chloride, and the potassium silicates, with their relatively high mol-fraction solubilities, and correspondingly large values of Δt_s, if maintained in appropriate concentration in the over-all boiler water in relation to caustic, can thus be made to restrain the caustic concentrations within limits recognized as safe. Examples of protection thus obtained, though not purposely, are found in the boilers of ocean-going vessels, in which embrittlement has only infrequently been recognized (37, 38), and whose boiler waters contain considerable chloride, resulting mainly from condenser leakage. Tighter condensers on the newer ships may alter this record unless appropriate protective measures are taken. The ratio of chloride along with sulphate, recommended by Straub (22), falls in the same category of protective measures. The potassium silicates are not only of high Δt_s value, but combine as well with that part of the captive alkalinity which must be credited to them in the over-all boiler water.

If the evaporation of the boiler water in concentrating the caustic occurs at high temperature but with escape of the steam readily so that pressure at the water-vapor interface is low, then about the only salts that would help in the protection from embrittlement by curbing alkalinity are the phosphates and potassium silicates on the basis of captive alkalinity, and potassium metasilicate by reason of its high solubility. Any effect of the other salts is apparently a scale-forming or plugging action.

If the evaporation is at a cooler temperature, the results are practically the same as for the high-temperature low-pressure conditions. It is interesting to note from Fig. 12, that sodium chloride for all conditions of temperature and pressure has a higher mol-fraction solubility than sodium sulphate, and is thus of more value in curbing caustic concentration. The same is true of potassium chloride. Perhaps scale-forming or plugging action of the sodium sulphate enhances its protective action against embrittlement. In view of its very small Δt_s value, that seems to be the only logical reason for any advantage in the different levels of the ratios of sodium sulphate to alkalinity in relation to pressure which have been so widely used for the purpose of protection from embrittlement.

On the Technique of Substituting Potassium for Sodium

In condensing plants supplied with evaporated make-up water, the feedwater is practically devoid of sodium save for small amounts derived from condenser leakage and evaporator carry-over, up to the point at which treating chemicals in the form of sodium salts are added. Use of potassium chemicals in the treatment in place of sodium chemicals will thus result in a boiler water in which the ratio of potassium to sodium is quite high, and controlling.

In those plants in which the make-up is treated with zeolite softeners of various types, substitution of potassium chloride for sodium chloride in the process of regeneration of the zeolite effects the result that the softener may be run to substitute potassium for sodium, as well as for calcium and magnesium. Work done in our laboratories shows that this is readily feasible and economical. This applies to the zeolite softeners run on the sodium cycle. On the other hand, if the zeolite is run on the acid cycle, neutralization of the treated water with potassium hydroxide or other alkaline potassium salts will supply a feedwater which in many instances will contain the required amount of potassium to establish satisfactory potassium equilibrium in the boiler water. If the zeolitic operation includes use both of the sodium and the acid cycles, then regeneration with potassium chloride will change the sodium cycle to a potassium cycle, and the neutralization of the water from the acid cycle with potassium hydroxide or with the water from the potassium cycle will result in a feedwater of sufficient potassium concentration.

If the softening operation is of the lime-soda type, the substitution of potash for soda ash will increase considerably the ratio of potassium to sodium in the water. In coagulation processes, the substitution of potassium for sodium salts will also aid in building the potassium concentration in the water.

In general, the requisite supply of potassium salts in the boiler water for potassium equilibrium will be accomplished if throughout the treating processes, the sodium chemicals now in use are replaced by corresponding potassium salts. In the case of some raw waters relatively low in sodium content, it may be possible to build a sufficient potassium concentration in the boiler water for the potassium equilibrium, by the addition of potassium treating chemicals appropriately chosen, and supplied in amount to maintain in the boiler water, as determined by analysis thereof,

the essential preponderance of potassium over sodium in the ratio K/Na. In a great majority of the cases, however, it will be advantageous to effect substitution of potassium for sodium in the feedwater by one of the methods of treatment as indicated. For the boiler water itself, in order to establish the relationships demanded on the basis of the Δt function, and the required ratio of SiO_2/K_2O for the prevention of any incongruent-solubility relationship in the turbine, the potassium chemicals of required type may be added as direct treatment.

Tiger (23) has recently proposed that the anion-cation exchangers, which produce water well-nigh equivalent to distilled water in so far as most of the dissolved salts are concerned, could well be used for make-up purposes in condensing plants in place of evaporators. He states, however, that silica is not removed in the process and suggests, therefore, that silica-removal equipment be supplied for preliminary treatment to remove silica before the water goes to the exchanger. The vast difference that is wrought by maintenance of potassium equilibrium on the boiler water, and substitution of potassium for sodium therein, is well illustrated by the fact that retention of silica in the water from the anion-cation exchangers may very well be advantageous for the purpose it serves in the boiler water, and in any event can be readily taken care of in the boiler water merely by proper attention to the demands, according to the Δt function, and the appropriate SiO_2/K_2O ratio. If Tiger's proposal to use the anion-cation exchangers will provide practically the equivalent of distilled water, except for a little silica present, and if it will fit into the heat balance of the plant, we see no reason at all to shy away from the scheme.

Conclusion

Starting with substitution in the boiler water of the potassium equilibrium for the universal sodium equilibrium, we have been led to give consideration to a number of problems concerning the boiler-water and steam cycle. In this discussion, we have included those relating to magnesium deposits, hide-out of boiler-water salts, corrosion by the bonded oxygen of the boiler water, silica in boiler and turbine, equilibria developed in the superheater in any carry-over of boiler water, and protection from embrittlement.

The problem of magnesium deposits involves equilibrium under the isobaric-isothermal conditions of the over-all boiler water, and has been included because of the usefulness of boiler-water silica, and the potassium equilibrium in its solution.

There is nothing fortuitous in this grouping of the other problems. Each one derives its origin from that fundamental and ubiquitous phenomenon of the boiler-water and steam cycle, the steam-water interface, where the manifold variations of isobaric-polythermal and polybaric-polythermal conditions are spurred on by the mighty forces set free in the boiler furnace. In systematizing the results which must ensue from the complex network of interrelations of temperature, pressure, and concentration under these conditions, the concept of the concentrating-film boiler water and the application of the Δt function have proved most useful, likewise the relationship of incongruent solubility between water and the silicates. We believe that we would have been considerably dismayed by the conclusions to which we were inevitably led, had not the tools of potassium equilibrium and, in that environment, the utility of silica, been at hand. Many more data are still needed, but we feel confident that this logical approach to the problems of the steam-water interfaces will give to the engineers those cleaner surfaces for the boiler-tube raceway which will bring calculated and actual circulation into better agreement.

Acknowledgment

Discussion

R. C. Corey.[13] Sixteen years ago, with the completion of a co-operative investigation by the Hagan Corporation and the Bureau of Mines, the author and his associates published a research bulletin,[14] in which the physicochemical basis for scale formation and prevention in steam boilers was presented. To the present day this bulletin is a sound fundamental guide to the principles of water-conditioning.

In the intervening years, the intensity factors, temperature and pressure, and the unit-heat-absorption rate of boilers have increased considerably to provide greater over-all thermal efficiency. It was inevitable that, as the operating temperatures and pressures increased, the sequence of events within a steaming boiler, from the standpoint of chemical reactions, should approach those of a geological nature. Witness, for example, the occurrence in boilers of analcite, acmite, and a host of other complex solid phases that are found as natural constituents in the earth's crust where they were formed as the result of high temperatures and pressures. The tools of the petrographer and the mineralogist, the polarizing microscope, and the X-ray diffraction apparatus, now are familiar equipment in water-conditioning technology.

The new problems presented by modern boiler-operating practice have become manifold. Hide-out, turbine-blade deposits, excessive metal temperatures as the result of resistance to heat transfer offered by unusual solid deposits, and corrosion of steel surfaces by alkali have required that new ideas be developed of the events occurring at the metal-water and metal-vapor interfaces in the boiler. In an effort to find an answer to the questions presented by these phenomena, the author has taken the initiative and applied the logical reasoning of physical chemistry, not the classical concepts found in our physical-chemistry textbooks, but data that have heretofore been of interest to a relatively small group concerned with the study of phase equilibria at high temperatures and pressures; a field of investigation in which the experimental procedures are very difficult. The principles presented in the present paper are not contradictory to those expressed 16 years ago, as the latter still are valid for the isobaric-isothermal conditions of the over-all boiler water. Rather, they have been developed with the realization that isobaric-polythermal and polybaric-polythermal conditions between the steaming surfaces and the turbine discharge can

[14] "A Physico-Chemical Study of Scale Formation and Boiler-Water Conditioning," by R. E. Hall, G. W. Smith, H. A. Jackson, J. A. Robb, H. S. Karch, and E. A. Hertzell, Bulletin No. 24, Carnegie Institute of Technology, 1927.

produce changes in the solid and liquid phases that are markedly different from those with which we have been familiar heretofore.

The writer was greatly interested in the author's statement that, when the potassium treatment was initiated at a station in which the sodium treatment still was in effect, the hide-out of salts became worse. The following may offer a possible explanation for this condition: Sodium and potassium sulphate will, either when fused together or when crystallized from an aqueous solution of the two salts, form a solid phase known as glaserite (or aphthitalite). The literature is not definite whether this phase is a double salt or a mixed crystal, i.e., a solid solution of limited range. The most recent view[15] is that at room temperature it is a solid solution of limited range of Na_2SO_4 in α-K_2SO_4 and is given the nominal formula $K_3Na(SO_4)_2$, indicating content of three mols of K_2SO_4 to one of Na_2SO_4. The factors applying most directly to the present case are its solubility and vapor pressure at high temperatures, and these data unfortunately are not available. Therefore the author may find it advisable to carry out such determinations in order to determine if excessive hide-out or other undesirable characteristics, associated with low solubility and Δt, values, are apt to occur when changing from sodium to potassium treatment or where condenser leakage introduces sodium ion.

With reference to the use of silica to precipitate magnesium silicate in lieu of magnesium hydroxide or phosphate, is this contradictory to the principles outlined in the previous bulletin?[14] The writer would guess that present-day practice results in a form of magnesium silicate, identified in high pressure boilers as serpentine, which differs in physical properties from that formed at lower temperatures.

Considering the extreme importance of the implications of Fig. 10 of the paper, in which the vapor pressure of saturated solutions of several salts is plotted against temperature, and the events at various isobars are described, it is believed that greater clarity of certain statements, particularly those referring to the descending branches of the vapor-pressure curves, would obtain if this material were introduced by a generalized statement of the characteristics of plots of this kind. Although vapor-pressure curves are familiar to many, it is not always evident that they are a special form of phase diagram.

With reference to Fig. 13 of the paper, described as an example of a tube embrittled by a relatively large Δt value in the presence of sodium sulphate and sodium hydroxide, it is not clear that the steel is embrittled in the usual sense of the word; rather it appears to resemble the type of attack which might occur as the result of contact with concentrated alkali at high temperature.

Data indicating the potential solubility of iron in caustic solutions at a concentration, that the author has shown may be easily attained on evaporative surfaces with sufficiently high Δt values, have been developed by Scholder and Weber,[16] who found a boiling 50 per cent NaOH solution to contain 5000 ppm of iron at equilibrium.

G. C. Daniels.[17] Most of the utilities treat their feedwater; some of them because of necessity, others through force of habit or fear of consequences if they did not follow the general practice.

The author admits that there is no problem with dissolved oxygen in the feedwater since it can readily be and is removed by various methods in practically all plants. Yet, the feeding of sodium sulphite is generally continued, and as it hides away in the boiler, more is added. When the boiler water is treated, the pH is maintained in the region of 10.5 to avoid corrosion which nevertheless takes place under steam bubbles where high concentrations and high causticity are reached, as pointed out by the author.

In contrast to the difficulties which have been encountered, when using boiler-water conditioning with its attendant high boiler concentrations, carry-over, and turbine-blade deposits, is the extreme simplicity of using no treatment whatsoever either to absorb any dissolved oxygen that might possibly be present or to maintain any predetermined pH. When pure water is fed into the boiler, the pH generally is found to be between 8 and 8.5. A very thin film of oxide is formed on the internal boiler surfaces which adequately protects the metal and is not dissolved, as is the case if caustic is present, and no concentrations of salts can form under the steam bubbles which are also very much smaller when no dissolved solids are present. The only tube failures that can result from the use of pure water will be those caused from inadequate boiler circulation or flame impingement.

When using no boiler-water conditioning, only three conditions must be observed, all external to the boiler, as follows:

1 The occluded oxygen in the feedwater must be kept below 0.05 ml per l.

2 The operation of the evaporator must be such as to keep the carry-over at a minimum.

3 Condenser leakage must be eliminated. This is not difficult to do with the instruments now available for detecting leaks immediately, and with the divided waterbox condenser, the leaks can readily be located and fixed without shutting down.

Our experience with no boiler-water treatment dates back to 1925 and covers many makes of boilers in the 400- and 900-psi-pressure class. Carry-over and turbine-blade deposits are practically nil or entirely absent. The total solids in the boiler water are frequently below 10 ppm after months of operation. No sludge or iron-oxide accumulations are found in these boilers, and the iron content in the boiler water is a very small fraction of one ppm.

Assuming that the author's theories are correct and that the potassium salts will ameliorate the conditions now encountered with sodium salts, would it not be better to determine in the individual plants whether it is at all necessary to condition the boiler water?

In referring to the experiment on the elevation of the boiling point of water by the addition of salts, the author gives the impression that the steam issuing from the flask is at 212 F instead of being superheated to the temperature of the liquid. The fact that the temperature of the vapor as shown by the thermometer immediately above the liquid is the same temperature as the boiling liquid might be accounted for by the radiation from the surface of the liquid in the flask, which is carefully insulated above the water line.

L. E. Hankison[18] and M. D. Baker.[19] Phosphate in the form of sodium phosphate was introduced for boiler-water conditioning into the 350-psi boilers at Springdale Station in 1923. Results obtained with this treatment have been satisfactory to the extent that some boilers erected in 1924 and 1925 have not been completely turbined since their installation. Clean internal surfaces were maintained by washing the boilers with a stream of water when they were down for overhauling. This type of cleaning did not require the removal of hand caps and,

consequently, some tubes in the boilers have never been inspected.

After 12 or 15 years of operation there was some loss in capacity of these boilers but inspections of the lower tubes disclosed no adhering scale or deposit. Because these tubes where the greatest evaporation occurred were clean, no inspections were made of the upper bank of tubes. When the 1350-psi boilers were installed in 1937, six 350-psi boilers, erected prior to 1923, were removed. An inspection made of all tubes in one of these boilers disclosed considerable analcite scale (sodium-aluminum silicate) in the tubes of the upper bank. This scale was found in spots and was possibly 1/4 to 3/8 in. thick. While the scale was quite prevalent in the upper bank of tubes, it is questionable whether the entire loss in load on the boilers could be attributed to scale.

After the 1350-psi boilers had been placed in continuous service, analcite scale was found in the generating-section tubes. In an endeavor to eliminate this scale, a steel tank was substituted for the concrete make-up-water storage tank from which silica was being dissolved. Following the use of the steel tank, the amount of silica as SiO_2 in the high-pressure-boiler water was reduced from about 20 ppm to 10 ppm per 1000-ppm concentration of boiler water. While this reduction in silica appeared to be beneficial, it was still necessary to turbine the generating tubes periodically for the removal of silica scale. This scale would form under the loose deposits which accumulated in the tubes in the generating section of the boilers. It was on the bottom of the tubes in patches varying from 1 to 3 in. length and 1/8 to 3/8 in. thickness. The formation of this scale could not be predicted as there were periods of 2 or 3 months' operation, following which an inspection showed no scale formation. At another inspection of the same boiler, sometimes after only 14 days' operation, there would be scale in 50 per cent of the tubes. There have been times when it required 4 hr of turbining to remove a patch of scale from one tube. The boilers were never operated for more than 6 months without requiring turbining in some of the tubes. An analysis of the hard scale that was found is as follows:

	Per cent
Sulphur trioxide (SO_3)	2.5
Carbon dioxide (CO_2)	0.0
Phosphorus pentoxide (P_2O_5)	8.9
Silica (SiO_2)	13.3
Iron oxide (Fe_3O_4)	45.9
Aluminum oxide (Al_2O_3)	10.7
Calcium oxide (CaO)	5.2
Magnesium oxide (MgO)	1.5
Sodium oxide (Na_2)	9.2
Copper (Cu)	1.1
Net ignition loss (calculated)	2.9

Trouble with scale of this nature emphasized the need for some correction in treatment. The problem was discussed with the the author, and upon his recommendation on August 25, 1942, potassium salts were substituted for the sodium salts used for boiler-water treatment. All boilers in the Springdale Station, high and low pressure, were placed under the potassium treatment.

After about 2 months' of treatment, leakage occurred around several handhole plates and at tube rolls. Within the next 6 weeks, the leakage had become so pronounced that there was no question as to the immediate cause for such a large amount of trouble. The potassium treatment was dissolving any silica that had deposited around the gaskets and at the tube rolls where it had been serving as a seal. The gaskets used were monel-clad asbestos, and their failure was caused by the cracking of the metal due to expansion and contraction during the time they were in service. There was no chemical attack on the monel. The potassium-treated water would dissolve the silica scale that was sealing the cracks and permit leakage to occur. This type of trouble was eliminated after regasketing the entire boiler completely, and rerolling all leaking tubes. With potassium treatment, any "sweating" or leakage of a gasket or roll on a hydrostatic test will not take up when the boiler is in service. Gasket-failure leakage had started prior to the use of potassium treatment but the change precipitated the trouble. Within a period of 2 months gasket leakage occurred that might otherwise have been extended over a period of several years.

About the time that gasket leakage was being corrected, large amounts of loose scale were noticed in the boilers. The scale found was mostly magnetic iron oxide containing less than 2 per cent of silica as SiO_2. Scale loosened from the evaporating surfaces of the boiler was found in all the headers and was most abundant about the fifth or sixth month after starting the potassium treatment. In some headers, there was sufficient scale to stop circulation and to cause failure of one tube. Following this failure, all headers were thoroughly cleaned and the loose scale removed. Also, all tubes were turbined to remove any material that might still be adhering to their internal surfaces. An analysis of this scale is as follows:

	Per cent
Sulphur trioxide (SO_3)	Trace
Carbon dioxide (CO_2)	Negative
Phosphorus pentoxide (P_2O_5)	10.7
Silica (SiO_2)	1.8
Iron oxide (Fe_3O_4)	60.3
Aluminum oxide (Al_2O_3)	0.4
Calcium oxide (CaO)	7.3
Magnesium oxide (MgO)	6.2
Copper (Cu)	8.1
Total ignition gain	2.3
Net ignition loss	2.2

This iron-oxide scale could have been caused by either of the following reasons:

1 The silica being dissolved from the acmite (sodium-iron-silica) scale that was present in the boilers when the treatment was started.

2 The hydroxide alkalinity (50 to 100 ppm OH) was concentrating at points of high evaporation and attacking the metal.

It is doubtful if scale was formed by the caustic attack, but the presence of large amounts of loose magnetic iron oxide in sludge deposits could readily be attributed to the high alkalinity. The pH value of the boiler water before and after the use of potassium was maintained in excess of 11. The maintenance of this pH value with potassium produced no hard scale in the sludge or on he evaporating surfaces.

A change in treatment was made to reduce and possibly eliminate caustic attack on the metal. This change was the reduction of the hydroxide content to 10 ppm with a pH value maintained at 10.5 or lower. Potassium chloride was added so that at all times the chloride (Cl) was considerably in excess of the hydroxide (OH). Normally the ratio is 5 of Cl to 1 of OH. The effect of the reduction in alkalinity was soon noticed in the characteristics of the boilers deposits. The sludge in the boilers instead of being soft and fine contained many little scale-like particles. Also, the boiler tubes instead of being clean had the appearance of dried sludge adhering to the entire surface of the tubes. No attack could be detected on the evaporating surface and the color of the deposits changed from black to light gray. In an endeavor to stop the formation of the scale-like particles in the sludge and on the evaporating surfaces, the alkalinity was restored to its former values but the chloride-hydroxide ratio was maintained. Inspections made since the increase in alkalinities have shown no attack on the evaporating surfaces, light-gray deposits in the boilers, and no adhering scale.

In the 1350-psi boilers, the potassium treatment has changed

the characteristics of sludge deposits so that at the present time no sticky sludge is adhering to the drum or tube surfaces. The drums are clean and the tubes are coated with a thin film of light-gray deposit throughout their length. This coating can be easily and completely removed with a stream of water. No adhering scale is found after washing. This condition may result from a change in characteristics of the magnesium compounds present in the sludge. Previously, large amounts of magnesium phosphate and magnesium hydroxide were noted when making microscopic examination. Now magnesium silicate is present. When using sodium treatment, the cleaning schedule was that each third time a boiler was removed from service, regardless of the time interval between, or the first outage after 3 months of service, the tubes in the generating section had to be washed and those containing scale turbined. Recently, with potassium treatment, the boiler had seven outages, due to gasket and roll leakage, during a 4-month period without cleaning the internal surfaces. The tubes were then washed but their condition was such that the boiler could safely have been put in service without cleaning. After 15 months of potassium treatment, there has been no need for turbining tubes to remove silica scale that was being formed.

Following the discovery of silica-bearing scale in the 1350-psi boilers a complete inspection of all tubes in some of the 350-psi boilers was made. The inspections showed thin layers of scale under loose sludge deposits in the upper bank of tubes where there is little circulation, and sludge accumulates. Several of the boilers were turbined to remove this scale. No boilers have been turbined since the introduction of potassium treatment, and the scale has disappeared from the boilers that were not turbined.

Since potassium treatment was started, no turbines have been opened, so the condition of the blades is not known. The reduction in capacity now existing may be restored by water-washing or spindle adjustment.

MAX HECHT.[20] Within a span of some 40 years, high-pressure steam generation has increased tenfold since the initial operation at 250 psi at the old Fish Street Station. Throughout this period, the general trend in so far as it concerns the purity of the boiler water has been to generate steam from relatively dilute boiler waters. Credit for this trend should be accepted by the mechanical engineers who demonstrated that pure water could be produced by distillation, and that one of the gases contributing to corrosion, dissolved oxygen, could be removed mechanically by deaeration. Credit for the application of distilled water for make-up in stationary plants is given to the late Prof. C. F. Hirshfeld, The Detroit Edison Company, for his pioneering work at the old Delray Station, and for deaeration, to the researches of J. R. McDermet of the Elliott Company, which resulted in the commercial utilization of the vacuum-type deaerator. Both of these developments came in the period, 1910–1920.

The concept of generation of steam from relatively dilute boiler water has persisted, marked by design changes in the equipment to meet the demands of higher steam pressures and temperatures, and the availability of new chemical processes for conditioning the boiler feedwater. New chemical processes and apparatus have been made commercially available for the primary conditioning of boiler-feed make-up, and numerous chemical reagents are used for the secondary conditioning of the boiler water. In the early 20's, boiler manufacturers supplied equipment of liberal design, and such units were operated at not too excessive ratings. Steam pressures were relatively moderate and steam temperatures were not unduly high.

The problems and difficulties of deposits on boiler tubes, in superheaters, and on turbine blades, and of corrosion now being encountered, were present in the earlier operations, either entirely masked, or if observed were of less major significance than they are today.

During the past 25 years, the water technologist has drawn heavily from the knowledge of the physical chemist, and in the paper under discussion, from the studies of the geophysicist. An important and notable contribution was made by George W. Morey, geophysical laboratory, Carnegie Institution of Washington, Washington, D. C., in his paper, "The Solubility of Solids in Water Vapor." This formed the principal paper of the Round Table Discussion on Action of Water Vapor at High Temperatures and Pressures, presented at the 1942 meeting of the American Society for Testing Materials, Proceedings of the A.S.T.M., vol. 42, 1942, pages 980–988. The proper utilization of this knowledge has permitted the water technologist more accurately to analyze conditions brought to his attention, and so make the proper recommendations to ameliorate the troubles that the operator is encountering. It is apparent that in the past the thought in treatment has been directed toward the main body of the boiler water. The investigations of F. G. Straub, pointing toward improvements in ratios for embrittlement protection and turbine-blade deposits are, in direction, a departure from this concept. Lack of adequate solution of problems encountered in the steam-and-water cycle of the present-day high-pressure-and-temperature stations demands a new approach, and this, it is believed, has been made by considering the behavior of water at the steam-water interface.

It is apparent that the operator has been demanding a fluid for use in evaporative processes, which has had removed from it all of the deposit-forming and corrosive characteristics, both in the liquid and vapor state. This implies either the complete removal of the solid phases or their conversion to a form that is not troublesome throughout the steam-and-water cycle, as well as the total elimination of all of the gases contributing to corrosion. In spite of the stepwise progress on separate phases of the general problem made in the past, to meet this demand, new and unpredictable water problems have confronted the operators. Are the present concepts in this paper adequate to overcome these difficulties?

The author has made an impressive and convincing presentation, based upon scientific information now available. His analysis requires detailed study to appreciate the valid theoretical considerations advanced. The operators may find adequate proof of the theoretical applications proposed, presumably from the short experience presented in the operating discussions, and possibly by trial in their own plants. The writer is frank to admit that it will require some time to digest the author's valuable presentation. There come to mind some minor items which may be of interest.

In the writer's opinion, "hide-out" is a self-aggrevating condition. It is most likely to begin in tubes with poor circulation. The deposition of salt further impedes the already restricted flow. The composition of the water must therefore be such that t_s is never reached, even in the tubes having the poorest circulation.

It has been observed that, when boilers are initially put into service, with no preparation other than the customary boiling-out, a considerable amount of iron oxide is found in the drums. This has been attributed to the mechanical removal of mill scale from the drums and tubes during the shakedown operation. Kaufman and Marcy removed iron oxide from bombs containing 5 per cent caustic soda at 470 F but found no attack on the iron. It might be of interest that in the same temperature range, with low alkalinities (pH 8. to 9.5), hydrogen has been detected in steam from boilers even though iron-oxide sludge was not a problem. Oxygen was also found simultaneously with the hydrogen. It is therefore not necessary to have com-

[20] Pittsburgh 17, Pa.

plete absence of dissolved oxygen in order to secure hydrogen evolution or attack of the iron by water.

The values reported[21] are as follows:

	Oxygen, cc per l	Hydrogen, cc per l
Boiler feedwater	0.20	0.0380
Boiler water (drum)	0.05	Not detectable
Steam superheater outlet	0.22	0.0648

C. E. KAUFMAN.[22] In the intelligent application to boiler-water treatment of many of the principles enumerated by the

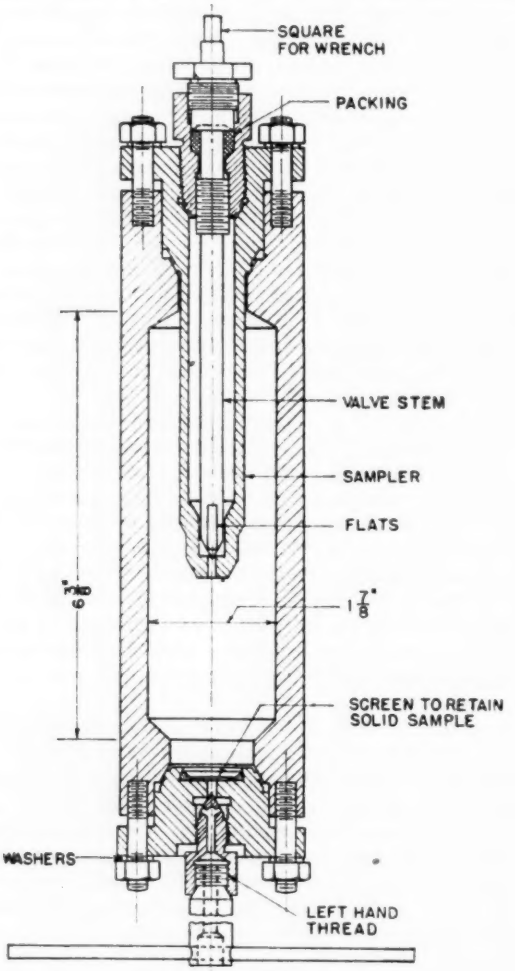

FIG. 14 SOLUBILITY BOMB

author, fundamental data on solubilities and vapor pressures at relatively high temperatures are required. The author has marshaled pertinent material available from the literature but gaps are evident, especially in the data relating to aqueous solutions of potassium compounds, and in the almost completely neglected field of salt mixtures in water.

We are endeavoring currently to fill in some of the missing facts. The experimental technique at elevated temperatures and pressures is somewhat involved, and fixing of quantitative values requires repeated trials. Therefore, at this time, we shall merely mention briefly qualitative behavior.

[21] "Corrosion, Its Causes and Prevention," by F. N. Speller, second edition, McGraw-Hill Book Company, Inc., New York, N. Y., 1935, Tables LXV and LXVI, pp. 424, 425.

[22] Research Engineer, Hall Laboratories, Inc., Pittsburgh, Pa.

The solubility bomb in Fig. 14 of this discussion, of the type used by Schroeder, Berk, Partridge, and Gabriel[23] at the U. S. Bureau of Mines, is being employed in a suitable thermostat. Saturated solution, representing the equilibrium existing at a fixed experimental temperature, is taken through the valved

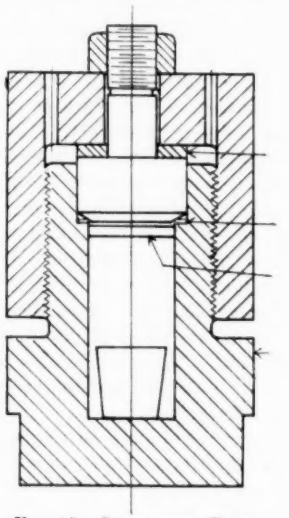

FIG. 15 QUENCHING BOMB

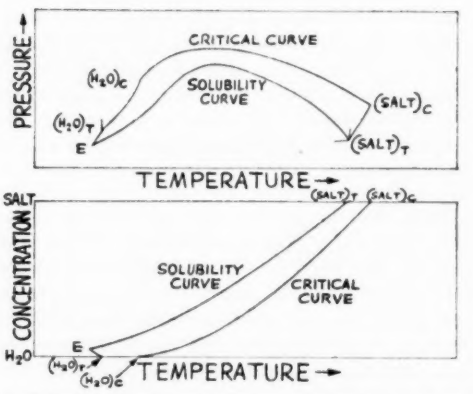

FIG. 16 NONINTERSECTING CRITICAL AND SOLUBILITY CURVES

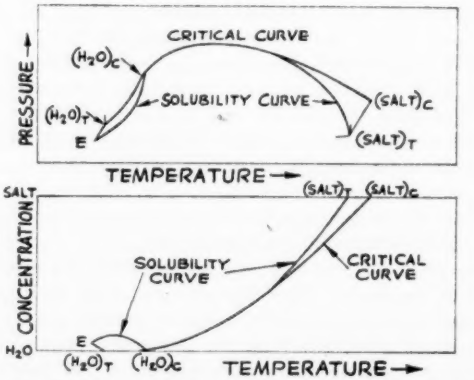

FIG. 17 INTERSECTING CRITICAL AND SOLUBILITY CURVES

sampler, while the solid phase can be isolated by blowing down excess liquid through the bottom valve. In other experiments,

[23] "Solubility Equilibria of Sodium Sulfate at Temperatures of 150 to 350°," by W. C. Schroeder, A. A. Berk, E. P. Partridge, and A. Gabriel, *Journal of the American Chemical Society*, vol. 57, 1935, p. 1539; vol. 58, 1936, p. 843; vol. 59, 1937, p. 1783.

the sampling head can be removed and connection made to a pressure gage. In a preliminary investigation with materials of glass-forming properties, the quenching bomb of Morey,[24] Fig. 15, is being utilized.

As the author has mentioned, aqueous solutions of individual salts, and perhaps mixtures, can be classified in two ways, subject to certain variations:

1 Those whose solubility or vapor-pressure curves do not intersect the critical curve.

2 Those with intersections.

Fig. 16 of this discussion illustrates the first type with continuous solubility extending up to the melting point of the pure salt. Sodium chloride, potassium chloride, and the potassium silicates behave in this manner. Fig. 17 shows typical plots for salts of the second type with the solubility curve interrupted by the critical curve. A number of substances of this class are normally found in boiler waters: sodium sulphate, sodium phosphate, and the sodium silicates, for example. Moreover, these salts show retrograde solubility in the temperature range before the first intersection with the critical curve and are assumed to have very low solubilities at the critical temperature of water.

The salts of constantly increasing solubility will naturally be of advantage in the boiler water, as explained in the paper, because their ΔT_s values are in general much greater than those of the retrograde type for the pressures corresponding to boiler operation.

We have then the following preliminary information: In confirmation of values in the literature, potassium sulphate appears to resemble sodium sulphate; solubility becomes retrograde well below the critical point of water, and ΔT_s is probably never very appreciable in any part of the range up to the intersection of the solubility curve with the critical curve at a point somewhat above the critical temperature of pure water.

On the other hand, tripotassium phosphate, from the evidence of both solubility and vapor-pressure measurements, has the properties of the salts shown in Fig. 16, a continuously increasing solubility curve which does not intersect the critical curve and large values of ΔT_s.

What does this mean in practice? For one thing, tripotassium phosphate is quite unlike trisodium phosphate, which follows the curves in Fig. 17. Trisodium phosphate is one of the worst offenders as far as hide-out is concerned in hard-pressed boilers. With tripotassium phosphate, any tendency to hide out should be entirely curbed or drastically minimized. Again, if a solution containing free alkali starts to concentrate on an overheated surface, trisodium phosphate cannot concentrate with the caustic to blunt in some measure the severity of attack, whereas tripotassium phosphate can do so. In brief, tripotassium phosphate is as advantageously unlike trisodium phosphate as the potassium silicates are advantageously unlike the sodium silicates.

Later on, it is expected that we shall have additional pressure-temperature-concentration data of a more comprehensive character, including information on the complex mixtures which represent the practical working media in all boilers.

N. B. KEEVIL.[25] Solubilities and vapor pressures of aqueous solutions at high temperatures are of considerable importance in interpreting the phenomena of boiler-water chemistry and in conditioning water for steam generation, as well as being essential to the understanding of hydrothermal processes responsible for ore-desposition in the earth's crust. Experimental data for soluble salts are meager, being limited to work by Morey at the geophysical laboratory, and the writer under the auspices of the

[24] "The Ternary System H_2O-K_2SiO_3-SiO_2," by G. W. Morey, *Journal of the American Chemical Society*, vol. 39, 1917, pp. 1173–1229.

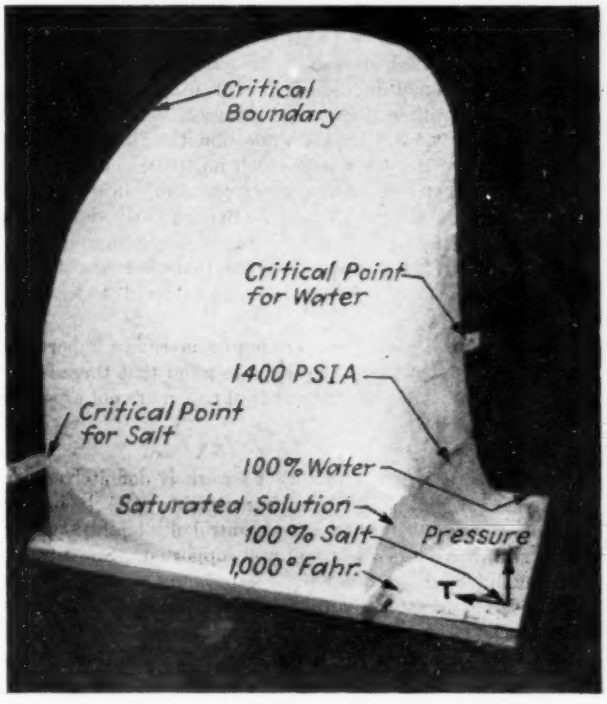

FIG. 18 PRESSURE-TEMPERATURE-COMPOSITION MODEL FOR AN AQUEOUS SOLUTION
(Data for NaI-H_2O; maximum is close to that of aqueous solutions of KCl-NaBr-H_2O and a little higher than $K_2Si_2O_5$-H_2O.)

Harvard Geophysics Committee. This work has revealed important differences in the properties of salts of potassium and sodium at the temperatures encountered industrially in boilers and in steam cycle, the halides and silicates of potassium being more soluble, and their solutions having lower vapor pressures than their sodium analogues.

The application of these differences to water-conditioning for steam generation has been developed by the author, by substituting potassium equilibria for convential sodium equilibria. Theoretically this should reduce many of the common difficulties of scale, hide-out, and sludge formation, and good practical results have been reported. The lowering of vapor pressure sufficiently to prevent precipitation is controlled largely by mol fraction, as well illustrated by the three-dimensional model for pressure P, temperature T, and composition X, shown in Fig. 18 of this discussion, and the results on various halides. This model, with pressure as the vertical axis, illustrates the remarkable effect of dissolved molecules in reducing the escaping tendency of water. In the two-component system shown in Fig. 18, the 1400-psia isobar intersects the P-T-X surface with resulting boiling and precipitation. Additional components in solution leading to a greater mol fraction would reduce the range of vapor pressure sufficiently to prevent precipitation and permit salts to remain in solution when they pass from the superheater at the full temperature of 1000 F.

The difficulty in predicting the exact conditions in the boiler and turbine is that experimental research has been of necessity, largely confined to solo solutions, while those met in practice are multicomponent systems. However, one result obtained by the writer for a two-component system has proved of considerable value in showing a marked lowering of vapor pressure below the equilibrium pressures exhibited by the pure saturated solutions of soluble salts.

There is some indication that in the competition for a place in

a complex solution, the most soluble component may be disproportionately high in the final solution, so that in the K^+, Na^+, Cl^-, Br^- solution studied by the writer the composition at 874 F might have mol fractions 0.23 KBr, 0.20 NaBr, 0.06 KCl, and 0.01 NaCl rather than those extrapolated by the author from the data at 245 F. In this connection, the use of potassium may be preferable to other ions which might be considered for their greater effect in reducing vapor pressure, since the solubilities of $K_2Si_2O_5$, KBr, KCl (and NaBr) are fairly close in the neighborhood of 900 F. Furthermore, in a system containing these components, it is reasonably certain that the range of vapor pressures would be lowered enough for the materials to leave the superheater in solution.

Although critical phenomena are not ordinarily of importance in boiler problems, it should be borne in mind that there is evidence that the phenomena in the critical region are not as simple as is generally believed.

I. G. McCHESNEY.[26] The author's work is definitely a forward step in methods of boiler-water treatment. His elaboration on the process of scale formation and control of solubilities within the concentrating film is clear and well supported. Substitution of a potassium equilibrium for the usual sodium equilibrium as a means of avoiding saturation in the concentrating film is a new and practical attack on analcite-scale formations.

The use of phosphates with sodium equilibrium, low boiler-water concentrations, and reduced alkalinities has brought trouble with analcite scales and turbine deposits.

High Boiler-Water Concentrations. The writer will cite an instance of successful water treatment in a modern high-pressure plant where the procedure closely follows an alternate method of water-conditioning suggested by the author. This plant uses from 40 to 60 per cent make-up. Lime-soda treatment of river water is followed with an aftertreatment of phosphate. Oxygen is efficiently removed by deaeration and an excess of sodium sulphite of approximately 5 ppm is used. Excess phosphates are in the order of 2 to 5 ppm.

Early in the operation of the plant, steam-washer tests were made with boiler-water concentrations up to 6800 ppm. In the final steam-washer design (tray type), priming was not appreciably increased until concentrations in excess of 5000 ppm were reached. Boiler operation at 3000 ppm was standardized after careful consideration of effect of concentration on priming over a range from 1800 ppm to 6800 ppm.

Operation with 3000 ppm total solids in the boiler water permitted an alkalinity of 11.5 without evidence of channeling corrosion. Over several years, corrosion and iron-oxide sludge have not been serious.

High concentrations and steam-washing have effectively prevented silica-scale formation on turbine blading. This is pointed to as experience in one of the makeshifts suggested by the author. His method is superior in many ways and shows good promise of overcoming many of the high-pressure feedwater problems.

Turbine Deposits. Deposition of quartz scales on the 3rd to 8th turbine stages indicates condensation of silicates. The powdery silica deposit in the 13th to 16th stages is likely formed from the repeated boiling to dryness which occurs near the dew point in the turbine expansion. In one Midwest plant this deposit in the later stages of the turbine was accompanied by embrittlement and failure of turbine blades. Maintaining the proper SiO_2/K_2O relation will likely prove effective in preventing both scale and embrittlement.

Messrs. L. E. Hankison and M. D. Baker should be commended for their task in pioneering and developing power-plant experience by the author's method.

D. S. McKINNEY.[27] The troubles that accompany steam generation in high-pressure boilers may logically be divided into two groups, as follows:

1 Those that arise due to faulty design of the boiler and can be eliminated by changing the design.

2 Those that arise primarily due to the chemical properties of the water and the materials dissolved in it.

In the writer's opinion, the problems of "hide-out," corrosion due to bonded oxygen in water, and, to a considerable extent, carry-over, belong to group 1. Proper design should eliminate "hide-out" and bonded-oxygen corrosion and should considerably reduce carry-over. Operators should insist upon and be willing to pay for properly designed boilers, in order that these difficulties may not plague them for the entire life of the boiler.

Chemical treatments to alleviate troubles falling in group 1 do not eliminate the cause of the trouble and should be resorted to only to make existing boilers usable; even in these cases the operator and the manufacturer should make every effort to correct the design in situ in order to eliminate the difficulty.

The problems of magnesium scale, silica in the boiler, and, to some extent, carry-over, belong to group 2. The use of potassium salts, as proposed by the author, is a logical solution of these problems. The advantageous properties of the potassium silicates over those of the corresponding sodium silicates should be especially valuable.

The reasons which the writer has for classifying "hide-out," corrosion due to bonded oxygen, and to a considerable extent, carry-over, as due to faulty design of the boiler, are as follows: The mechanism given by the author for explaining hide-out is undoubtedly correct. However, he does not go quite far enough. The conditions necessary for maintaining the hide-out are not explained.

Consider the hide-out of sodium sulphate. The author gives its solubility at a temperature corresponding to 1800 psi as 0.0095 mol fraction and at 1400 psi as 20 per cent. These figures, expressed in parts per million, are: at 1800 psi, 70,000 ppm, and at 1400 psi, 200,000 ppm. Assuming that the bulk boiler water contains 1000 ppm of Na_2SO_4, then 98.6 per cent of the water must evaporate to reach 70,000 ppm, and 99.5 per cent to reach 200,000 ppm. If evaporation proceeds beyond these figures (at the respective pressures and temperatures), solid Na_2SO_4 will deposit. However, if the evaporating steam bubble breaks away, and a new supply of fresh boiler water arrives, the solid Na_2SO_4 will immediately begin to redissolve. Hence in order that Na_2SO_4 form scale of appreciable thickness, the rate of supply of fresh water to the tube must not exceed the rate of evaporation by more than about 2 per cent at 1400 psi, and about 0.5 per cent at 1800 psi. In other words, nearly complete evaporation must occur in one pass through the tube. Such a state of affairs can be caused only by poor circulation, or by excessive rates of heat transfer; or by both, since excessive heat transfer may cause poor circulation.

It is very likely that such a state of affairs is confined to relatively few tubes or parts of tubes in the boiler. The solution to the problem is to reduce the heat transfer by relocation of the tubes or to provide sufficient circulation to allow them to handle the heat transfer demanded.

Regarding corrosion due to bonded oxygen, and assuming the author's mechanism to be correct, it is necessary that very high concentrations of caustic be produced by the same mechanism that causes hide-out, in order to dissolve or peptize the pro-

[26] Lieutenant, U.S.N.R., Barberton, Ohio. Jun. A.S.M.E.

[27] Assistant Professor of Chemistry, Carnegie Institute of Technology, Pittsburgh Pa.

tecting film of iron oxide from the tube wall. Obviously, the solution of the problem is the same as in the case of hide-out. If his mechanism is not correct, and the attack is due merely to steam-binding with attendant overheating of the tube, the solution is again one of improving circulation by allowing more ready release of steam.

Finally, turning to the problem of carry-over, it appears reasonable that if the tremendous concentrations previously mentioned are permitted in the steam-generating tubes, a portion of this very concentrated water will be carried along as a mist with the escaping steam. Hence an appreciable amount of boiler solids will be carried into the superheater, even though the amount of liquid water accompanying the solids is very low. This condition, too, can be improved by improving circulation or reducing the heat-transfer rate as just suggested. In addition, the modern high-pressure boiler still suffers from many of the same defects as older boilers. Provisions are poor for separating steam from water as it comes from the steam-generating tubes. Much splashing must occur in the drums. Redesign to secure smoother steam release from the water in the drums without splashing and droplet formation, together with adequate provision for release of droplets carried with the steam, should greatly reduce carry-over troubles.

A. C. Pasini.[28] This paper offers a theory for boiler treatment which throws some light on results that have puzzled and worried power-plant managers. In this field there has been confusion and misunderstanding.

A little over a year ago, we had occasion to discontinue sodium-sulphite treatment so that a study could be made to determine where the oxygen was entering the feedwater system. (This treatment was stopped because reducing agents such as sulphite affected the accuracy of the determination of dissolved oxygen.) We were told that if the proper sodium sulphate to sodium hydroxide ratio were maintained by the addition of sodium sulphate, no trouble from carry-over should result. In less than 2 months the first-stage pressure on our turbines increased more than 10 per cent, while the plant heat rate went up 200 Btu per kwhr. Considering that the plant output was in excess of 5,000,000 kwhr daily, the loss was substantial. Further inquiry disclosed that, in other plants where the proper ratio had been maintained and with very little carry-over, both sodium sulphite and sodium sulphate were used.

Another theory which gained prominence was and is known as "total phosphate control." It is stated that proper water-conditioning will result. But this means carrying high residuals. We feel that the lower the residuals carried in the boiler water, the less chance there is for carry-over.

We have silica and iron-oxide deposits amounting to an increase in turbine first-stage pressure of approximately 2 per cent per year. On 3-year inspections we remove the deposits by hand. It is a dirty and tedious job. We want to eliminate this work.

The author states that the silica deposits will be held to a minimum or eliminated, but the residuals to be carried will be higher than ever. Are we going to get into more trouble from some other source? The chemists will have to search diligently.

In the paper, it is stated that chloride concentrations for years prevented boiler troubles on ocean-going vessels. It is unfortunate that this significant fact was not recognized sooner and applied to land boilers. What was the drawback?

If tube temperatures are 200 to 300 F above the temperature of saturation and also above the temperature of superheat, what effect has this on Δt and on the action of the potassium salts?

Nevertheless, the theory now advanced at least gives to power-plant managers an engineering appraisal of the phenomena of boiler-water equilibrium. Dr. Hall is to be congratulated.

W. C. Schroeder[29] and A. A. Berk.[30,31] Over a period of several years, and particularly since the advent of the waterwall furnace with high rates of heat transfer, there has been a disquieting but rather vague feeling that boiler water was not always acting as a dilute solution. The hiding-out of boiler-water salts, the formation of silica scale, and the appearance of intercrystalline cracks in boiler tubes all indicated concentrations much greater than normal.

The author has made a frontal assault upon this problem, proposing (*a*) what appears to be a reasonable explanation of how the dilute solution can concentrate, at least momentarily, at tube surfaces, and (*b*) the beginning of a sound analysis of the effect of this concentration upon the deposition of salts from the boiler water.

Existence of dilute and concentrated boiler water makes it necessary to analyze the effect of the various salts under both conditions. For example, Fig. 6 of the paper shows that enough sodium hydroxide to give a pH of about 11.5 (measured at room temperature) corresponds to a minimum attack upon the steel. When this dilute solution concentrates, however, the caustic will soon reach proportions that will cause the solution to attack the steel more vigorously than it would if water alone were present. In brief, the caustic added to minimize corrosion in the dilute boiler water accelerates corrosion in the concentrated boiler water. Presumably then, if the maintenance of a pH above 7 in a boiler water with caustic is still believed to be desirable, it is because (1) the area of metal exposed to the concentrated solution may be reduced to zero by proper boiler design and operation, (2) the concentration reached is not high enough to cause corrosion at a rate appreciably greater than that caused by water alone, or (3) the time during which the concentrated solution can act at a given area may be too short to cause damage.

Considering only the chemicals added for feedwater treatment, two procedures are available to eliminate the action of the concentrated caustic. The first is to operate the boiler with distilled water alone. Theoretically, this would cause general corrosion over the entire boiler surface at a rate slightly in excess of that for a boiler water at a pH of 10 to 12, but it would cause less corrosion at points of concentration. This scheme has been tried and is reported to be successful in some boilers at present. It has been unsuccessful in others, and in any event it demands that evaporators and condensers must function especially well to prevent entrance of extraneous solids. Deaeration also must be very good, or oxygen corrosion will occur.

The alternative method would be to substitute an alkaline salt, such as sodium or potassium phosphate, for caustic. This makes it possible to control the pH at the desired level, but at points on the tube surfaces that are very hot the solution cannot attain a high concentration of caustic that will rapidly attack the metal. Instead, there will be only a deposit or concentrated solution of phosphate salt. There is strong reason to believe that iron or steel is much less soluble in these salts than in caustic and, consequently, less corrosion of the tube surface would be anticipated. Maintenance of alkalinity with sodium phosphate is now being tried in several boilers operating in the range from 400 to 2000 psi. So far, these tests appear to have been quite successful. On the other hand, the corrosivity of concentrated

[31] Discussion published by permission of the Director, Bureau of Mines, U. S. Dept. of Interior.

solutions of sodium or potassium silicates or chlorides on steel is as yet unknown.

The author states that the decreasing solubility of sodium silicate with increase in temperature will tend to promote the deposition of insoluble silica at relatively hot surfaces. On the other hand, if the salt is potassium silicate instead of sodium silicate, the solubility characteristics are reversed, and in contact with high-pressure steam it becomes difficult if not impossible to reach temperatures high enough to drive all the water out of the solid and to deposit potassium silicate in a form in which it cannot rapidly redissolve when the surface is again wet. If the effect of the other salts that may be present in a boiler water on the solubility characteristcs of the sodium and potassium silicates at high temperatures were known, a major tool for the solution of boiler-water problems would be available. The solubility and vapor-pressure data for the potassium and sodium salts should be extended as rapidly as possible, at least to the critical temperature of water. If sodium silicate is insoluble under conditions that may exist in steam-generating tubes and may incongruently form silica scale, it is also necessary to know the limiting ratio of sodium to potassium at which this effect no longer occurs.

On the basis of solubility and vapor-pressure data, the author offers a brief explanation of how chlorides can raise the boiling temperature of the solution on an overheated surface to such a degree that the concentration of caustic required to cause embrittlement-cracking could not be attained. How effective these salts are in preventing such concentrated caustic solutions will depend upon the temperature reached at the overheated surface. With respect to the embrittlement detector, where the difference between the operating temperature in the boiler and the atmospheric boiling temperature is available to concentrate the solution, it has been found that ratios of sodium chloride to caustic of 20 to 1 had no effect in preventing cracking. This statement applies to tests conducted at pressures as low as 210 psi.

In embrittlement-testing equipment developed by Straub, where concentration of the solution occurs by loss of water vapor toward the full steam pressure, the effect of this factor may be more important. It appears also to offer a partial explanation of the different results obtained with mixtures of chloride with sodium sulphate or R_2O_3 in this unit, as compared with the results obtained in the embrittlement detector. It would seem therefore that maintaining a high chloride concentration would tend to prevent intercrystalline cracking of tubes that overheat at high ratings rather than of boiler seams and tube ends which generally do not receive direct heat.

For protecting riveted seams, the author recommends "captive" alkalinity, in which the alkalinity of the water is captured in the form of phosphates and silicates as the water is concentrated. The embrittlement detector has shown this method to be successful with phosphate alkalinity, and it has been proved that concentrated solutions of trisodium phosphate in the absence of sodium hydroxide will not cause embrittlement cracking. It has not yet been shown that concentrated solutions of potassium or sodium silicate, which may be much more alkaline, will similarly not cause embrittlement. Embrittlement-detector tests with sodium or potassium silicates are now being carried out.

Turning from the boiler, the chemist is still awaiting enough data to determine how salts are carried from the boiler water to the superheater and then into the turbine. Carry-over from the boiler water undoubtedly is a major factor, but at the high steam pressures now employed some salts may be soluble in steam. The factors that influence carry-over are not clear, and a bare beginning has been made in studying solubility in steam. In the superheater, the higher temperatures would tend to increase solubility of some salts in steam, but at the same time the lower specific gravity of the steam would tend to decrease their solubility.[32] The effect of these factors doubtless will have to be determined for each salt involved. The situation in the turbine is equally as involved, and few data are available to help in analyzing it.

Since the specific gravity of steam, or, in other words, the close packing of the molecules, appears to be the largest factor in its ability to act as a solvent for salts, it may be possible to determine the conditions under which the boiler salts could dissolve and where they might deposit in the turbine. Spillner[33] compared observed volumes of vapors at their critical points with values calculated from pressure-temperature-volume relationships and concluded that to act as a solvent a vapor must show a certain minimum departure from the gas laws. The crowding of steam molecules at high pressures can be estimated from the specific gravity and the Maxwell distribution law. It is quite

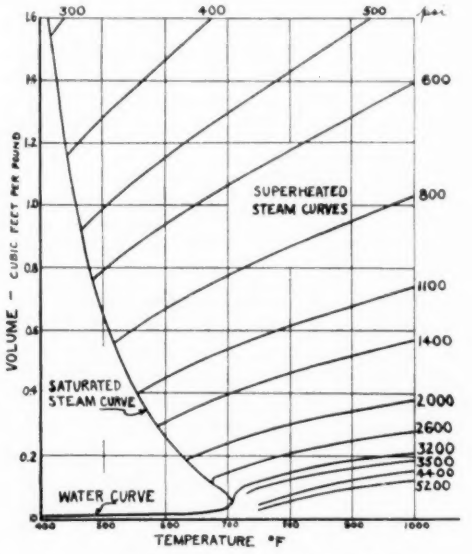

FIG. 19 VOLUME OF SUPERHEATED STEAM

probable that a mathematician could tell us at what special arrangement the molecules will be so far apart as to be able no longer to attract salt molecules sufficiently strongly to hold them in solution.

As a start in this direction, Fig. 19 of this discussion compares the volume occupied by 1 lb of steam at different temperatures and pressures with the volume occupied by 1 lb of water in equilibrium with saturated steam. Saturated steam expands as it is superheated, approaching a perfect gas at lower pressures and higher temperatures. Of special significance is the region around the critical point. At about 650 F, the specific gravity of water begins to decrease rapidly. Saturated steam formed at this temperature shows a similar unusually high coefficient of expansion for a very small region on the curve. At the critical point, this effect is much more pronounced, and the specific gravity of critical steam is reduced by half during a rise in temperature of about 15 deg F. This behavior may be very significant, as the attraction of steam molecules for each other has been shown to increase very rapidly as the distance between them is decreased.[34]

[33] "High-Pressure Steam as a Solvent," by F. Spillner, *Die Chemische Fabrik*, vol. 13, 1940, pp. 405–424.

[34] "Steam Research Program, Part 3," by L. B. Smith and F. G. Keyes, Proceedings American Academy of Arts and Sciences, vol. 69, 1935, pp. 285–314.

It is believed that such attraction controls the degree of solubility of salts in steam.

The author has called attention to the possible marked effect substitution of potassium salts for sodium salts may have upon turbine deposits. As yet it is difficult to associate the separation of silica as an insoluble phase with the appearance of compact crystalline masses on turbine blades. How do they get there?

Also, what is the boiler operator to do while the chemist is unwinding this complex solubility-vapor-pressure-temperature equilibrium? He can rely upon chemical treatment to correct one set of difficulties, but this may accelerate others or move the trouble from the boiler to the superheater or turbine. At the same time, a method that has been applied successfully in one plant will not necessarily work equally well in another, for factors affecting the results may be overlooked owing to lack of data or failure to understand an involved but important chemical effect.

It must also be realized that the analysis of solubility and vapor-pressure equilibrium, as applied to boiler operation, has so far been tried for relatively simple solutions containing one or two compounds. Actually, most boiler waters contain half a dozen salts or compounds, each of which may alter drastically the relationships involved in the mixture. The treatment of so complex a solution to determine the conditions it can produce in a boiler, superheater, or turbine can be extremely involved, assuming that all the necessary data are available.

These statements are not intended to discourage the accumulation or full application of solubility and vapor-pressure data to the modern high-pressure boilers. Instead, they indicate that the work must be pursued vigorously and without delay to determine just how far valuable application can be made. While this is being done, there is also the chance that test methods or devices will appear or be developed that, together with a better understanding of the physical chemistry of the processes, will allow direct determination of the action of a given boiler water, or the steam from it, in boiler, superheater, and turbine. Such a development may furnish a shortcut that the boiler operator can readily interpret to test the effect of any specific set of conditions. It may also place a greater burden upon the manufacturers of boilers and auxiliary equipment to avoid trouble created primarily by design characteristics.

While the boiler operator is awaiting this further work, the one thing he can do to relieve difficulty is to reduce to a minimum the salts carried into the system through condenser leakage and evaporator carry-over. If they are at a minimum in the boiler water, it is reasonable to assume that this condition will favor the best operation of boiler, turbine, and superheater. The boiler operator who does not exercise the greatest care in this regard is missing the best opportunity for preventing trouble. Assuming that this does not overcome all his difficulties, he is then in a position to apply a minimum of chemical treatment to help solve any remaining problems.

F. G. Straub.[35] It is rather difficult to discuss this paper since the author attempts to cover the entire field of water treatment from steam-blanketed tubes, superheaters, and embrittlement through turbine-blade deposits, and offers one method of approach to solve all these difficulties experienced by the power-plant industry. As he points out, the data available are few and incomplete. Thus in Fig. 5 of the paper, he compares the solubility of sodium and potassium di- and metasilicates. The sodium salts have only two points on the curve over a range of 450 F. In a previous theory advanced by the author, he based his reasoning on the increase of solubility with increasing temperature curve of calcium carbonate, as compared to the decrease in solubility with increase in temperature of calcium sulphate. A short time later, Partridge showed that both salts decreased in solubility with increase in temperature. The writer would suggest that more data be made available before such definite conclusions can be drawn.

The real importance of the suggested potassium substitution for sodium will depend upon the results obtained in actual operation. Here again, caution should be the watchword in drawing conclusions. Often, several changes are made at one time and it becomes difficult to point out definitely which change actually caused the beneficial results obtained.

In 1936, the writer[36] called attention to the fact that sodium hydroxide would not produce a saturated solution in superheated steams, while sodium carbonate and sulphate would form saturated solutions and precipitate the dry salts under similar conditions. In 1939, we showed[37] that in steam-blanketed areas the corrosion (or as the author refers to it "embrittlement") could be controlled by chemical treatment. However, we found that if the metal temperature increased above a certain point, the chemical treatment was no longer effective. These results indicated that it would be possible to retard tube corrosion and resulting deposits as long as the tube temperature could be controlled and kept below a certain value. The author's recommended treatment should be beneficial in boilers where the steam-blanketing is such that the metal temperature is below this limiting temperature; however, if this temperature increases, the treatment will fail. It is believed that the ultimate solution of this type of trouble will involve proper circulation and wetting of the tube.

The author states that sodium hydroxide is not guilty of hide-out propensities due to its high Δt_s value. The writer knows of many boilers where sodium hydroxide is guilty of hide-out.

The statement is made to the effect that the silica deposition in the turbines is the result of the mechanical carrying of the silicates in the boiler water into the steam. A. Splittgerber[38] calls attention to the fact that dilute solutions of the silicates will hydrolyze at higher temperatures and liberate appreciable amounts of silicic acid. The silicic acid will be present in the steam even with the absence of mechanical carry-over. The deposition of the silica from the silicic acid at the lower temperatures and pressures in the turbine is a much more logical explanation of the silica deposition than that of the author.

W. L. Webb.[39] Regardless of whether the theories presented in this paper are borne out entirely in practice, this attack of the problem stimulates productive thinking and will lead the way to fundamental improvement in control technique.

Our experience with potassium treatment has been confined to its use in two boilers rated 750,000 lb per hr, 1350 psi, 950 F steam temperature at the Beech Bottom Power Company's Windsor Station since early in April, 1943. These 3-drum bent-tube tangentially-fired wet-bottom boilers are two of four boilers of approximately the same capacity which supply steam to two 60,000-kw topping turbines exhausting at 230 psi, 550 F to six 30,000-kw condensing units.

The two 1350-psi boilers under test present a number of problems considered susceptible of solution by potassium treatment. These include the following:

1 Sludge accumulation on the steam scrubbers and driers and downtake and riser tubes.

2 Deposition of sodium-aluminum-silicate scale on heating surfaces.

3 Water-insoluble deposits in low-pressure turbines.

The sludge-and-scale problem comes about primarily from excessive condenser leakage, bringing into the system raw Ohio River water containing hardness, silica, and alumina.

Between late 1941, when the boilers were first put into service, and the time potassium treatment was started, much trouble was experienced with furnace-tube wastage. In the wastage zones, many tubes blistered, and a number developed leaks in longitudinal cracks usually located in slight bulges. On inspection these tubes showed thin hard deposits of sodium-aluminum-silicate scale. Several other tube failures occurred which were attributed to design faults.

Inasmuch as a number of new aspects developed during October and November, 1943, in the boilers under potassium treatment, the discussion of our experience is divided into two parts:

First Six Months of Experience With Potassium Treatment

Under potassium treatment from April to September, 1943, inclusive, only two boiler-tube failures occurred, both in the same boiler, on May 3. These failures were in wastage areas and were repaired by window-welding. What bearing, if any, potassium treatment may have on furnace-tube wastage rates is not known.

Contrary to expectations, no leakage of gaskets in contact with boiler water has occurred. Flexitallic hand-hole gaskets are used throughout.

Riser Tube Deposits. Typical analyses of the more important constituents of deposits turbined from wall bifurcated tubes under the two treatments are shown in columns 1, 2, 3, and 4, of Table 6 of this discussion.

It was concluded that sodium-aluminum-silicate deposits not only were not forming but also that previously formed deposits were being removed by the potassium chemicals. Furthermore, at least some of the silica was being precipitated as magnesium-silicate sludge.

[a] Hard scale taken from area of failure of Boiler 82 north wall tube after removal of soft sludge.

Sludge Deposits. With substantially the same condenser leakage under the two treatments, the drum internal and visible tube surfaces were appreciably cleaner under the potassium treatment than under the sodium treatment, following operating periods of comparable steam output. This has been particularly true of the steam scrubbers and downcomer tubes, Table 7 indicating typical analyses of these sludge deposits.

Average chemical cost (per million pounds of feedwater), cents	2.6	7.6	10.0

Turbine Deposits. The relative rates of build-up of deposits in low-pressure turbines under the two treatments are confused

somewhat by the fact that these units receive some steam from sodium-treated low-pressure boilers.

The deposits became troublesome during the first half of 1942, during which time condenser leakage was unusually high and the cooling water high in suspended matter. Caustic-washing of turbines was started soon thereafter. Condenser leakage was greatly reduced but deposits continued to build up.

The washing dates of the turbines receiving steam from the potassium-treated boilers and approximate capacities regained by washing are indicated in Table 8 of this discussion.

Since July, 1943, stage-pressure data of units Nos. 2, 4, and 6 have been obtained and plotted. The curves for unit No. 6 only show progressive increases in pressures with time. Further experience is needed to show definitely the effect of potassium versus sodium on deposit build-up especially since units Nos. 1, 3, and 5, receiving steam only from sodium-treated boilers, now show slower rates of accumulation of deposits.

Boiler-Water Conditions. Typical boiler-water conditions, and chemical feed rates and costs under the two treatments are shown in Table 9.

Governed principally by changing rates of condenser leakage, the boiler-water sampling and analysis schedules are normally the same under the two treatments. Determinations ordinarily are made for OH and PO_4 five times and the other usual constituents once per 24 hr per boiler.

Conclusions. Based upon the first 6 months of experience with potassium treatment in the two 1350-psi boilers, the following tentative conclusions are drawn:

1 Indications point to complete elimination of sodium-aluminum-silicate scale and presumably all silica scales from heating surfaces.

2 All surfaces of the boiler circuits and of the steam scrubber are freer of sludge deposits than when sodium treatment was used.

3 Indications point to a reduced rate of build-up of low-pressure-turbine deposits under potassium treatment than under sodium treatment.

Eighth and Ninth Month of Experience With Potassium Treatment

During an outage of boiler 82 on October 10, one tube in the furnace wastage area of the north wall was found to be leaking, the failure being in the form of a series of longitudinal cracks in a small bulge. The 12-ft section of this tube, removed for internal examination, revealed the presence of thin hard scale on the fire side and some slight internal corrosion in the scaled areas. About half a dozen small bulges in other tubes in the wastage area in this wall were found and about half that number were observed in the east wall, a condition not previously experienced under potassium treatment. To what extent the formation of bulges can be attributed to old scale laid down under sodium treatment is not known.

The study of the thin, hard scale in the failed tube is as yet incomplete but X-ray analyses show the absence of analcite. The scale appears to be some form of potassium-aluminum silicate. Its chemical analysis is indicated in column 5 of Table 6 of this discussion.

During the November 21 outage of boiler 84, no bulges were observed on any of the wall tubes. Sludge deposits, however, were somewhat heavier than usual, due perhaps to a greater than normal time interval between shutdown and draining. The following quantities of deposits were turbined from selected bifurcated tubes of the north wall:

Tubes Nos. 5 and 6—3 g (previously turbined 7/24/43)
Tubes Nos. 17 and 18—385 g
Tubes Nos. 43 and 44—333 g

Analyses of the foregoing deposits have not yet been made.

Lacking details concerning the October-November run with potassium treatment, no conclusions are being drawn. Consideration, however, is being given to the following:

(*a*) Raising the silica in the boiler water by feeding potassium silicate to assist in precipitating magnesium as magnesium silicate for the purpose of reducing the tendency of the sludge to adhere to boiler surfaces.

(*b*) Removal of existing deposits from one of the high-pressure boilers by acid-cleaning to determine whether scales containing alumina and silicon are formed under potassium treatment.

It is possible that the scales, recently observed, were initially deposited under sodium treatment as analcite, and under potassium treatment they are being converted to a potassium-sodium-aluminum-silicate complex through zeolitic action.

Potassium treatment like all other pioneering must be modified to fit new conditions as they arise in practice. That in some respects it should meet with apparent failure is no cause for discouragement. The writer is confident that as needed vapor-pressure and solubility data become available, and the theories derived thereform are tempered by field application, boiler deposits will cease to be the problem they are today.

S. F. Whirl.[40] A new mode of thinking in the field of boiler-water treatment has been born. In diagnosing the water-steam problems encountered in high-pressure high-temperature operation, the author has utilized sound physicochemical reasoning instead of trial-and-error methods. Substitution of potassium for sodium salts is an outgrowth of this innovation. The approach is so fundamental and logical that we naturally ask ourselves the question, why did not someone conceive and apply it years ago?

Perhaps the main reason for the delay in attacking these problems in the present scientific manner has been a lack of apparent data. The author is to be complimented for the compilation and utilization of the data presented in the paper, particularly Morey's data on the behavior of silicates at high temperatures and pressures, presumably of interest only to the geophysicist and the glass manufacturer. Too often in seeking a practical solution of troubles, we overlook the findings of chemists in other fields of endeavor.

As repeatedly pointed out in the paper, the data supporting many of his contentions are very meager, and considerable research will be necessary to attain a thorough understanding of the behavior of the solids in the boiler, superheater, and turbine.

The available data deal chiefly with "solo" solutions, those in which only one chemical is dissolved in water. As other substances are added to these solutions, as in the case of actual boiler waters, the original data no longer apply, and therefore theoretical consideration of such a complex system as boiler water may lead to erroneous conclusions. This is aptly illustrated by the behavior of KCl-NaBr mixtures as compared to the behavior of these salts individually, shown in Fig. 11 of the paper.

Iron-Oxide Sludge. Corrosion of boiler metal by water is a natural oxidation process whereby iron tends to seek its most stable form under the conditions of its environment. It will continue as long as metal and water are in contact. All we can hope for is to reduce the intensity of the reaction to a negligible value by chemical treatment which favors the development and maintenance of a protective iron-oxide film on the metal surface. In the absence of dissolved oxygen in the boiler water, the reaction is fundamentally the capture of oxygen from the H_2O molecule by the iron with an unleashing of a corresponding amount of hydrogen. In fact, the amount of molecular hydrogen

[40] Chief Chemist, Duquesne Light Company, Pittsburgh, Pa.

in the steam is an indication of the intensity of the corrosion. Since caustic indirectly promotes the corrosion process by destroying the protective barrier, any efforts to reduce its concentration at the evaporative surfaces will be a step in the right direction, whether it be by the addition of other salts having high Δt, values or by co-ordinated phosphate—pH control, as suggested by Purcell and Whirl.[41,42,43]

The presence of iron-oxide sludge in the boiler, however, does not necessarily indicate wastage of boiler metal. Iron oxide is continuously being formed throughout the entire system and is transported from the economizer, deaerator, heaters, condensers, pipe lines, etc., into the catch-all, the boiler. We must bear these facts in mind and not be misled on finding accumulations of iron oxide in the boiler at inspections, especially on starting up new units which are inclined to contain considerable iron oxide as a result of atmospheric rusting.

Boiler Water Carry-Over and Deposits in Steam System. In spite of improvements in steam quality in recent years, troubles

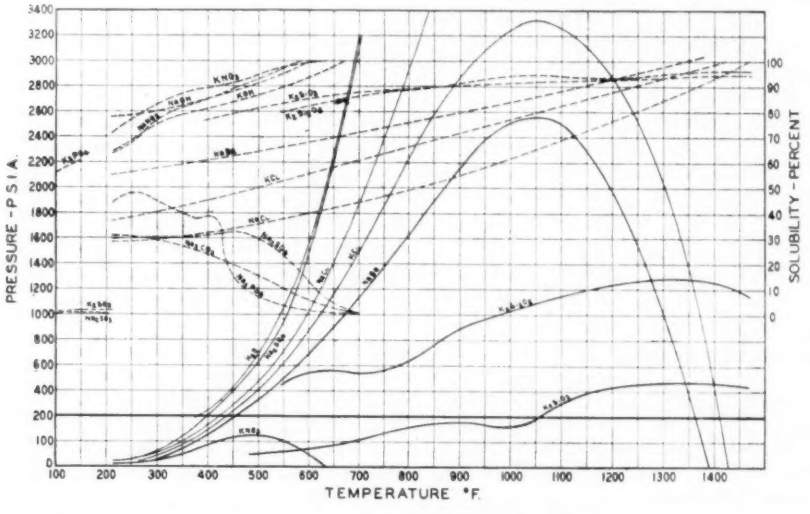

FIG. 20 SOLUBILITY-TEMPERATURE-VAPOR PRESSURE RELATIONS FOR WATER SOLUTIONS OF VARIOUS SALTS

with turbine deposits continue. This is not surprising, however, when one considers that even with steam containing less than 1 ppm of solids, the amount of chemicals entering a turbine over a period of a year is a matter of tons, not of pounds. The important item in turbine operation is whether or not these chemicals "stick and stay stuck." The extent to which operation is affected depends upon the amount of deposit and its location. Such factors as the nature of the solids carried over, temperature, pressure, velocity, pH of the steam, and turbine operation evidently all play a part. The author has supplied us with a very important piece of this complex jig-saw puzzle. Since silica is the chief offender in high-pressure operation, he suggests a method of boiler-water treatment designed to keep the silica in solution as it passes through the turbine. It must be recognized, however, that the supporting data deal only with solo solutions, and the effect of other salts may completely alter the behavior of the silica. This can be determined only by experimental investigation.

Is keeping the silica in solution the complete answer, though? Let us consider a droplet of boiler water carried over with the steam. By the time it has passed through the superheater and entered the turbine, certainly it will be a concentrated solution of some chemicals. Some salts will precipitate and their behavior is a matter of conjecture. Will they settle out, or will they remain with the concentrated droplet? Most important, however, will the final droplet be a liquid which will pass on through the turbine or will it be a viscous, pasty, wet mass which will adhere to the blading?

To give an idea of the extent of the solubility of different salts under superheater and turbine conditions, some of the solubility and pressure-temperature data in the appendix have been plotted in Fig. 20 of this discussion. By means of these curves the weight per cent of the salt in solution is given directly for various pressure-temperature conditions. It is interesting to note that at 1000 psi and 900 F, a number of the solutions are richer in chemicals than in water; for instance, 70 per cent KCl, 30 per cent H_2O; 100 per cent KOH; 91 per cent K_2SiO_3, 9 per cent H_2O. We would naturally expect a mixture of these to be quite viscous.

There are many questions concerning the behavior of silica which cannot be readily explained. The silica concentration in the saturated steam at one of our plants operating at 900 psi has been found, by careful evaporation studies, to be more than tenfold that which would be expected. Is this indicated selective carry-over due to the solubility of silica in the vapor or to mechanical carry-over, promoted by the tendency of silicates to concentrate at the steam-water interface?

Another question is prompted by the E.E.I. investigation of several years ago,[44] and the comprehensive study now under way. A number of cases are on record where no silica difficulties were encountered in the low-pressure turbines until after topping units were installed. In general, the quality of the steam has been improved. In some instances, the treatment in the high-pressure and the low-pressure boilers has been essentially the same. The tendency has been to carry lower alkalinities in the high-pressure boilers, but there are a few cases where the reverse is true. There is one principal difference, however, that is, the higher superheat temperature to which the droplets of boiler water are subjected in the high-pressure superheater. Would we expect this factor to have any particular influence on the behavior of silica in the turbine, using sodium treatment in the boiler water? A phase-rule study similar to that presented in Fig. 8 of the paper, but including all of the salts present, would most certainly determine the conditions under which the various constitutents would precipitate from solution. Whether or not and where they may "stick and stay stuck" are different problems.

The same phase-rule study would apply to deposition of solids in the boiler and might correlate many experiences which now seem contradictory. As an example, after several months'

[41] "Embrittlement of Boiler Steel—Experiences With the Schroeder Detector," by T. E. Purcell and S. F. Whirl, Trans. A.S.M.E., vol. 64, 1942, pp. 397–402.

[44] "Power Station Chemistry," Edison Electric Institute, Publication No. E 10, 1937

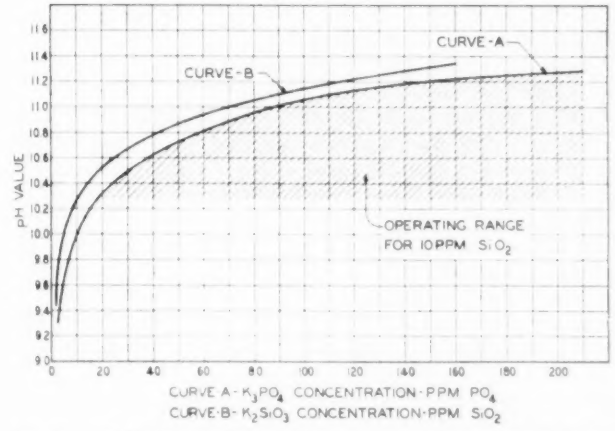

FIG. 21 pH VALUES OF WATER SOLUTIONS OF TRIPOTASSIUM PHOSPHATE AND POTASSIUM METASILICATE

operation with co-ordinated phosphate-pH control in two 300-psi B&W cross-drum boilers, the silica-rope scale, always found tightly adhering to the sides of the top rows of generating and upper steam-circulating tubes, was observed to be loosening, and many pieces, several inches in length, were flaked off and lying on the bottoms of the tubes. This observation is offered for what it may be worth and not as a recommendation of a method of treatment for removing silica.

Caustic Embrittlement. At the last two Annual Meetings of this Society, the corrective measures offered for the prevention of caustic embrittlement, when the boiler water was treated with sodium salts, included inhibitors and our co-ordinated phosphate-pH control of alkalinity,[41,42,43] the latter being especially suited to high-pressure operation. That the principle of our method might apply to other salts of weak acids and strong bases was fully recognized. The author terms this application "captive alkalinity." However, in utilizing the potassium silicates for this purpose, as suggested by the author, the question logically arises, can these salts in themselves promote embrittlement, especially the potassium metasilicate, because of its high solubility and high Δt_s value? The reason why pure trisodium phosphate will not cause embrittlement is evidently due to its low Δt_s value with consequent insufficient alkalinity in its saturated solution to promote this type of attack. We would expect much higher alkalinities from a saturated potassium-metasilicate solution.[45]

Since no two boilers have the same characteristics with respect to concentrating-film boiling at localized areas, and since the addition of other salts like KCl with high Δt_s values are not effective when the concentration is produced by evaporation to atmosphere, the only assured protection against caustic embrittlement is the elimination of caustic as such from the boiler water. The method of treatment to be described is offered as a practical means of protection against caustic embrittlement and, at the same time, a possible means of holding the silica in check.

Additional experimental data will be necessary to determine its effectiveness with respect to the latter. In Fig. 21 of this discussion are plotted separately the pH values of solutions of K_3PO_4 and K_2SiO_3. It is suggested that the pH of the boiler water be maintained below the phosphate-pH curve and above the pH value corresponding to the silica concentration in the boiler water, assuming the silica to be present as K_2SiO_3. The operating region for 10 ppm SiO_2 in the boiler water is indicated in Fig. 21 of this discussion.

[45] "Silicate of Soda in the Building Industry," by J. A. Vail, *Industrial and Engineering Chemistry*, vol. 27, 1935, pp. 888–893.

It is realized that, in the light of the data presented in Fig. 8 of the paper, this method may not appear logical with respect to preventing silica deposits. However, it should be pointed out that these data deal only with silicates and caustic potash; we do not know what effect the phosphates will exert on the equilibrium, especially when the pH is below that corresponding to the K_3PO_4 concentration. We would expect the Δt_s values of the phosphates to be higher with lower pH, and as the Δt of the solution increases and the vapor pressure decreases, what effects will the phosphates have on the silicate equilibrium? The nature of the phosphate salts which separate will also have a bearing on the ultimate behavior of the silica. For the complete picture, we must go still further and consider what happens to the concentrated boiler-water droplets as dilution occurs with lowering temperature in the turbine in an environment of various dry salts, having varying degrees of solubility at the different temperatures.

Potassium treatment was started in the 900-psi boilers of our Frank R. Phillips Station on August 1, 1943. The boiler-water condition is summarized in Table 10 of this discussion.

TABLE 10 AVERAGE ANALYSIS OF BOILER WATER; NO. 1 BOILER, F. R. PHILLIPS POWER STATION; AUGUST 1 TO NOVEMBER 20, 1943

pH: Determined	10.59
From phosphate-pH curve	10.86
Sp. Cond., micromhos	625
Dissolved salts, ppm	374

Hydroxide, OH, ppm[a]	0
Silica, SiO_2, ppm	8

[a] By modified Winkler method.[44]

Since inspections have not been made in the interim, no information can be offered concerning the effect of the treatment on boiler, superheater, and turbine deposits.

An embrittlement-detector test, however, was terminated at the end of 58 days instead of our usual 90 days, for the purpose of submitting the information in this discussion. Neither the hot- nor the cold-rolled specimen cracked. It is noteworthy that the deposit accumulations on the specimens were much softer and more readily dissolved in water than those of any previous test, using sodium treatment in the boiler water.

It is apparent that this paper opens a new and wide field of research in boiler-water treatment, and we may be certain that the method of approach will serve to guide others in future study.

AUTHOR'S CLOSURE

The constructive character of the discussion is outstanding. Only a few points need be given further consideration.

Mr. Corey's impression regarding higher hide-out by potassium than by sodium salts must be reversed. *Less* hide-out occurs with potassium than with sodium salts.

Mr. Daniels, who completely eschews any treatment of the boiler water, ably supports his position by the excellence of results in his plants. By maintaining his condensers tight, and avoiding carry-over from his evaporators, he is in position to say "Go thou and do likewise" to anyone objecting to his methods, because these sources may provide impurities in the boiler water. Many, however, conservatively sanction the added insurance embodied in a second defense line maintained in the boiler water, no matter how impregnable they may consider their primary defenses to be. As pointed out in the section on "The Iron Oxide Sludge Problem," the low pH value of untreated boiler water "provides optimum conditions for silica deposition in boiler and turbine." Also, where salt water is used in condensers, in addi-

tion to more severe problems of corrosion, the operator is confronted with a hundredfold or more increase of dissolved impurities over that derived from the same per cent of inleakage of typical fresh water.

Professor Keevil emphasizes the dearth of solubility and vapor-pressure data on multicomponent systems at temperatures and pressures such as those met in boilers and turbines. Continuance of the work discussed by Mr. Kaufman will in time result in obtaining such data, and probably with results as unexpected as the totally unlike solubilities of sodium and potassium phosphate.

It is pleasing to note that Dr. Schroeder and Mr. Berk, in their discussion, by use of the principles set forth in the section on "Protection From Embrittlement in the Light of the Δt Function" arrive at a logical explanation of the differences in results obtained by use of the embrittlement-testing equipment developed by Straub, on the one hand, and, on the other, by use of the embrittlement detector of Schroeder and Berk.

Professor Straub notes in relation to the tentative solubility curve of sodium meta- or disilicate (Fig. 5) that there are "only two points on the curve over a range of 450 F," and that he "would suggest that more data be made available before such definite conclusions can be drawn." Relative to this solubility, Dr. George W. Morey, of the Geophysical Laboratory, Carnegie Institution, Washington, D. C., states (14): "Experiments at comparatively low temperatures have shown that the solubility of sodium metasilicate is strongly retrograde. For example, at 100 C, the saturated solution of sodium metasilicate in water contains about 50 per cent of the anhydrous compound, but at 350 C, the solubility is measured only in tenths of a per cent." The broken curve of Fig. 5 for sodium metasilicate has been drawn in accordance with these data.

Professor Straub states, "The statement is made to the effect that the silica deposition in the turbines is the result of the mechanical carrying of the silicates in the boiler water into the steam." On the contrary, both in this paper (Section on "Role of Silica in the Turbine") and in the A.S.T.M. Round-Table Discussion of 1942 (43), the author has taken the position that the question of mechanical transfer, on the one hand, or transfer by vaporization, on the other, is an open one whose answer must await further data.

Professor Straub states, "We showed that in steam-blanketed areas the corrosion (or as the author refers to it 'embrittlement') could be controlled by chemical treatment." Reference to the section of the paper entitled, "The Iron Oxide Sludge Problem: Corrosion by the Bonded Oxygen of the Boiler Water," fails to disclose any mention of embrittlement in connection with this type of corrosion. However, in some cases, a type of embrittlement develops under such conditions, as noted in the section "Protection From Embrittlement, etc."

As brought out in Mr. Webb's discussion, and particularly by analysis No. 5, Table 6, potassium aluminum silicate, analogous to sodium aluminum silicate, will form under severe conditions. The conclusion is thus inescapable that with either sodium or potassium conditioning of the boiler water, the concentration of aluminum therein must be held to the minimum possible.

The author is very appreciative of the time and thought which has been given by the several contributors in the development of this discussion.

Theoretical Regenerative-Steam-Cycle Heat Rates

By A. M. SELVEY,[1] PITTSBURG, CALIF., AND P. H. KNOWLTON,[2] SCHENECTADY, N. Y.

The calculation of heat rates for a theoretical steam cycle with an infinite number of heaters regenerating feedwater to throttle saturation temperature is facilitated by the development of a simple tabular-integration method of computation which takes into account boiler-feed-pump work. A table of theoretical heat rates is presented for throttle-steam conditions, ranging from 300 to 3200 psia, and from saturation temperature to 1200 F, and for an absolute exhaust pressure of 1 in. of mercury. Means are provided for calculating heat rates at other exhaust pressures within the wet-steam region. These heat rates serve two purposes, i.e., (1) as a standard of power-plant performance; and (2), as a first step in estimating regenerative-cycle economy at unfamiliar steam conditions. The derivation of factors necessary to complete economic estimates, however, must await a more favorable opportunity. In the meantime, existing plant records can be made to provide approximate factors as substitutes for those it is hoped will be computed and published later. The economy of using superheated steam, integral moisture extraction, etc., are discussed briefly. An Appendix provides full directions for using or adapting the tabular-integration method for steam-cycle studies.

FOR several years a need has existed for a simple method of calculating theoretical regenerative-steam-cycle heat rates to serve as a standard of comparison for steam-power-plant performance. Such a standard has been set for the simple Rankine cycle by publication at various times of theoretical steam rates.[3] This paper presents a similar set of tables for a hypothetical regenerative cycle as described hereinafter.

Many expositions have been made by various writers of means for determining the performance of regenerative cycles, but it appears to the present authors that such performance is best obtained in two main steps, namely, (1) the determination of theoretical heat rates with zero engine and heat losses; and (2) the use of factors of "efficiency" for the various actual pieces of the working-cycle apparatus, to reduce the theoretical heat rates to practical cases. Information concerning step (1), namely, the production of the necessary tables of theoretical performance, is contained in this paper, with a description of the method and a set of tables showing the resulting heat rates, which are proposed as an acceptable standard, depending only upon the properties of steam, and therefore not subject to change unless, as appears unlikely, the basic steam tables are revised.

Step (2), the delineation of factors of actual performance, will be concerned with evaluating the effects of such losses as occur in actual apparatus—engines, boilers, feed heaters, pumps, etc., and in their arrangement. Work on step (2), however, has been postponed because of prior demands by the war effort. It is hoped that the work will be executed later. In the meantime, with the theoretical heat rates completed, there seemed good reason for making this material available for use in engineering studies. Estimating plant heat rates for higher steam conditions than are now in general use can be accomplished with reasonable accuracy by computing a series of proportionality factors or ratios from the performance of an actual plant and applying them in turn to the new conditions. This procedure should prove of some use until time is available for work on step (2).

Numerous interesting problems arose while work was proceeding on this study. Neither time nor space, however, will permit more than one or two of these secondary topics being introduced and discussed. Accordingly, this paper is confined to defining and describing the chosen theoretical regenerative cycle, discussing the mathematical procedure for computing heat rates, some brief mention of possible applications for the data, and some views on two recent proposals concerning the regenerative cycle. An Appendix demonstrates two computation forms, a short and a long, which may be adapted as desired to suit various modifications of the regenerative cycle.

The Theoretical Regenerative Cycle

A clear picture of the theoretical regenerative cycle considered in this paper is essential as several writers have proposed and discussed different modifications which also can be classified strictly as regenerative cycles. In addition, engineers still lack a universally acceptable steam-cycle terminology and, consequently, have resorted to naming cycles as they personally feel justified. Under such circumstances, definitions, descriptions, and diagrams need to be complete.

Definition. The theoretical regenerative steam cycle is viewed herein as one in which steam, expanded isentropically (at constant entropy) through a prime mover, in this case a turbine, is extracted (bled) for heating feedwater to throttle saturation temperature in an infinite number of progressive steps of zero terminal difference, each assisted by an attendant boiler feed pump of 100 per cent efficiency powered from the prime mover.

Other terms sometimes used instead of "theoretical," in speaking of such a cycle, are "ideal," "perfect," "hypothetical," etc. The term "ideal" is used often to indicate 100 per cent mechanical efficiency, reversibility, and possibly the idea of the cycle being "imaginary." The designation "ideal cycle," however, has been applied also to regenerative cycles of less than an infinite number of feedwater heaters and to a cycle in which only saturated steam and wet steam are bled for feedwater regeneration. Whatever the cycle is called, a more lengthy description is desirable.

Description. The heat rates provided by this paper are for a regenerative steam cycle of the following component parts:

1 A turbine, having no mechanical losses, through which steam is expanded at constant entropy (engine efficiency is 100 per cent).

2 A regenerative feedwater system having an infinite number

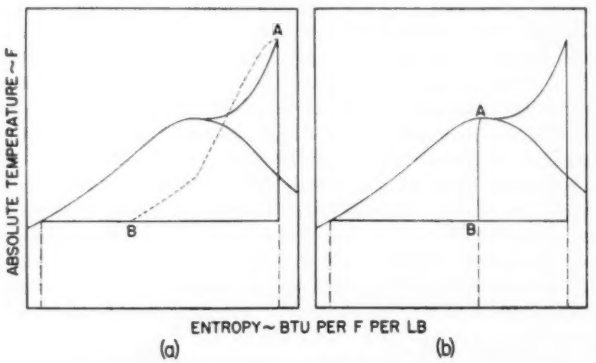

FIG. 2 TEMPERATURE-ENTROPY DIAGRAM FOR THEORETICAL REGENERATIVE STEAM CYCLE, OPERATING BETWEEN 3200 PSIA 1200 F AND 1 IN. HG STEAM CONDITIONS

(*a*, Conventional diagram. *b*, Diagram based on same construction method as used for Fig. 1*b*.)

of bled-steam heaters heating to the saturation temperature corresponding to the throttle-steam pressure, and with zero terminal difference between the saturation temperature of the bled steam and the temperature of the feedwater leaving the heater, even when superheat is present in bled steam,[4] and an attendant feed pump of 100 per cent efficiency with each heater to step up the feedwater pressure to the level of the next higher heater.

3 An electric generator of 100 per cent efficiency, which supplies, without line loss, the boiler feed pumps.

4 A steam generator of 100 per cent efficiency, in which blowdown, soot-blowing losses, etc., are zero.

Since energy required to drive fans, fuel equipment, general services, etc., is considered zero in a theoretical cycle, auxiliary-power usage other than that required for the boiler feed pumps, as described in item (2), is not included.

Diagrams. A conventional diagram for the theoretical regenerative cycle is shown in Fig. 1(*a*) for throttle-steam conditions of 1000 psia 700 F and 1 in. Hg exhaust pressure. The dotted line *AB*, representing the reduction in weight of steam passing through the turbine, is not an expansion line. The area below the dotted line is not significant. The chief advantage of the diagram is that it appears familiar.

In attempting to make a diagram in which areas are significant and bear the correct relationship of cycle efficiency, recourse was taken to a method of construction described fully by Barnard, Ellenwood, and Hirshfeld.[5] This method was used to produce Fig. 1(*b*) which is drawn for same steam conditions as Fig. 1(*a*). In Fig. 1(*b*) the area below the saturation line, bounded by condensate entropy and line *AB*, represents heat given up to feedwater.

With high-pressure and high-temperature throttle steam conditions, such as 3200 psia 1200 F, these diagrams, however, undergo unusual changes as are indicated in Figs. 2(*a*) and 2(*b*). Parallelism between line *AB* and the isentropic expansion line, the apparently meritorious feature of Fig. 1(*b*), no longer extends over the whole length of *AB*, in Fig. 2(*b*), but exists only up to the temperature level where the expansion line crosses the saturated-vapor line. Above that point, line *AB* shows to a more or less pronounced degree the effect of bleeding superheated steam. Curvature of line *AB* in Figs. 1(*b*) and 2(*b*) actually will exist whenever superheated steam is bled, but it is only noticeable on a small-scale diagram with throttle steam relatively highly superheated. Even then, curvature is apparently so slight that casual inspection of Fig. 2(*b*) might lead to the contention that a simple formula could be developed for calculating theoretical regenerative-cycle heat rates even for top throttle conditions. The significance of this curvature in line *AB* of Fig. 2(*b*) is not easily apparent, and it is hoped that the discussion will bring forth an explanation.

The closest approximation by "short-cut" formula would obtain if a straight line could be drawn vertically through point *B*. But the location of *B* cannot be found without recourse to the integration method to be described later. Accordingly, no labor can be saved in this case. The next approximation would be based on the assumption that the straight line passed vertically through known point, *A*. A short-cut formula for this case would be

$$\text{Theoretical heat rate}^{6}\ \text{(inaccurate)} = \frac{3412.75\ (H_t - h_f)}{H_t - h_f - T_s(S_t - S_f)}$$

[4] In actual practice, where a desuperheating zone is provided in a feedwater heater, a temperature crossover or negative terminal difference may exist where superheated steam is being bled. Since the number of degrees crossover varies with heater design and the degrees of superheat, an acceptable allowance for this effect feasibly cannot be included in a theoretical study.

[6] An approximately similar incorrect equation will be found in connection with Fig. 712, of "Steam Power Plant Engineering," by F. G. Gebhardt, sixth edition, John Wiley & Sons, Inc., New York, N. Y., 1925.

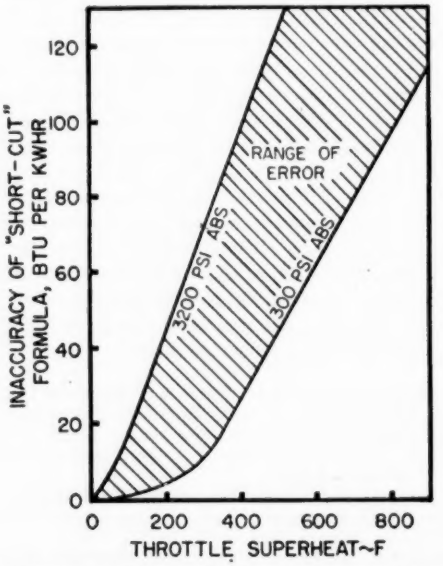

FIG. 3 A SIMPLE OR "SHORT-CUT" FORMULA FOR DETERMINING APPROXIMATE THEORETICAL REGENERATIVE-CYCLE HEAT RATES PRODUCES RESULTS WHICH ARE TOO LOW

(The diagram demonstrates how this inaccuracy increases with the amount of superheat in the throttle steam.)

where subscript t refers to throttle, f to saturated feedwater, and e to turbine-exhaust conditions. This formula is incorrect because it fails to take into account the sizable vertical strip bounded on one side by the line AB and on the other by a vertical through A. Heat rates computed by the short-cut formula are too low. The extent of the error is shown in Fig. 3.

The theoretical regenerative cycle, as defined and described, has been considered commonly as representing the best economy actually approachable in practice and, on this score, has been viewed by many as a standard of attainment. A recent suggestion, to be described later, of a novel but probably impractical regenerative cycle having Carnot efficiency does not seem to detract from the already established regenerative-cycle standard. The fact that a simple computation method, which will be described next, has been developed and heat rates calculated for a wide range of steam pressures and temperatures should minimize objections on the grounds of complication to the continued use of the theoretical regenerative cycle as an acceptable standard.

Development of Computation Methods

The Ernest L. Robinson equations for calculating the theoretical weight and energy value of bled steam appear in the Appendix of his 1923 paper.[7] The heat balance for an infinitesimal heater is

$$dw(H - h) = (1 + w)dh$$

which, when integrated, gives

$$1 + w = e^{\int_{h_2}^{h_1} \frac{dh}{H-h}}$$

where $(1 + w)$ is the pounds of steam at any point in the turbine. In the 1923 paper,[7] with a maximum steam condition of 1000 psia 800 F, integration was performed graphically. (The nomenclature used appears in the Appendix.)

Twenty years later, attention is focused on much higher steam conditions. There appears a definite need to provide theoretical regenerative-cycle heat rates for a wide range of throttle pressure and temperature up to 3200 psia and 1200 F. Because the effect of pump work on cycle efficiency is appreciable at high feedwater pressure, and because of the larger number of heat rates that would have to be computed to cover the greater range of steam conditions, Robinson's equation[7] had to be modified and adapted to a tabular method of computation.

Step-by-Step Integration. If $dh/(H - h)$ were to be integrated graphically, the quantity $1/(H - h)$ would be plotted against h as shown in Fig. 4. The product $dh/(H - h)$ is the area of an infinitesimal strip below the curve AB. The integral of $dh/(H - h)$, by the Robinson equation, is the whole area $ABCD$. Some energy, however, is added by the boiler feed pump. For each strip, dh, representing heat added by bled steam, there is an attendant strip, dF, representing the boiler-feed-pump work. Since the steam flow in the turbine depends upon the amount of steam bled, the enthalpy added by the pump in each step must be subtracted from the gross gain in enthalpy.[8]

In order to calculate accurately rather than to planimeter the area below the curve, it is necessary that sufficiently narrow strips be so chosen that the section of curve bounding the top of each strip is essentially a straight line. This provision permits determining the area of the strip by taking the equivalent height as the average of the two sides. About 35 steps from throttle to condenser for steam pressures of 2000 to 3200 psia have proved adequate. (An extra 20 steps were found unnecessary.) The steps, however, must be chosen so that the area of each strip, i.e., $dh/(H - h)$, is the same. An initial selection with constant increments of h may be proportioned to give constant values of $dh/(H - h)$ on a second or third trial. The method is described in the Appendix under "Short-Form Computation." With throttle pressure of 1000 psia or less, 25 steps may be chosen, and equal values of dh are satisfactory.

Checking the Method. Only one independent check on the method is available. A theoretical regenerative cycle supplied with saturated steam will have Carnot-cycle efficiency. Checks made on this basis have proved the method to be reliable.

[7] "The Margins of Possible Improvement in the Central-Station Steam Plant," by Ernest L Robinson, Trans. A.S.M.E., vol. 45, 1923, p. 644.

[8] The work done by the perfect boiler feed pump should be read from Fig. 3, p. 75, of the Keenan and Keyes "Thermodynamic Properties of Steam," John Wiley & Sons, Inc., N. Y., 1936. In the tabular-integration method, however, steps are so small that Fig. 3 cannot be read accurately enough. Since the change in specific volume of compressed water is insignificant on three scores, namely, (1) the change in feedwater temperature during compression is small, (2) the change in pressure is small, and (3) the effects of the foregoing oppose each other, the simple equation $F = Nv/5.4$ proved satisfactory. This form substitutes for the correction

$$-\frac{1}{J}\int_{r-1}^{r} v\,dP$$

recently suggested by Dr. W. J. Kearton; see *Journal* and Proceedings of The Institution of Mechanical Engineers, vol. 147, 1942, pp. 114–115, comment on paper by H. S. Horsman, reference 9.

The fact that a simple computation method, which will be described next, has been developed and heat rates calculated for a wide range of steam pressures and temperatures should minimize objections on the grounds of complication to the continued use of the theoretical regenerative cycle as an acceptable standard.

Development of Computation Methods

The Ernest L. Robinson equations for calculating the theoretical weight and energy value of bled steam appear in the Appendix of his 1923 paper.[7] The heat balance for an infinitesimal heater is

$$dw(H - h) = (1 + w)dh$$

which, when integrated, gives

$$1 + w = e^{\int_{h_2}^{h_1} \frac{dh}{H-h}}$$

where $(1 + w)$ is the pounds of steam at any point in the turbine. In the 1923 paper,[7] with a maximum steam condition of 1000 psia 800 F, integration was performed graphically. (The nomenclature used appears in the Appendix.)

Twenty years later, attention is focused on much higher steam conditions. There appears a definite need to provide theoretical regenerative-cycle heat rates for a wide range of throttle pressure and temperature up to 3200 psia and 1200 F. Because the effect of pump work on cycle efficiency is appreciable at high feedwater pressure, and because of the larger number of heat rates that would have to be computed to cover the greater range of steam conditions, Robinson's equation[7] had to be modified and adapted to a tabular method of computation.

Step-by-Step Integration. If $dh/(H - h)$ were to be integrated graphically, the quantity $1/(H - h)$ would be plotted against h as shown in Fig. 4. The product $dh/(H - h)$ is the area of an infinitesimal strip below the curve AB. The integral of $dh/(H - h)$, by the Robinson equation, is the whole area $ABCD$. Some energy, however, is added by the boiler feed pump. For each strip, dh, representing heat added by bled steam, there is an attendant strip, dF, representing the boiler-feed-pump work. Since the steam flow in the turbine depends upon the amount of steam bled, the enthalpy added by the pump in each step must be subtracted from the gross gain in enthalpy.[8]

In order to calculate accurately rather than to planimeter the area below the curve, it is necessary that sufficiently narrow strips be so chosen that the section of curve bounding the top of each strip is essentially a straight line. This provision permits determining the area of the strip by taking the equivalent height as the average of the two sides. About 35 steps from throttle to condenser for steam pressures of 2000 to 3200 psia have proved adequate. (An extra 20 steps were found unnecessary.) The steps, however, must be chosen so that the area of each strip, i.e., $dh/(H - h)$, is the same. An initial selection with constant increments of h may be proportioned to give constant values of $dh/(H - h)$ on a second or third trial. The method is described in the Appendix under "Short-Form Computation." With throttle pressure of 1000 psia or less, 25 steps may be chosen, and equal values of dh are satisfactory.

Checking the Method. Only one independent check on the method is available. A theoretical regenerative cycle supplied with saturated steam will have Carnot-cycle efficiency. Checks made on this basis have proved the method to be reliable.

Since the change in specific volume of compressed water is insignificant on three scores, namely, (1) the change in feedwater temperature during compression is small, (2) the change in pressure is small, and (3) the effects of the foregoing oppose each other, the simple equation $F = Ns/5.4$ proved satisfactory. This form substitutes for the correction

$$-\frac{1}{J}\int_{r-1}^{r} v_w dP$$

recently suggested by Dr. W. J. Kearton; see *Journal* and Proceedings of The Institution of Mechanical Engineers, vol. 147, 1942, pp. 114–115, comment on paper by H. S. Horsman, reference 9.

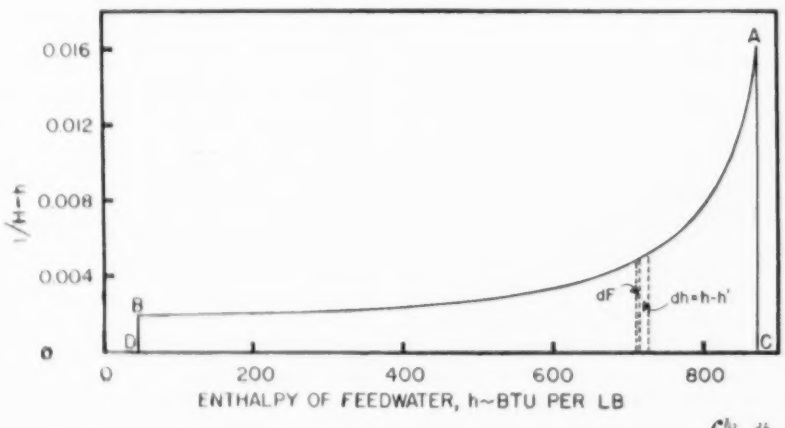

Fig. 4 Graphical Representation of Robinson's Equation $1 + w = e^{\int_{h_2}^{h_1} \frac{dh}{H-h}}$ Determining Weight of Steam Bled in a Theoretical Regenerative Cycle
(Example is for 3200 psia saturated steam.)

Application to Modified Regenerative Cycles. The step-by-step integration can be used to compute heat rates of other theoretical cycles such as the moisture-extraction cycle, the isothermal compression regenerative cycle, etc. It may be applied also to theoretical cycles where dry-stage efficiencies less than 100 per cent have been taken into account. In some cases, the second Robinson equation

$$E = \int_{h_2}^{h_1} \frac{H_1 - H}{H - h} (1 + w)dh$$

will have to be used. The method of handling this equation is explained in the Appendix under "Long-Form Computation."

To those interested in studying theoretical cycles, the tabular-integration method should prove a useful tool. The theoretical regenerative-steam-cycle heat-rate table, given in this paper, is a typical application of the method.

Theoretical Heat-Rate Tables

The production of a theoretical heat-rate table is a straightforward enough operation, although some ingenuity is required to minimize the necessary work to be done. Applying the short-form method, described in the foregoing discussion and illustrated in the Appendix, heat rates were calculated for a number of "key points," where throttle pressure and temperature are represented by round numbers. Temperature intervals were taken every 100 F; pressure intervals varied from 100 to 300 psia to suit circumstances.

Heat rates thus computed were plotted on a large curve sheet. A cross-plot also was used. The combination of the main and cross-plots established the principal connecting links between key points. Work sheets consisting of large skeleton tables were made up from the heat-rate readings given by the curve sheet. The skeleton was adjusted slightly where obviously necessary and eventually filled in mathematically by a system of uniform progressive differences. The application of this system to the data on the work sheets minimized errors of interpolation.

Table 1 gives theoretical regenerative-cycle heat rates at 1 in. Hg abs exhaust pressure for steam pressures from 300 to 3200 psia and from saturation temperature to 1200 F. The selection of pressures and temperatures for which heat rates are given was based (1) on the steps used in the 1936 steam tables and (2) on the need to insure that proportional interpolation between readings would be accurate. The table provides a means of determining quickly the heat rate of any theoretical regenerative-cycle power plant.[9] Theoretical heat rates at 1 in. Hg abs exhaust pressure are shown also in Fig. 5(*a*).

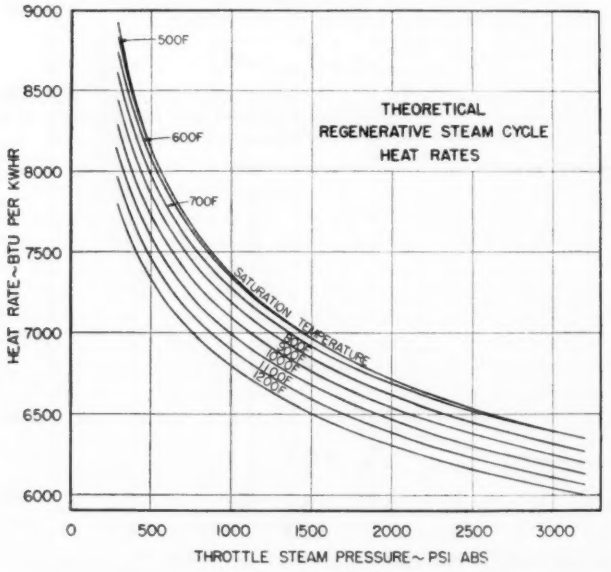

Fig. 5(*a*) Theoretical Regenerative-Steam-Cycle Heat Rates

(Throttle steam conditions as noted; exhaust pressure = 1 in. Hg abs. Infinite number of bled-steam feedwater heaters and attendant boiler feed pumps. Zero terminal difference. Feedwater heated to throttle saturation temperature.)

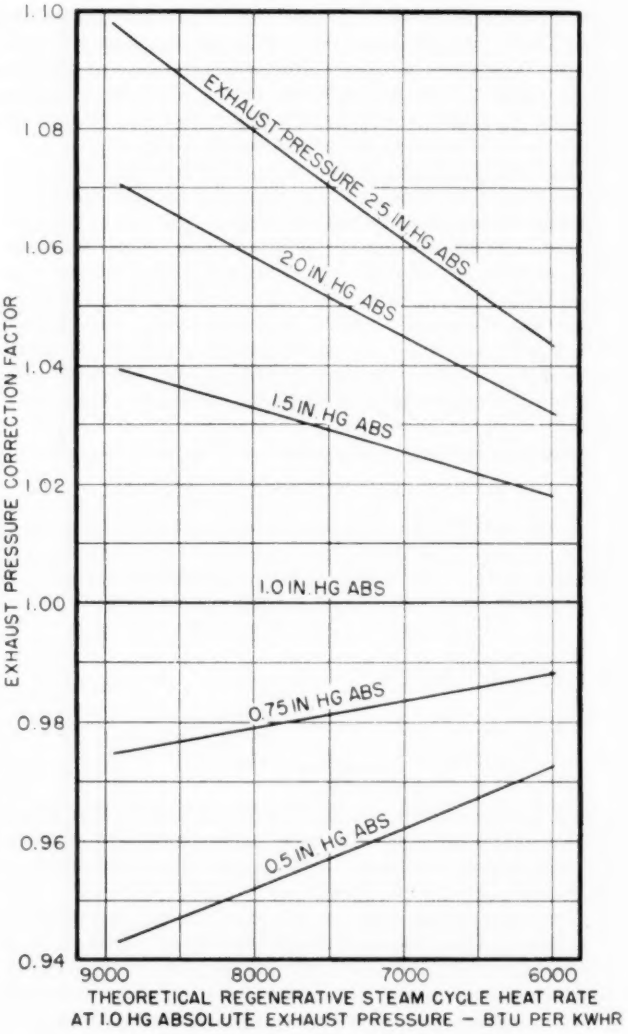

Fig. 5(*b*) Exhaust-Pressure Correction Factor

(To obtain the heat rate, HR_T, at a particular exhaust pressure within the wet-steam region: [1] Read the heat rate, HR_0, from Table 1 or Fig. 5*a* for 1 in. Hg abs exhaust pressure; [2] find the correction factor, F, from Fig. 5*b* corresponding to HR_0 and the new exhaust pressure; [3] multiply HR_0 by F to get HR_T. See revised Fig. 5(*b*) on page 511.)

Exhaust-pressure corrections are based upon the fact that, within the wet-steam region, the theoretical regenerative cycle has Carnot efficiency, from which it follows that, with constant throttle conditions, the heat rejected is proportional to the abso-

[9] A comprehensive paper titled, "The Regenerative Cycle: An Efficiency Basis Having Special Reference to the Number of Feedwater Heating Stages," by H. S. Horsman, was published in the *Journal* and Proceedings of The Institution of Mechanical Engineers, vol. 146, 1941, pp. 5–19. In the foregoing paper, however, feedwater temperature is limited to a maximum of 460 F, corresponding to 467 psia saturation pressure, and hence provides little opportunity to check data given here in Table 1, where final feedwater temperatures may be up to 705 F.

lute temperature of the exhaust. The generation of A Btu of useful work (say 1 kwhr or 3412.75 Btu) requires a heat input of HR_0 (the theoretical heat rate in Btu per kwhr given in Table 1), followed by the rejection of $(HR_0 - A)$ Btu at T_0 exhaust temperature. If the exhaust temperature is reduced by ΔT to T, then additional useful work for the same heat input is obtained, amounting to

$$\frac{\Delta T}{T_0}(HR_0 - A)$$

As the heat rates of the cycle at constant steam conditions, but varying exhaust temperatures, are inversely proportional to the amounts of useful work generated, a heat-rate correction factor F may be obtained from the equation

$$F = \frac{HR_T}{HR_0} = \frac{A}{A + \frac{\Delta T}{T_0}(HR_0 - A)} = \frac{1}{1 + \frac{\Delta T}{T_0}\left(\frac{HR_0}{A} - 1\right)}$$

$$= \frac{T_0}{T_0 + \Delta T\left(\frac{HR_0}{A} - 1\right)}$$

Substituting $T_0 - T$ for ΔT, cycle efficiency η for A/HR_0

$$F = \frac{\eta T_0}{T_0 - T(1 - \eta)} = \frac{538.72\eta}{538.72 - T(1 - \eta)}$$

Where T = new exhaust temperature in absolute degrees F, and $\eta = 3412.75/$(theoretical heat rate) from Table 1, or Fig. 5(*a*). The corrected heat rate, for exhaust pressure other than 1 in. Hg abs, is obtained from the equation

$$HR_T = F \times HR_0$$

Values of F for various exhaust pressures are given in Fig. 5(*b*). The alteration in heat rate, $D = HR_T - HR_0$, to be added to the heat rate found in Table 1, is obtained from the equation

$$D = \frac{HR_0(T - 538.72)(1 - \eta)}{538.72 - T(1 - \eta)}$$

When the value of D is negative, as is the case when the exhaust pressure is less than 1 in. Hg abs, D is to be subtracted from the heat rate given in Table 1.

Possible Application of Data

Two ways in which the heat-rate table might be used are (1) as a comparative standard of power-plant design and operation; and (2) as an aid in estimating plant performance with steam conditions somewhat above the current level.

In recent years, several technical papers have been written proposing this or that standard for use as a bogey for particular plant installations. The percentage ratio of actual to theoretical heat rate for any plant, however, combines inefficiencies both of design and operation. To gage plant operation alone, additional factors must be included in the standard.

These additional factors are required also where power-plant performance is to be estimated. For estimating purposes, modifying factors would be applied to the theoretical heat rate. For instance, turbine efficiency would change the heat rate so much. The use of four instead of an infinite number of heaters would result in an increase in heat rate. Similarly, modifying factors would be required for boiler efficiency, auxiliary power, exhaust pressure, etc. With these factors available, it would be possible to compute operating efficiency and estimate performance exactly.

These modifying factors, however, have not been computed yet, as prior demands on the authors' time by the war effort prevented any further extensive work being done on the study. In addition, it is felt that the factors will be extensive enough to warrant being the subject of a second or companion paper. The method of computing factors has not definitely crystallized but it is viewed as requiring about three steps, as follows:

1 Turbine engine efficiencies would be obtained from a paper by Warren and Knowlton.[10]

2 A number of heat-balance calculations would be made for typical feedwater-heater arrangements[11] using a range of terminal difference and final feedwater temperature, and taking into account condensate- and feedwater-pump efficiency.

3 Power-plant operating data for different steam conditions would be analyzed for as many stations as obtainable, to determine the effect on plant efficiency of boiler performance and auxiliary services.

Data would be tabulated ultimately as "efficiency" factors to show what increase in turbine and plant heat rate was due to each particular item of power-plant heat balance and operation. It is hoped that, with the publication of these theoretical cycle heat rates, others may be encouraged to take a hand in supplying needed performance data, in determining some of the factors, and in making them available to the engineering profession.

In the meantime, the data here presented can be helpful if a certain amount of ingenuity is used. In making estimates, existing plant and turbine-performance data usually will provide sufficient information for calculating approximate modifying factors which in turn may be applied directly or after adjustment to the theoretical heat rate at the steam conditions under investigation. Plant performance can be reported as a percentage of the theoretical figure. By so doing, the advantage one plant has over another through using higher steam pressure and temperature is eliminated from the performance comparison. Undoubtedly, other uses in addition to these two will come to mind.

An example of the relationship between theoretical-cycle and actual plant heat rates is shown in Table 2. Although in the cases cited, plants B and C differ in economy by 700 Btu per kwhr, they are operating almost equally effectively, as indicated by the similarity in plant-design and performance factors. To demonstrate roughly how modifying factors might be applied to theoretical heat rates, Table 2 shows a typical but incomplete breakdown of the over-all factors into a list of items and attendant factors which affect plant performance.

These factors were obtained from turbogenerator heat-balance data and actual plant performance of three different stations. In the normal course of events, the companion paper will contain tables of factors covering a complete pressure-temperature range of steam and feedwater conditions for typical power-plant design based upon available up-to-date information on turbine and station performance. Subsequently, if a marked change in power-plant design occurs, supplementary factors would be published to bring the series again up to date.

Lacking time now to make heat-balance computations and analyze plant records, the authors provide Table 2 solely to illustrate how factors might apply in the cases cited for three different power stations. A discussion of methods used to obtain factors will be incorporated in the companion paper. Items, it is hoped, will be subdivided eventually to indicate the effect on economy of the more detailed phases of plant design and operation. In the meantime, correlations between theoretical cycle and plant heat

[10] "Relative 'Engine Efficiencies' Realizable From Large Modern Steam-Turbine-Generator Units," by G. B. Warren and P. H. Knowlton, Trans. A.S.M.E., vol. 63, 1941, pp. 125–135.

[11] As, for instance, any "standardized" cycles which may be the outcome of the "Preferred Standards for Steam Turbine Generators," proposed Nov. 3, 1938, by the Subcommittee on Standardization of the National Defense Power Committee, and subsequent work thereon instigated by the A.S.M.E.

rates of existing power stations will help engineers in predicting heat rates for somewhat extended throttle conditions.

Other Regenerative Cycles

At least two modifications of the regenerative cycle proposed in recent years merit comment. One suggestion is for moisture extraction in the wet stages, and the other, for isothermal compression of superheated bled steam.

Moisture Extraction. Within the wet-steam region, the theoretical regenerative cycle has Carnot efficiency without requiring 100 per cent moisture withdrawal, as proposed by Dr. W. M. Meijer,[12] since expansion is assumed to take place isentropically. This thoughtful proposal of an integral moisture-withdrawal provision, however, merits serious attention on two practical scores, i.e., (1) moisture causes a definite loss of efficiency in an actual turbine attributable to bucket-impingement shock and supersaturation effect, and (2) the possibility of bucket erosion by moisture in the lower stages appreciably restricts turbine designers in the selection of turbine-throttle conditions.

Moisture withdrawal of 100 per cent might be difficult to attain without occasioning other serious thermodynamic losses. Fortunately, such effectiveness is not essential. For instance, if 12 per cent moisture were deemed the maximum permissible practical limit, and if in any stage not more than 2 to 3 per cent moisture were produced, then it would be necessary to withdraw only 2 to 3 per cent moisture to keep within the 12 per cent limit. Efficiency of withdrawal then need be only 15 to 25 per cent in each stage to permit steam expansion to continue to low exhaust conditions which otherwise might be equivalent to 20 per cent moisture or better. Hence provision for moisture withdrawal at even this low efficiency would be sufficient to overcome present objections on the score of bucket erosion to using high throttle steam pressures without attendant high superheated-steam temperatures. There remains, however, sufficient reason for the present high superheat temperatures, on the grounds of improved cycle efficiency as well as improved turbine efficiency, as compared to what is possible with the saturated-steam cycle.

With the application of superheat, the efficiency of the theoretical regenerative steam cycle does increase although not to the extent of the Carnot cycle. The use of superheat, however, is advantageous, and particularly so where superheated steam is bled for regeneration. Even where an arbitrary restriction is placed on the regenerative cycle that only dry-saturated and wet steam may be bled, the provision of superheated steam to the cycle is still advantageous. Fig. 6 shows the relation of theoretical heat rates versus throttle steam temperature for the two foregoing cycles, namely, regeneration only by saturated and wet steam,[13] and regeneration up to throttle saturation temperature using bled superheated steam. In either case, a reduction in heat rate with increased superheat is noticeable.

Isothermal Compression. While, with the use of superheated steam, the theoretical regenerative-cycle efficiency does increase, it falls below the corresponding Carnot efficiency because it is not a wholly reversible cycle. James F. Field[14] points out that "the ideal engine would therefore require additional elements to compress this superheated bled steam isothermally to the corresponding saturation temperature and pressure before actually mixing with feedwater." This cycle can be studied by means of the tabular-integration method. A typical example, taking into account all auxiliary power usage, showed the cycle to have Carnot efficiency.

The choice of a system for gaging power-plant performance cannot be made arbitrarily. At present, the economy of American power plants is reported in terms of British thermal units per kilowatthour. British plants use a scale of percentage efficiency. In both cases, a plant of high steam conditions would be recorded as having a better economy than one with lower steam conditions. The latter, however, may have been operated more creditably and deserves proper recognition. By relating plant performance to some standard, whether it be the theoretical regenerative-cycle heat rate, the Carnot cycle, or even the basic efficiency,[15] a somewhat better gage can be obtained of what advantage operating personnel is taking of the facilities at their command. Before a universal gage is established, however, engineers will have to agree among themselves as to what standard they will adopt, how closely such a standard needs to match the steam cycles for which it is established, and what allowance will be made for uncontrollable losses attendant on the number of feedwater heaters installed, load distribution, etc.

Conclusion

This paper has described a tabular-integration method for computing theoretical heat rates, and demonstrated its use by presenting a table of heat rates for a theoretical regenerative steam cycle. It is hoped that this table will prove helpful in at least three ways:

[12] "The Extraction of Condensate From Expanding Steam," by Dr. W. M. Meijer, Trans. Institution of Naval Architects, vol. 81, 1939, pp. 36–58; see also *Engineering*, vol. 147, April 7, 1939, p. 147.

[13] A Typical formula for computing the efficiency of wet-steam-regeneration cycle may be found in "High Pressure, Reheating, and Regenerating for Steam Power Plants," by C. F. Hirshfeld and F. O. Ellenwood, Trans. A.S.M.E., vol. 45, 1923, p. 663.

[14] "A Suggested Basis of Comparison for the Efficiency of Steam Turbo-Generators and Steam-Electric Generating Stations," *Journal* of The Institution of Civil Engineers, vol. 10, 1938, pp. 241–253.

[15] The use of basic efficiency was described by Sir Leonard Pearce, C.B.E., D.Sc., in his Thomas Hawksley Lecture on "A Review of Forty Years' Development in Mechanical Engineering Plant for Power Stations," *Journal* of The Institution of Mechanical Engineers, vol. 142, 1940, pp. 305–363. In an appendix under "Operating Efficiency," Sir Leonard discusses the use of some major factors modifying theoretical or basic plant efficiency.

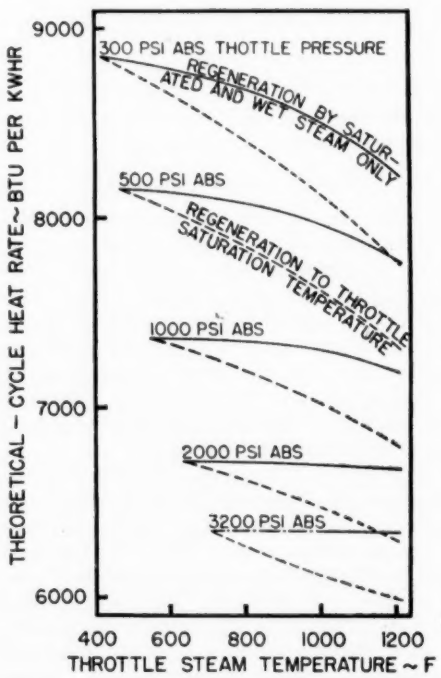

Fig. 6 Reduction in Theoretical Regenerative-Cycle Heat Rates With Increased Superheat in Throttle Steam

1 In comparing design and operation of different power plants operating at different steam conditions.

2 In estimating the approximate performance of power plants.

3 In stimulating others to undertake preparation of tables of modifying factors for use in making exact performance estimates.

Since the tabular-integration method of calculating heat rates can be adapted readily, it is thought that it will prove useful to others in studying new cycles.

Acknowledgment

The authors wish to express their appreciation for the assistance of everyone concerned with the preparation of this paper. We are indebted to Mr. Sabin Crocker whose stimulating interest and hearty encouragement helped on the work; to Mr. Max W. Benjamin and Mr. E. L. Robinson for timely and helpful suggestions; to the General Electric Company for providing the means for computing "key-point" heat rates; and to The Detroit Edison Company for making the study possible.

Appendix

Nomenclature

The following nomenclature is used in the first part of the paper and in the Appendix:

H_1 = enthalpy of throttle steam, Btu per lb
H = enthalpy of steam at any stage in the prime mover, Btu per lb
h = enthalpy of saturated feedwater, corresponding to the pressure in the selected stage of the prime mover, Btu per lb
$F = Nv/5.4$ = energy added by the perfect boiler feed pump, Btu per lb
N = increase in feedwater pressure in the pump, psi
v = specific volume of feedwater at pump suction, cu ft per lb
$h' = h + F$ = enthalpy of feedwater leaving the boiler feed pump after isentropic compression, and entering the next higher heater, Btu per lb
$dh = h - h'$ = heat added in heater by bled steam, Btu per lb of feedwater
$1 + w$ = weight of steam at any turbine stage, lb
= weight of feedwater returning at any stage, lb
dw = weight of steam bled at any turbine stage, lb
e = Naperian logarithmic base

Short Form for Computing Theoretical Regenerative-Cycle Heat Rates

In Table 3, an example is carried through according to the short form for computing theoretical regenerative-cycle heat rates. The conditions stated are throttle-steam pressure = 3200 psia; throttle-steam temperature = 1200 F; throttle-steam entropy = 1.5745.

To complete the computations of Table 3, by short form, the following steps must be taken:

(*a*)

$$1 + w = e^{\sum_{\text{avg}} \frac{dh}{(H-h)}}$$

Add up column (9) = 0.9773690
Convert to logarithmic base 10
$0.9773690 \times 0.43428 = 0.4244518$
Find antilog = 2.6574

(*b*) Heat input to cycle = heat supplied at throttle less heat returned to steam generator

$= (1 + w)(H_1 - h_1)$
$= 2.6574 \times 697.5$ from column (7)
= 1853.54 Btu per lb of steam at condenser

(*c*) Heat rejected to condenser

$= 1(H_e - h_e)$
$= 1 \times 799.14$ Btu from column (7)

(*d*) Heat converted to energy and delivered at electric-generator terminals = item (*b*) — item (*c*) = 1853.54 — 799.14 = 1054.40 Btu

(*e*) Cycle efficiency = output/input = 1054.40/1853.54 = 0.56886

(*f*) Theoretical heat rate = 3412.75/cycle efficiency = 5999 Btu per kwhr.

Computations by Long Form

For the same example, the long form for computing regenerative-cycle heat rates and boiler-feed-pump work is demonstrated in Table 4, which is a continuation of the short form.

To complete the computations by long form, the following steps must be taken:

(*a*) Rankine cycle output = heat at throttle minus heat at exhaust
= first minus last reading, column (2)
= 1569.9 — 846.19
= 723.71 Btu

(*b*) Extra output by regenerative cycle = E = 359.64 Btu

(*c*) Total prime-mover output (*a*) + (*b*) = 1083.35 Btu

(*d*) Less boiler-feed-pump work = 28.99 Btu from column (14)

(*e*) Net regenerative-cycle output = 1054.36 Btu

(*f*) Heat rejected = 799.14 Btu from column (7)

(*g*) Cycle input = 1853.50 Btu

(*h*) Cycle efficiency = 1054.36/1853.50 = 0.56885

(*i*) Theoretical cycle heat rate = 3412.75/0.56885 = 5999 Btu per kwhr

Note: Investigation of the isothermal-compression regenerative cycle, for example, would require the use of the long form of computation. Calculations of the work of compressing bled steam would be handled in a manner similar to that used for the boiler feed pump. Additional columns of calculations, however, would be required to suit the case being studied.

TABLE 2 APPLICATION OF DESIGN AND PERFORMANCE FACTORS TO THEORETICAL REGENERATIVE-CYCLE HEAT RATES FOR THREE POWER PLANTS

		A		B		C	
	Power plant						
	Throttle pressure, psia	396		628		841	
	Throttle temperature, F	693		815		899	
	Exhaust pressure, in. hg	0.89		0.99		0.98	
		Performance factor	Heat rate, Btu per kwhr	Performance factor	Heat rate, Btu per kwhr	Performance factor	Heat rate, Btu per kwhr
1	Theoretical heat rate		8237		7612		7223
2	Engine-efficiency and exhaust-loss factor	0.8130		0.8328		0.8352	
3	Cycle-design factor[a]	0.9523		0.9592		0.9625	
4	Operating efficiency[b]	0.9756		0.9752		0.9668	
5	Mechanical and electrical efficiency	0.9580		0.9698		0.9740	
6	Turbine heat rate, gross output, Item 1 / (Item 2 × item 3 × item 4 × item 5)		11383		10075		9542
7	Auxiliary-power-usage factor	0.9270		0.9585		0.9707	
8	Evaporated make-up factor	0.9977		0.999		0.997	
9	Pipe-radiation-loss factor	0.9888		0.9929		0.993	
10	Soot-blowing and miscellaneous steam-usage factor	0.9918		0.9952		0.996	
11	Steam-generating efficiency	0.8869		0.885		0.881	
12	Plant heat rate, net output, Item 6 / (Item 7 × item 8 × item 9 × item 10 × item 11)		14150		12030		11317
13	Plant design and performance factor	0.582		0.6328		0.6382	

[a] If and when the second stage of this study is developed, Item 3 along with many of the other items undoubtedly will be subdivided into several smaller factors for significant plant losses.

[b] Includes influence on turbine heat rate of (*a*) operation off ME point; (*b*) dirtiness of turbine blading; (*c*) departure from designed heater-terminal difference, etc.

TABLE 3 SHORT FORM FOR COMPUTING THEORETICAL REGENERATIVE-CYCLE HEAT RATES

Example: Throttle-Steam Pressure = 3200 psia; Throttle-Steam Temperature = 1200 F; Throttle-Steam Entropy = 1.5745

Column no.	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
Heading	Throttle and stage pressures, psia P	Enthalpy of throttle and bled steam, Btu per lb H	Enthalpy of feedwater at saturation pressure and temperature, Btu per lb h	Boiler feed pump work, Btu per lb $F = Nv/5.4$	Enthalpy of feedwater at pump discharge, Btu per lb $h' = h + F$	Increase in feedwater enthalpy by bled-steam heating, Btu per lb $dh = h - h'$	Heat given up by bled steam in heating feedwater, Btu per lb $H - h$	Average of two adjacent readings of $(H - h)$	$\frac{dh}{\text{avg } (H - h)}$
Computation instructions	(a) Throttle pressure (b) Pressures corresponding to enthalpy shown in column (3) (c) Condenser pressure	(a) Throttle enthalpy (b) Enthalpy of steam at pressures given in column (1) and at throttle-steam entropy for isentropic expansion	(a) Enthalpy of saturated feedwater. [b] As calculated $(1 + w)$ is the theoretical flow of steam or feedwater past a chosen point in the infinite number of steps or stages of steam expansion and feedwater heating.

Discussion

THEODORE BAUMEISTER.[16] This paper is in many respects a companion piece to that offered by H. S. Horsman[9] before the British Institution in 1942, and cited by the authors. Both papers offer an ideal or theoretical standard of performance for regenerative steam-power-plant cycles.

The questions which the writer raised with reference to Mr. Horsman's paper can similarly be raised in discussion of the current paper. The criterion for judging the real worth of such a paper is in its practical utility. Will it facilitate or help in the solution of design and operating problems on actual steam power plants? If the answer is affirmative then the value of the current paper is demonstrated. If it does not give an affirmative answer then the paper is essentially an academic exercise. The authors imply, in Table 2 and its attendant paragraphs, that much additional work is necessary to accomplish this important affirmative step. Presumably it is the result of their experience that the theoretical heat rates of Table 1 can be used for the comparison of two proposed real alternate cycles. Or better, upon accumulation and correlation of further experience and data, Table 1 may then be used to answer the recurrent question of choice between two real alternate power-plant cycles.

Thus from detailed and accurate calculations the over-all heat rate may have been determined as 11,000 Btu per kwhr of net output, including all allowances for inefficiencies and auxiliaries. The appropriate theoretical heat rate of the idealized cycle might be read from Table 2, as 6945 Btu per kwhr. If the same arrangement of equipment and the same inefficiencies were applicable then some second cycle, which might have a threoretical heat rate of 6759 Btu per kwhr from Table 2, could then be estimated to give an actual over-all thermal performance of

$$11{,}000\,\frac{6759}{6845} = 10{,}860 \text{ Btu per kwhr net output}$$

This procedure, of course, would be a great convenience and reduce the tedium and errors of lengthy heat-balance calculations. Unfortunately, however, the mechanism or engine efficiencies will usually change along with the cyclic values, and the solution is not as convenient as may be anticipated.

In any event, high orders of accuracy are necessary because the power engineer is concerned with the evaluation of savings, i.e., differences in heat rates. These differences are small numbers and unless a high degree of accuracy is otained the answers, because of too few significant figures, cannot be used. The writer therefore would like to inquire if the authors believe that their paper can be so used to give reliable and convenient answers to the following typical questions which arise in the development of a plant cycle:

1 Proposed alternate use of drip pumps, drain coolers, or direct flashing for heater drains.

2 Terminal temperature differences to be used on closed feed heaters.

3 Proper disposition of turbine gland leakage.

4 Make-up evaporator location in the cycle.

5 Thermal advantages of alternate locations of feed pumps in the cycle.

6 Recovery or nonrecovery of heat supplied to generator coolers and lubricating-oil coolers in the feedwater.

7 Electrically driven, steam-driven or internal-combustion-engine-driven plant auxiliaries.

8 Pressure drop between turbine shell and heater.

If the authors believe that the solution of these and similar problems can be expedited by the methods outlined in their paper, then it is the writer's opinion that they should be encouraged to collect and correlate the necessary data for the preparation of the supplementary paper which they recommend.

M. W. BENJAMIN.[17] This contribution to steam-power engineering provides, in Table 1, data which are just as fundamental to the regenerative cycle as are the tables of theoretical steam rates to the Rankine cycle. The practical usefulness of the theoretical heat rates will depend to a large extent upon the successful working out of a second paper to provide the factors necessary for bridging the gap between the hypothetical and the practical. In years past the existence of such information could have saved unknown man-hours of calculation in the planning of new plants and rehabilitation projects.

As applied to the design of new plants, the value of this paper and its proposed companion may be limited henceforth to the investigation of projects outside the range of the standardized turbines now being considered by the industry. Performance figures for standard units will be well known, and calculations will be unnecessary except for minor changes in the cycle. It is doubtful whether the companion paper could provide factors for all such possible refinements. It would be a mistake to assume, however, that the present paper had come too late merely because turbine standardization is now being considered seriously. Until some radically new method of producing electricity is devised, it would seem reasonable to believe that engineers will continue to explore the possibilities of the regenerative cycle. The theoretical heat rates are now established with a high degree of precision, and from this paper one can determine quite easily the order of magnitude of improvement which still is possible. It appears from Fig. 5(*a*) and Table 2, that between good modern practice and the heat rate of an actual plant at the upper limit of this study (3200 psi at 1200 F), there is a margin of at least 1500 to 1700 Btu per kwhr (440 to 500 whr per kwhr).

Figure 5(*a*) also illustrates a point that has been made before, viz., that, as pressures and temperatures are increased, the rate of thermal economy improvement becomes smaller, thus making it more difficult to justify the improved conditions economically.

The authors have indicated, without elaboration, another use for these data in conjunction with the companion paper in establishing reasonable standards of plant operation by means of which it will be possible to estimate the degree of excellence with which a plant is operated. For many years it has been the practice in England to refer to some kind of standard for this purpose whereas in our country the emphasis has been more on designing the plant for economy and ease of operation and then expecting the operating staff to get the utmost in efficiency from the equipment that has been provided. One weakness of this arrangement is that it offers no incentive for careful operation of older plants in competition with newer ones. Perhaps Americans do not require a measuring stick for operating excellence, but for those who see merit in the idea the present paper offers data for determining a basis of comparison of regenerative-cycle plants.

The theoretical heat rates given in Table 1 are the result of a large amount of careful work for which the industry is grateful. The paper may develop into a tool of many uses.

A. A. BROOKS.[18] The writer believes that the requirement $dh(H - h)$ be constant, could be eliminated by using a sufficiently large number of steps with possibly less labor involved than recalculation to get equal steps.

No practical purpose is served for limiting the regeneration to saturated steam only. The use of superheated steam is simply a question of proportioning the heaters intelligently. It is doubtful if, in actual practice, it is feasible to get higher than the saturation temperature of the steam in the heater, and it would be interesting to see how figures on this basis compare with the author's figures. It is not clear whether the curves in Fig. 6, are given on this basis or on the basis of a perfect counterflow system for superheated steam.

That the cycle efficiency of better than 50 per cent for steam pressures has already been approached in actual practice is extremely interesting.

W. W. Dulmage.[19] In Table 2 of their paper Messrs. Selvey and Knowlton have applied design and performance factors for relating the operating results from three actual plants to the respective theoretical regenerative-cycle heat rates. Since further information of the same sort is needed for other plant cycles, the writer is pleased to furnish the following description of the cycle for River Rouge No. 1 power plant of the Ford Motor Co. with operating results for the year 1943.

In that power plant there are three steeple-compound condensing turbine-generators of 110,000-kw capacity each, and one 15,000-kw noncondensing turbine-generator. One of the large units operates on the reheating-regenerative cycle using throttle steam at 1200 psi 725 F and employing live-steam reheat to about 570 F at the crossover. The other two large units operate on the regenerative cycle without reheat, using throttle steam at 1200 psig 900 F. The noncondensing machine operates on throttle steam at 1200 psig 900 F and exhausts to large process evaporators at 250 psig. Since the paper deals only with the regenerative cycle the following remarks apply only to the two large units operating on that cycle, and are based on over-all plant data for the calendar year 1943 as adjusted to represent the performance of those two generating units. Several complications arise when attempting to allocate properly between the different cycles existing in the power plant such items, among others, as auxiliary power and soot-blowing steam. Therefore several of the factors of the authors' Table 2 have been grouped together in estimating the performance factors presented in Table 5 for the straight regenerative units. The cycle diagram for one of these units is given in Fig. 7 while the turbogenerator heat-rate curve obtained from tests[20] and corrected to standard conditions of throttle pressure and temperature and exhaust pressure is shown in Fig. 8.

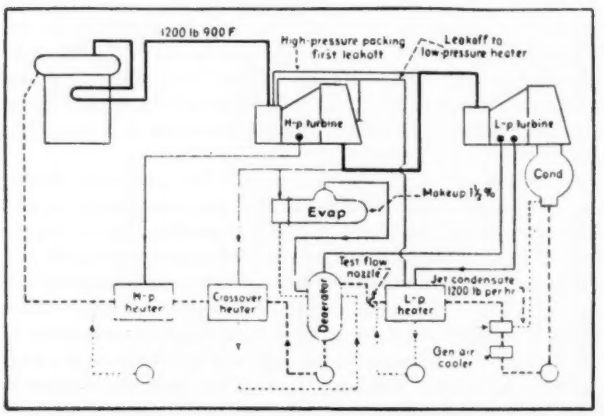

Fig. 7 Flow Diagram for Two 110,000 Kw Steeple-Compound Turbine-Generators Operating on 1200 Psig 900 F Regenerative Cycle in River Rouge No. 1 Power Plant of Ford Motor Co.

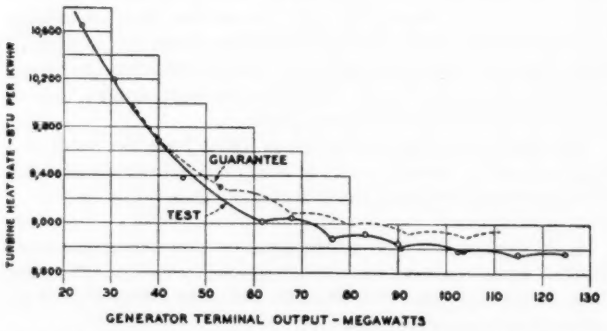

Fig. 8 Guarantee and Test Heat Rates for 110,000 Kw Steeple-Compound Turbine Generators Operating on 1200 Psig and 900 F Regenerative Cycle in River Rouge No. 1 Power Plant of Ford Motor Co.

Average values of the pertinent data for the year 1943 are as follows:

(1)	Over-all station heat rate, Btu per net kwhr	11,220
(2)	Over-all station coal rate, lb dry coal per kwhr	0.795
(3)	Heat value of coal, Btu per lb dry coal	14,107
(4)	Over-all boiler-room efficiency, per cent	87.1
(5)	Feedwater make-up, per cent	2.4
(6)	Auxiliary power, per cent of gross generation	4.5
(7)	Average load on regenerative units, kw each	52,600

TABLE 5 APPLICATION OF DESIGN AND PERFORMANCE FACTORS TO THEORETICAL REGENERATIVE-CYCLE HEAT RATES FOR RIVER ROUGE NO. 1 POWER PLANT OF FORD MOTOR CO.

		Factor	Btu per kwhr
(1)	Theoretical heat rate		6935
(2)	Engine-efficiency and exhaust-loss factor		
(3)	Cycle design factor		
(4)	Operating efficiency[a]	0.7497	
(5)	Mechanical and electrical efficiency		
(6)	Turbine heat rate, gross output (at average load)[a]		9250
(7)	Auxiliary-power usage factor		
(8)	Evaporated make-up factor		
(9)	Pipe-radiation-loss factor	0.9465	
(10)	Soot-blowing and miscellaneous-steam-usage factor		
(11)	Steam-generating efficiency	0.871	
(12)	Plant heat rate, net output		11,220
(13)	Plant-design and performance factor	0.6181	

[a] Average load was less than 50 per cent of rated capacity, which results in low value of item called Operating Efficiency in Table 2 of Selvey-Knowlton paper.

G. M. Dusinberre.[21] The authors ask for an explanation of the curvature of line A-B in Fig. 2(b). This line, by its deviation from the vertical, reflects the departure from reversibility in the feed-heating operation. This deviation is greatest at the top. Under the assumption of an infinite number of feed heaters, we are at this point using steam at 1200 F to heat water at 705 F, evidently with great thermal irreversibility. The situation is also apparent from the fourth line of Tables 3 and 4. Column 12 shows that we have extracted about 10 per cent of the throttle steam and column 2 shows that the through steam has done only 11 Btu of work per lb. This is not much different from heating the feed irreversibly in the boiler.

In their Appendix the authors state that a long form of computation would be necessary for investigation of the isothermal-compression regenerative cycle. This is true as regards pump and compressor work. But for net work or net heat rate, the calculations would be extremely simple. Such a cycle could ideally be made entirely reversible, internally, and the heat rejected per pound of throttle steam would be simply the tempera-

[20] See "Performance Test at Ford Motor Co.," by W. W. Dulmage and C. J. Walker, *Power*, vol. 85, July, 1941, p. 72.

[21] Assistant Professor of Mechanical Engineering, Virginia Polytechnic Institute, Blacksburg, Va. Now on duty at U. S. Naval Academy, Annapolis, Md. Mem. A.S.M.E.

ture at rejection times the change of entropy during heat supply. Thus, the "short-cut" formula, shown above Fig. 3 of the paper, would be precisely correct for this cycle.

The writer was impressed with the suggestion by A. A. Markson of an analysis based on a divided cycle and has prepared a brief outline of the form which the proposed tables might take. It is true that the work done by the saturated cycle can be obtained by multiplying its Carnot efficiency by the heat rejected by the superheat cycle, but there are certain advantages in having additional tables instead (Tables 6 and 7 of this discussion).

TABLE 6 SUPERHEAT-REGENERATIVE DATA

p	t	800	1000	1200

	q'	316.7	500.5	635.5
	w	45.1	145.1	242.8
	y	0.570	0.531	0.524
	p_s	1343	385.8	141.0
(385.8)	q		1102.8	
	q'		318.5	
	w		337.1	
	y		0.786	
	p_s		13.0	

TABLE 7 SATURATED-REGENERATIVE DATA

p	tf	90	(79.03)	70	50
1400	w	273.0		283.9	294.9
	y	0.445		0.432	0.420
(1343)	w		282.0		
	y		0.446		
(385.8)	w		314.6		
	y		0.624		
(141.0)	w		293.0		
	y		0.720		
14	w	173.7		202.7	231.8
	y	0.881		0.861	0.842
(13.0)	w		185.2		
	y		0.875		

p—throttle (or reheat) pressure, psia
t—temperature at throttle (or after reheating), F
q—heat supplied to throttle steam, Btu/lb
q'—heat supplied to reheated steam, Btu/lb
w—work (net, turbine less feed pump) per lb steam supplied, Btu/lb
y—ratio of through steam to throttle steam
p_s—pressure at saturation, for isentropic expansion, psia
tf—condenser (or cooling water) temperature, F

The method of calculation was similar to the authors' short form except that no effort was made to keep the feed-heating increments equal as long as they were sufficiently small. The use of the tables may be illustrated by an example:

Throttle steam 3200 psia, 1200 F, lowest temperature 79.03 F (this temperature is chosen to agree with the authors' 1 in. Hg).

	Steam	Heat	Work
From superheat-regenerative Table 5	1.000	697.5	242.8
To saturated-regenerative at 141 psia	0.524		
Interpolating for 141 and 79.03			
Work, 293.0 × 0.524			153.5
Steam to condenser 0.720 × 0.524	0.377		
Totals		697.5	396.3

Heat rate 3413 × 697.5/396.3 = 6000 Btu per kwhr (5999 by authors)
Throttle steam/through steam 1/0.377 = 2.65 (2.6574 by authors)

So far, we have little that could not have been obtained more readily from the authors' tables. But what about reheat? Is it not possible and desirable to set an ideal standard for regenerative plants which is also applicable when reheat is employed?

The advantage of reheat lies in the reduction of moisture in the low-pressure stages of the turbine, rather than in any striking gain in ideal-cycle efficiency. Since this is the case, it would be logical to base a "standard" cycle on reheat at the pressure where the throttle isentropic reaches the saturation line. This would mean that reheat actually began with a moderate amount of superheat, which is not out of line with current practice.

If such a standard should be acceptable, the analysis of the ideal cycle can be made very readily with Tables 6 and 7, for example: Throttle steam 3200 psia, 1000 F, reheat to 1000 F, lowest temperature 79.03 F.

	Steam	Heat	Work
From superheat regenerative Table 5	1.000	562.5	145.1
To reheat regenerative at 385.8 psia	0.531		
Heat (use q') 318.5 × 0.531		169.1	
Work 337.1 × 0.531			179.0
Steam 0.786 × 0.531	0.417		
To saturated regenerative at 13.0 psia			
Work 185.2 × .417			77.2
Steam to condenser 0.875 × 0.417	0.365		
Totals		731.6	401.3

Heat rate 3413 × 731.6/401.2 = 6220 Btu per kwhr

This division of the cycle should lend itself better to the application of performance factors. The efficiency of a turbine, operating only in the superheat region, and of another operating only saturated, can be set forth in a more representative way than the efficiency of a turbine operating in both regions.

The saturated-regenerative Table 7, based on temperatures, can be used for condensation temperature or, as suggested by P. H. Hardie, for cooling-water temperature. This latter seems more logical in a study of purely ideal performance.

M. D. ENGLE.[22] A standard of measurement is a fundamental requirement of engineering progress. Many business enterprises having to do with the sale of a service have been really unsuccessful until a suitable device was developed to measure the service supplied. The electrical industry was greatly hindered in development until a suitable kilowatthour meter was developed. The hot-water district-heating business has never fully developed and one of the principal reasons for this lack of success is the nonexistence of a suitable device for measuring the service supplied. On the other hand, the district steam-heat business, having suitable measuring devices, is growing quite rapidly.

So it is in the business of designing and constructing steam-electric generating stations. While it is true that big advances have been made in design, we have long needed a suitable standard of measurement of the success of our design.

The net Btu per kwhr performance of a station is a useful factor but it does not really show how closely we have approached the ideal performance for the steam conditions and cycle adopted.

The data in this paper will be very useful to powerplant design engineers in calculating just how good a job they have done.

Furthermore, the careful analysis of the losses, as shown in Table 2, will more clearly focus the attention of the designers upon the particular items to be investigated for possible improvement.

We have been so much interested in the problem of keeping the turbine blades clean that probably very few have given much thought to the loss in station economy due to the blade deposits. Maybe such an analysis will show that we are justified in spending much more money in reducing the amount of deposit.

Likewise such an analysis will focus our attention upon the loss due to excessive auxiliary power usage, evaporated make-up losses due to avoidable steam leaks and condenser leakage, and the losses due to so-called "soot-blowing." (In this day and age that term should really be changed to "ash and slag" blowing.)

The operating engineers should also become more fully acquainted with such a detailed analysis of the possibilities of, and losses in, the stations which they are operating. They have of course studied station losses for years but, when they have the theoretical possibilities of their plant in mind, a more careful analysis of the losses will quite often pay handsome dividends.

[22] Assistant Superintendent of Engineering, Boston Edison Co., Boston, Mass. Mem. A.S.M.E.

The writer feels that both design and operating engineers will benefit greatly by the work done by the authors and is sure that they will co-operate by supplying the data which are needed to complete the study.

P. H. HARDIE.[23] The table of theoretical regenerative steam-cycle heat rates presented by the authors is a valuable contribution. The authors' suggested method of using this table as a basis for appraising plant performance should be adopted as an American standard, with possibly a slight modification which will be discussed later.

There are several points relating to the application of this table worth careful consideration. For example, the authors have proposed using the throttle steam conditions for the upper limit of the cycle instead of drum or superheater-outlet steam conditions. From a practical standpoint this would seem to be the best choice. However, for the lower boundary of the cycle, it would seem preferable to use the saturation pressure corresponding to the temperature of the condensing water, rather than the turbine exhaust pressure. This pressure is the theoretical minimum and will be more nearly constant for all units in a plant. Furthermore, it will not be affected by the differences in design, load, and cleanliness factor of the different condensers. These factors should properly appear in the plant-design-and-performance factor. If the authors agree to this change it would be helpful to have the data, presented in Fig. 5(*b*), replotted for condensing-water temperature.

No method has been proposed by the authors for computing the theoretical regeneration-steam-cycle heat rate of a plant having units operating at two or more pressures or temperatures. The theoretical heat rates of the different systems would have to be weight-averaged, but what is the proper basis of weighting? Boiler-steam output would not be satisfactory because of the differences in the enthalpy of the steam and/or the feedwater. Generator output would also be unsatisfactory because some of the steam may be throttled from the high-pressure system to the low-pressure system. Therefore fuel input would seem to be the only satisfactory basis for weight-averaging the theoretical regenerative-steam-cycle heat rates to determine the average for such plants.

The authors have shown good judgment in refraining from proposing the use of their table of the theoretical heat rates for appraising turbine performance. Barnard and Ellenwood's method of computing the ideal regenerative-cycle heat rates, based upon the actual number of heaters, is a more equitable standard for turbines. However when appraising the entire plant, the authors' tabular values for an infinite number of heaters should be used.

M. L. IRELAND, JR.[24] It would appear that the usefulness of the table of theoretical regenerative-steam-cycle heat rates presented in this paper can be increased by further comparison with the results obtained by "short-cut" formulas.

In the first place the comparison shown in Fig. 3 may give a somewhat exaggerated impression of the magnitude of error involved in the stated short-cut formula. When this error is expressed as a percentage correction and plotted against throttle temperature as shown in Fig. 9 of this discussion, it becomes apparent that up to about 2300 lb pressure, the correction is practically constant for a particular temperature, varying from about 0.2 per cent for 800 F to 1.2 per cent for 1200 F.

The necessity for a carefully prepared table such as is presented by the authors is particularly evident when considering steam temperatures above 1000 F and pressures over 2300 lb. However, the use of this table as a reference standard for actual power-plant cycles is subject to the basic disadvantage that actual cycles do not employ complete regeneration. A criterion based on actual or designed final feedwater temperature appears to be necessary. The short-cut formula, suitably corrected for additional feed-pump work done above the saturation pressure, corresponding to the final feed temperature, does supply such a criterion, but it is admittedly approximate. On the other hand, the computation of accurate results for individual cases by the authors' tabular integration method is quite laborious.

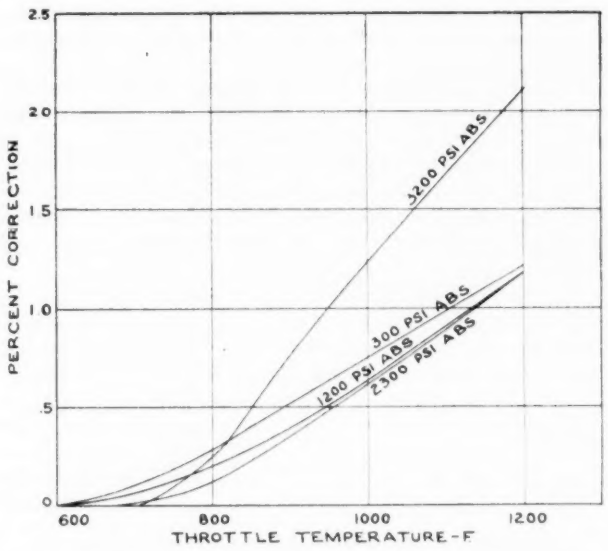

FIG. 9 CORRECTION TO APPROXIMATE REGENERATIVE-STEAM-CYCLE HEAT RATES OBTAINED BY "SHORT-CUT" FORMULA

It is understood that the authors intend to prepare a companion paper in which many such factors will be considered; however, in the meantime it would be helpful if the authors can suggest a means to make further corrections to the short-cut formula for computing heat rates of partial-regeneration cycles. It has occurred to this writer that, since the errors of the short-cut method are associated with regeneration by superheated steam, it might be satisfactory to use the correction curves of Fig. 9, at the pressure and temperature on the turbine-expansion line which correspond to the final feed temperature and saturation pressure.

A. A. MARKSON.[25] One who estimates the value of this paper by its literal applicability to design problems may be disappointed, but the student of such matters will find in it exactly what he needs. The cycle chosen by the authors is of high conceptual usefulness. It is defined incompletely in the paper despite the careful assumptions given. The additional statement that nowhere in such a cycle is there a degradation of energy which is not inherent in the cycle itself would complete the definition, as it would include frictional pressure drops, supersaturation, etc.

The authors have wisely chosen to represent this cycle in tabular form, giving efficiencies correlated with different throttle conditions and a constant condensing pressure. The writer believes that a conceptually more logical method of constructing such tables might be of interest. Inasmuch as the saturated region has Carnot efficiency, there is at once an alternate method of

[23] Engineer, Sanderson & Porter, New York, N. Y. Mem. A.S.M.E.

[24] Newport News Shipbuilding and Dry Dock Company, Newport News, Va. Mem. A.S.M.E.

[25] Hagan Corporation, Pittsburgh, Pa. Mem. A.S.M.E.

tabulation which eliminates the necessity of assuming a constant condenser pressure.

Starting with 1 lb of throttle steam as the basis, using throttle pressure and temperature as the main tabular entries, the efficiencies could be tabulated for the superheated expansion zone alone. The pressure at which the isentropic expansion crosses the saturation line is also tabulated. This completes the skeleton of the tables, but for convenience, the weight ratio passing to the saturated zone might be given. To use these tables to any saturated back pressure whatever, the user simply calculates the Carnot efficiency of his saturated cycle and makes a simple weighted average of this and the superheated cycle. This would eliminate the necessity for the exhaust-pressure corrections used by the authors, thus gaining considerable simplicity of concept.

The writer closes by suggesting that performance figures, such as shown in Fig. 5(*a*), be referred to as the "thermodynamic merit" of the cycle to avoid possibility of misunderstanding. Thus an actual cycle having a certain heat rate could be assigned an efficiency analogous to Rankine efficiency on the basis of the "thermodynamic merit" figure.

C. A. MEYER.[26] It appears to the writer that a simpler and more accurate definition for the theoretical regenerative-steam-cycle heat rate can be obtained by utilizing the well-known concept of available energy.

In any cycle in which heat (dQ) is added at variable temperature T (deg abs) and rejected at constant temperature T_e (deg abs), the maximum work obtainable (W_M) is given by

$$W_M = \int_{T_1}^{T_2} dQ \left(\frac{T - T_e}{T}\right) = Q_{1-2} - T_e \int_{T_1}^{T_2} \frac{dQ}{T} = Q_{1-2} - T_e(S_2 - S_1) \quad \ldots\ldots [1]$$

At constant pressure, the heat added is equal to the enthalpy rise

$$Q_{1-2} = h_2 - h_1$$

so that

$$W_M = (h_2 - T_e S_2) - (h_1 - T_e S_1) = A_2 - A_1 \quad \ldots\ldots [2]$$

where $A = h - T_e S$ is the total available energy measured above an arbitrary state point. The available energy at any state point is obtained as the difference between the value of A at the given state point and the value of A at the state point which we regard as having zero availability (atmospheric temperature and pressure). The relation Equation [2] is quite general and could have been written directly.

The maximum thermal efficiency of the regenerative cycle is then

$$\eta_M = \frac{(h_t - T_e S_t) - (h_f - T_e S_f)}{h_t - h_f} = 1 - \frac{T_e(S_t - S_f)}{h_t - h_f} \quad \ldots\ldots [3]$$

The theoretical heat rate is then

$$THR = \frac{3412.75(h_t - h_f)}{h_t - h_f - T_e(S_t - S_f)} \quad \ldots\ldots [4]$$

where h_t, S_t = throttle enthalpy and entropy, respectively
h_f, S_f = feedwater enthalpy and entropy, respectively
T_e = absolute temperature of cooling water

Relation, Equation [4], has been labeled "inaccurate" in the paper for reasons which are not clearly stated. However, Equation [4] gives the correct heat rate of the ideal cycle, defined by the four specifications given in the paper (perfect processes allowing for required pump work).

It is of interest to show that the theoretical heat rate of any cycle can be obtained in a similar manner. As an example, the efficiency of the Rankine cycle is easily written as

$$\eta_R = \frac{A_t - A_f}{h_t - h_f} = \frac{(h_t - T_e S_t) - (h_f - T_e S_f)}{h_t - h_f} \quad \ldots\ldots [5]$$

Since

$$T_e(S_2 - S_c) = h_2 - h_c \qquad S_2 = S_t$$
$$S_c = S_f \quad \text{and} \quad P = h_f - h_c$$

where P = pump work
h_c, S_c = enthalpy and entropy of condensate
h_2, S_2 = enthalpy and entropy at turbine exhaust

Equation [5] becomes the well-known expression for Rankine-cycle efficiency

$$\eta_R = \frac{h_t - h_2 - P}{h_t - h_c - P} \quad \ldots\ldots [6]$$

Returning to the regenerative cycle, a further point of interest is that factors correcting for the various inefficiencies in actual cycles can easily be defined. For instance by setting down the loss of available energy in an extraction turbine, a suitable correction factor for the inefficiency of the turbine can be obtained. The loss of available energy in a single extraction turbine is written as

$$L = G_t A_t - G_1 A_1 - G_e A_e - W$$

where L = loss of available energy in turbine
W = useful work output
$= G_t(h_t - h_1) + (G_t - G_1)(h_1 - h_e)$
G = flow
A = available energy $= h - T_e S$

Subscripts t, 1, e refer to throttle, bleed point, and exhaust, respectively.

The cycle efficiency (for losses in the turbine only) then becomes

$$\eta = \eta_M \times C_t = \left(\frac{A_t - A_f}{h_t - h_f}\right) \times \left(1 - \frac{L}{A_t - A_f}\right)$$

where $C_t = \left(1 - \dfrac{L}{A_t - A_f}\right)$ = turbine efficiency factor

Similar correction factors for terminal difference, mixing and pressure losses are easily obtainable from the losses in available energy due to these causes.

ERNEST L. ROBINSON.[27] Just 20 years ago the writer presented a chart showing the efficiencies of the theoretical extraction cycle in comparison with efficiencies obtainable with the Rankine cycle.[28] This was a small-scale diagram outlining in a general way the possibilities of cycle improvement. This diagram was extended to a temperature of 700 F and a pressure of 1000 psia, limits which were then thought to represent the fringes of possibility.

The calculations on which these efficiencies were obtained were based upon the Goodenough chart of 1917. Although we did not then know it, the Goodenough steam table at that time was an

excellent steam table. All circumstances considered, the efficiencies then given corresponded remarkably well with the heat rates given in this paper on the basis of present-day steam tables up to the values then used.

Ever since the steam tables have gone through the process of refinement and improvement to which they have been subjected during the past 20 years, the writer has felt that theoretical heat rates for the extraction cycle should be determined with the same degree of precision as the theoretical water rates for the Rankine cycle. This has never been done until the authors undertook the task a couple of years ago with the result which is now presented.

The authors have suggested certain further steps toward the analysis of station performance. The writer would like to mention one or two other investigations into the nature of steam which might well be undertaken.

The question of reheat factors has never been satisfactorily cleared up. Three important contributions on the subject appeared several years ago, one in England and two in this country. The excellent British article by Dr. D. M. Smith[29] was based upon an unjustified use of the moisture correction, and another paper by Dr. R. B. Smith[30] was based upon certain analytical assumptions. The writer would prefer to see reheat factors based strictly upon the steam table without any analytic assumptions. Such an attempt was made by Prof. C. G. Thatcher.[31] However, the writer's attempt to apply Professor Thatcher's results differed by as much as 1 per cent in turbine performance from Professor Thatcher's application of his own results. Without being completely in the dark as to the reasons for this uncertainty, it is evident that there is still a job to be done in the matter of reheat factors.

The evaluation of reheating effects in connection with the extraction cycle requires determination of the weight flow at various stages in the turbine and heat rates corresponding to actual stage efficiencies. The writer previously charted these quantities for expansion lines at 70 and 80 per cent efficiency.[32] Professor Thatcher's reheat factors were based on 85 per cent stage efficiency from which suitable correction to neighboring efficiencies may be made. A table of heat rates for a theoretical extraction cycle with 85 per cent stage efficiency would be a welcome contribution.

In addition to the heat rates to 1 in. Hg abs back pressure, it is advantageous for a number of reasons to know the weight flow at any point in the course of the expansion through the turbine. A knowledge of the weight flow is necessary for the proportioning of the areas of cross section of the many successive passages throughout the turbine. This is particularly true of the extraction cycle where the steam entering the throttle is likely to be in the order of 50 to 100 per cent more than what enters the condenser. This is the quantity $(1 + w)$ which appears throughout the formulas and tables in the paper. Mollier charts for the weight flow per pound of steam at 1 in. Hg abs back pressure were given in the writer's article[31] for expansion lines of 70 and 80 per cent efficiency. Under modern conditions, a chart for 85 per cent efficiency would be more useful.

A further advantage of the weight-flow data lies in the ability to determine over-all performance between any two levels of pressure without resorting to superheat, pressure, or vacuum corrections. The vacuum corrections given in the paper are good as long as the expansion ends in the wet region. However, if one wishes to know the performance of the high-pressure element of a cross-compound machine, it may be determined directly when the weight flows entering and leaving are known.

Data of this sort automatically include the evaluation of the reheating effect and indicate the energy actually available from the steam when expanding at a definite stage efficiency. Of course, in any case there must be suitable corrections for the deviation from an infinite number of turbine stages and points of extraction.

However, when weight-flow data are available, one may readily determine the heat rate and corresponding thermal efficiency for any particular initial steam conditions and back pressure. It is then approximately correct to assume a linear relation between the thermal efficiency and the stage efficiency. Thus, knowing the thermal efficiency for 85 and 100 per cent stage efficiencies, it may readily be determined for any stage efficiency between 80 and 90 per cent. Of course, the linear assumption could be avoided by preparing data at both 80 and 90 per cent as well as for 100 per cent. With such a line drawn for the steam conditions in question, it is as easy to determine the internal efficiency corresponding to a test result as it is to determine the expected performance corresponding to the internal efficiency of a design.

The writer believes this procedure to be one of the best methods, if not indeed the best, of taking complete account of the influence of the steam conditions on the turbine performance. (It does not deal with stage design.) Beyond this point the analysis of station performance might well follow the lines outlined by the authors.

J. Kenneth Salisbury.[33] In most studies of the regenerative cycle, the ultimate objective is to simplify the evaluation of power-plant turbine cycles, and to facilitate the comparison, on an extraction basis, of different steam conditions used with a given heater arrangement. At least two methods of approach are possible.

One is exemplified by the material presented by the present authors. They use as a basis the best possible heat rate which can be obtained in a conventional steam power plant, namely, the heat rate of a turbine having 100 per cent efficiency (and an isentropic expansion line) and heating its own feedwater in an infinite number of heaters to the saturation enthalpy corresponding to throttle pressure. Such a heat rate, when divided by the turbine-generator efficiency, yields the turbine-cycle heat rate, if a correction is made to a finite number of heaters operating at the desired final feedwater temperature, and "cycle corrections," etc., are neglected.

A second method of approach is that used by the writer in a paper presented before the A.S.M.E. in 1941.[34] In this method the actual nonextraction heat rate (including the actual turbine-generator efficiency) is used as a starting point. To this nonextraction heat rate is applied again factor $(1 - PG)$, which depends upon such parameters as the number of heaters used, the steam conditions, and the feedwater temperature. A small additional correction is required to obtain the actual heat rate because of departures of the actual cycle from the assumed cycle (a series of equally spaced contact heaters, each having no pressure drop in the extraction line, and no terminal difference).

Neither of the two general methods can, in a simple straightforward manner, take care of all of the combinations and permutations which can be conceived by power-plant designers. It is necessary therefore that certain "cycle-correction" factors be applied for either method to take care of departures from the standard cycles. Such correction factors should meet the following requirements:

1 There should be a minimum number of corrections, for ease in handling.

2 The cycle corrections should be clearly defined and arranged so as to be easily applied to heat rates determined by test of operating units, thus greatly reducing the uncertainties and drudgery now involved in correction to standard conditions of such tests.

3 The corrections should, when possible, be independent of each other so as to permit isolation of the various losses and independent appraisal of various features of the cycle.

4 The corrections should, of course, be accurate, relative to the over-all heat rate, but since they are small, considerable tolerance may be allowed in the corrections themselves.

The writer's original conception of the problem was that, as a first step, a method should be devised which would properly consider the major variables, such as the following:

1 Number of heaters
2 Feedwater temperature
3 Operating steam conditions
4 Turbine efficiency.

This was accomplished in the original paper.[34] It was considered that the second step should be calculation of a set of correction factors, the function of which would be to increase the accuracy of the calculations made using the first set of data but which, in the meantime, could be estimated from experience. The entire analysis to be covered in the second step would be devoted to the accurate determination of the 1 to $1^1/_2$ per cent (total) correction to the heat rate found using the original data.

The present authors have embarked on a similar task by tabulating the heat rates for theoretical cycles at the optimum feedwater temperature (that is, saturation) for an infinite number of heaters. These heat rates are listed for intervals which are closer than required for accurate interpolation, but which are desirable for convenience in use with the present steam tables. The next step in the analysis, that is, corrections to these tabulated heat rates for cycles having a finite number of heaters at various final feedwater temperatures other than the optimum for an infinite number of heaters, will no doubt eventuate to be closely related to those given in the references cited.[34]

The necessary work has been completed, and will be published, on a method of correcting heat rates from the original somewhat idealized basis to the actual cycle.[35] All of these correction factors should be adaptable, with little change, to the present authors' data, with the exception of the boiler-feed-pump correction. An additional correction will, however, be required to correct the authors' state line (an isentropic line) to the actual case, that is, a state line having the applicable efficiency.

The corrections which have been analyzed by the writer are for the following:

1 Heater terminal difference.
2 Pressure drop in the extraction piping.
3 Flashing of one or more heaters to lower heaters with or without drip coolers, of any terminal difference.
4 Distribution of heaters.
5 Evaporators in cycle.
6 Heat-recovery apparatus in cycle.
7 Boiler-feed-pump loss.

(Suggestions are solicited as to other correction factors which might be required in heat-balance calculation.)

The present authors have used an isentropic state line which is never encountered in actual practice. It has, however, the merit of being easily and precisely defined, and of having the absolute support of classicism. The gain due to feedwater heating (the heat rate is not relevant, at the moment—only the gain) depends upon an average value of $(H - h)$, which was integrated essentially graphically by the present authors and analytically by the writer.[34] Since $(H - h)$ at a given extraction pressure or value of h depends only upon the location of the state line, the gain which is obtained by feedwater heating is a function both of the turbine efficiency and the assumed curvature, for given steam conditions. In obtaining actual heat rates from the authors' theoretical heat rates, an additional correction will therefore be required for these items. The correction may be from 0.5 to 1 per cent. This difference in state line assumption, plus the difference in the assumption relative to the boiler-feed-pump work, prevents valid cross checks between the authors' work and the writer's work. Making estimates of the effect of the foregoing items, it is, however, possible to arrive at reasonably close checks between the two sets of data.

A correction will have to be provided by the present authors for the use of a single boiler feed pump (or two boiler feed pumps) instead of the infinite number of pumps which have been used in their study. It is believed that the authors' data, as presented, properly charge the boiler-feed-pump loss for an infinite number of pumps having 100 per cent hydraulic efficiency, in that the power required to run the pumps is deducted from the main output, and the increase in enthalpy realized from the pumps is credited as heat. The data presented in the paper do not, without amplification, readily permit taking into account the effect of using a finite number of pumps, nor are the effects of extra pumping pressure and pump efficiency readily evaluated.

The writer evaluated the expression

$$\left(\frac{\text{P.W.}_{\infty}}{\text{P.W.}_{1}}\right)_{\text{1lb}} = \frac{\int_0^{P_1} V dP}{V_0(P_1 - P_0)}$$

(which neglects the small compressibility effect) to obtain an approximation of the power when using an infinite number of pumps

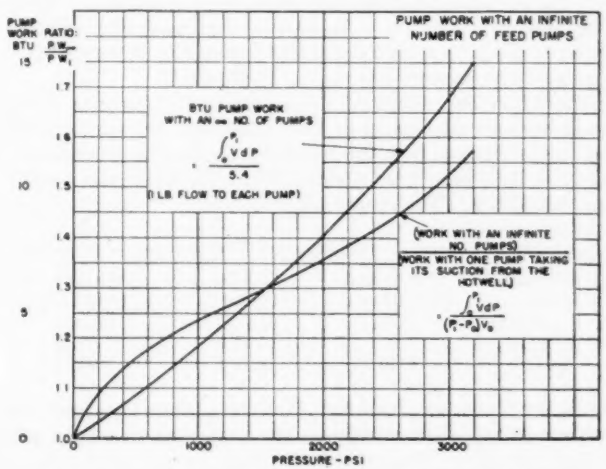

FIG. 10 PUMP WORK WITH AN INFINITE NUMBER OF PUMPS

[35] A few of the results of this work appear in vol. 2 of "Marine Engineering," Chapter 1, on "Heat Engineering and Thermodynamics," to be published by The Society of Naval Architects and Marine Engineers, New York, N. Y., 1944.

as compared with one hypothetical pump taking water from the hot well. The results, which are approximate only, are shown in Fig. 8 of this discussion, for equal flow to all pumps.

To obtain the true pump work included in the authors' heat rates with an infinite number of pumps, the expression used would have to include a term describing the flow to each infinitesimal pump

$$\left(\frac{\text{P.W.}_{\infty}}{\text{P.W.}_{1}}\right)_{(1+w)\text{ lb}} = \frac{\int_0^{P_1}(1+w)\ V dP}{(1+w)_t V_0(P_1 - P_0)}$$

where $(1 + w) = f(P$, etc.)
and $(1 + w)_t$ = throttle flow (= flow to pump when all drips are cascaded to hot well)

It may be found expedient in many cases to remove the loss due to boiler-feed-pump work so that, until corrections are available, the authors' theoretical heat rates will be of maximum usefulness. These data are apparently all available from the calculations made in obtaining the heat rates. Could the authors therefore undertake to present in their closure the boiler-feed-pump loss in some form such as the ratio just given, or in any other more suitable way?

A. H. SHAPIRO.[36] The exhaust-temperature correction for cycles supplied with wet steam can be derived directly and simply from the equations for the cycle efficiency, namely

$$\eta_0 = (T_1 - T_0)/T_1$$

and

$$\eta_T = (T_1 - T)/T_1$$

where η_0 and η_T are the thermal efficiencies for the throttle temperature T_1 and for exhaust temperatures T_0 and T, respectively. The ratio of heat rates at T_0 and T is given by the inverse ratio of efficiencies. Thus

$$F = HR_T/HR_0 = \eta_0/\eta_T$$

Elimination of η_T and T_1 from the system of three equations yields the expression

$$F = HR_T/HR_0 = \frac{\eta_0 T_0}{T_0 - T\,(1 - \eta_0)}$$

The authors point out that this correction loses validity when the throttle steam is superheated. Have calculations been carried out for cases involving large amounts of superheat to determine how large an error is incurred through using Fig. 5(*b*) and Table 1, rather than an independent calculation of the heat rate for an exhaust pressure other than 1 in. Hg abs?

The writer has compared the tabulated heat-rates of cycles using dry saturated steam at 3200, 1200, and 300 psia with the heat rates obtained from the expression for the Carnot efficiency, using for the temperature of absolute zero the two values —460 F and —459.69 F. The results are as follows:

Pressure, psia	Heat rates (Btu per kwhr) Selvey and Knowlton	Carnot (—460)	Carnot (—459.69)
3200	6351	6351.0	6349.3
1200	7181	7180.9	7178.7
300	8850	8850.4	8847.3

From the tabulation it appears that the authors have used the value —460 F when calculating the heat rates of cycles with saturated steam at the throttle. For the sake of thermodynamic consistency and of smoothness of the tables, the value —459.69 F would have been preferable, since this value is the one on which the "Steam Tables" of Keenan and Keyes is based and since most of the values in the heat-rate table are based in turn on the "Steam Tables."

The authors state that the intervals selected for the numerical integration of $\int dh/(H - h)$ must be so chosen that each of the intervals has the same value of $\Delta h/(H - h)$. From a mathematical standpoint there is no necessity for this restriction. The intervals Δh may be chosen at random, the sole requirement for application of the trapezoidal rule being that the quantity $1/(H - h)$ be linear with respect to h (to the degree of accuracy specified for the final results) throughout each interval Δh. There is an advantage in employing equal intervals of Δh, as either the trapezoidal rule or Simpson's rule may then conveniently be employed for calculating the total value of the integral between the condenser pressure and the throttle pressure.

In evaluating $\int dh/(H - h)$ the authors take the summation $\sum \frac{\Delta h}{(H - h)_{avg}}$. There should be employed instead the summation $\sum \left(\frac{1}{H - h}\right)_{avg} \Delta h$.

The difference between $\frac{1}{(H - h)_{avg}}$ and $\left(\frac{1}{H - h}\right)_{avg}$ is small when the two neighboring values of $(H - h)$ are nearly alike, but can appreciably affect the results when the two neighboring values of $(H - h)$ differ by more than a few per cent. In the example given by the authors, the error is of the order of two parts in 10,000 and will probably affect the heat rates by the same order of magnitude. The tabulated heat rates are therefore too small by about 1 or 2 Btu per kwhr.

There appears to be a fundamental inconsistency in the method of the authors for calculating the throttle flow. To begin with, the integral which is the starting point for the calculations, i.e.

$$\int_{h_e}^{h_t} dh/(H - h)$$

is not, as used by the authors, a true integral in the mathematical sense, since the summation of the infinitesimal values of dh is not equal to $h_i - h_e$. In other words, the integral is taken only over those portions of the $(h_i - h_e)$ interval which correspond to feedwater heating, the remaining portion of $(h_i - h_e)$ being accounted for by feed-pump work. The means employed by the authors for overcoming this difficulty seems (to the writer, at least) to involve the confusion of two fundamentally different methods of attack for calculating the throttle flow, namely:

Method 1. Calculations are made for a cycle with a finite number of heaters, the bleed rate to each heater being determined by a heat balance on the individual heater. In principle, the heat rate of the cycle with an infinite number of heaters may be calculated to any desired accuracy by selecting a large finite number of heaters.

Method 2. The differential equation for a single infinitesimal heater is developed and is then integrated to give the total throttle flow. For purposes of numerical integration, values of the integrand may be chosen at finitely separated intervals, but this in no way alters the distinction between the two methods, i.e., that in one case the heat rate for a finite number of heaters is calculated, while for the other case the heat rate for an infinite number of heaters is calculated.

The authors have used Method 1 for calculating the enthalpy change of the feedwater stream across each finite heater but have

[36] Assistant Professor, Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Mass. Jun.A.S.M.E.

used an equation of Method 2 which applies to infinitesimal heaters for calculating the amount of steam bled to that heater. This combination of portions of two different procedures is inconsistent and leads to errors of unknown magnitude.

There follow the analyses for the two methods:

Method 1. Fig. 11 of this discussion shows a finite heater. A heat balance yields

$$\Delta w = \Delta(1 + w) = \frac{\Delta h}{H - h}(1 + w)$$

where h is the enthalpy of the feedwater stream entering the heater, Δh is the change in enthalpy of the feedwater stream across the heater, and $(H - h)$ pertains to that heater alone (in contrast to the procedure of the authors, in which $(H - h)$ is the average value for two neighboring heaters). Having tabulated

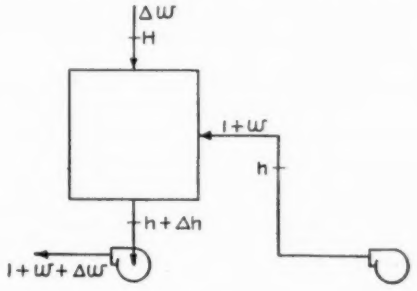

FIG. 11

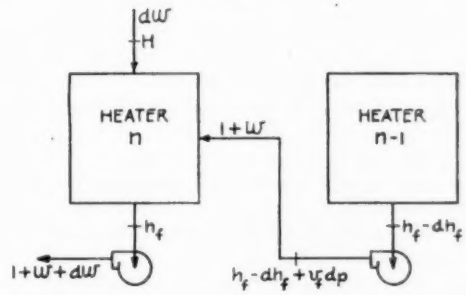

FIG. 12

the values of Δh and of $(H - h)$ for heaters at a number of different pressures, the bleed rate to each heater may be calculated in turn, starting from the low-pressure end. The throttle flow is then the sum of the bleeder flows and the condenser flow.

Method 2. Fig. 12 of this discussion shows two infinitesimal heaters. The symbol h_f refers to the enthalpy of saturated liquid leaving heater n. The enthalpy of saturated liquid leaving heater $n - 1$ is $h_f - dh_f$, and the enthalpy of the feedwater stream entering heater n is $h_f - dh_f + v_f dp$ (note [37]). Equating the enthalpy influx and outflux for heater n, as follows

$$(1 + w + dw)h_f = H\,dw + (h_f - dh_f + v_f dp)(1 + w) \quad \ldots\ldots [7]$$

there is obtained after rearrangement the expression

$$\frac{d(1 + w)}{1 + w} = \frac{dh_f}{H - h_f} - \frac{v_f}{H - h_f}dp \quad \ldots\ldots [8]$$

Integration of Equation [8] between condenser and throttle conditions yields for $(1 + w)$ at the throttle

$$\log_e (1 + w)_t = \int_{(h_f)_c}^{(h_f)_t} \frac{dh_f}{H - h_f} - \int_{p_c}^{p_t} \frac{v_f}{H - h_f}dp \quad \ldots\ldots [9]$$

The total feed-pump work is obtained from the integral

$$F = \int_{p_c}^{p_t} (1 + w)v_f dp \quad \ldots\ldots [10]$$

in which the value of $(1 + w)$ corresponding to any pressure p is found from an integral like that of Equation [9], except that the limits of Equation [9] are modified to correspond to condenser conditions and the conditions at the pressure p.

Analysis of an infinitesimal stage of the turbine yields for the turbine work the expression

$$dW = (1 + w + dw)(H + dH) - (1 + w)H \quad \ldots\ldots [11]$$

After rearrangement and combination of Equation [11] with Equation [8], the total turbine work may be written

$$W = \int_{\text{condenser}}^{\text{throttle}} (1 + w)\left[dH + \frac{H}{H - h_f}dh_f - \frac{v_f H}{H - h_f}dp\right] \quad \ldots [12]$$

The writer has used Equation [9] for calculating the throttle flow and the heat rate for the illustrative example given by the authors, i.e., throttle conditions of 3200 psia and 1200 F and condenser pressure of 1 in. Hg abs. The value of

$$\int_{(h_f)_c}^{(h_f)_t} \frac{(dh)_f}{H - h_f}$$

was determined numerically with Simpson's rule, using 16, 8, 4, and 2 intervals in $(h_t - h_c)$ to determine the necessary number of intervals. To avoid a separate series of steam-table calculations for the value of $\int_{p_c}^{p_t} \frac{v_f}{H - h_f}$ the expression $v_f/H - h_f$ was plotted against p for the same values of h_f which were previously used for the first integral of Equation [9]. From this plot there were read values of $v_f/H - h_f$ at equal intervals of pressure and the second integral of Equation [9] was evaluated with the aid of Simpson's rule. This semigraphical procedure was found to be amply precise for the second integral, because the value of the latter is very small as compared to the value of the first integral. The following table summarizes the results of the calculations:

$$\int_{p_c}^{p_t} \frac{v_f}{H - h_f}\,dp = 0.018089$$

Number of intervals	$\int_{(h_f)_c}^{(h_f)_t} \frac{dh_f}{H - h_f}$	$1 + w$	HR Btu per kwhr
16	0.995033	2.65632	6001.2
8	0.995032	2.65632	6001.2
4	0.995833	2.65844	5997.5
2	1.00524	2.68359	5955.3

The authors give for the heat rate 5999 Btu per kwhr. It appears from the tabulation that not more than 8 intervals are required in this case, as compared with 25 or 35 intervals used by the authors in conjunction with the trapezoidal rule.[38] For certain throttle conditions more than 8 intervals may be required, but the number of intervals will always be vastly less than that required with the trapezoidal rule.

The writer has pointed out what appear to him to be several defects in the construction of the table of heat rates. This

[37] From the thermodynamic expression $Tds = dh - vdp$ it follows that the change of enthalpy across an infinitesimal and reversible adiabatic pump is given exactly by the expression vdp, irrespective of volume changes.

[38] Simpson's rule requires that the relation between $1/H - h_f$ and h_f be of the third order or less throughout the chosen intervals of h_f. The trapezoidal rule requires that $1/H - h_f$ be linear with respect to h_f throughout the chosen intervals of h_f. Far fewer intervals may therefore be used with Simpson's rule than with the trapezoidal rule.

scarcely alters the worth of the table, since these defects generally cause errors only in the final digit of the tabulated heat rates. The introduction of these errors is unfortunate in the sense that the table of heat rates does not reflect the accuracy and precision of the thermal data on which the "Steam Tables" of Keenan and Keyes is based.

G. B. WARREN.[39] The work that led to this paper was started several years ago, following the quite successful application of a system of quickly determining turbine extracting performance which had been in use by the writer's company for some time.

This first system consisted of curves giving the heat consumption of turbines of 100 per cent efficiency based upon available energy and operating with two, three, four, or five extraction points, also with no pressure or temperature drop, and with the extracted steam mixed with the feedwater being heated. If to the data obtainable from such curves, internal turbine-efficiency figures similar to those given in the Knowlton and Warren paper[40] of 1941 are applied, corrections made for leaving loss and for the usually small departure of the actual from the ideal extraction cycle, a close approximation to the real turbine performance can be arrived at. If the feedwater temperature is known, and it can be chosen over quite a range without affecting greatly the foregoing results, the throttle and condenser flows can be easily obtained.

During the early study of this problem, it apparently appeared as though the original form of presenting these data should be modified, and it was put upon the basis of an infinite number of heaters heating the feedwater to the saturation temperature of the boiler, going back to a conception introduced in 1923, by Ernest L. Robinson.[41]

It is to be hoped that the present authors will have an opportunity to prepare the remaining portion of this work which will permit making full practical use of the data.

In the meantime, while the work from which this present paper was prepared was progressing rather slowly, J. K. Salisbury worked up his very excellent system of determining turbine-extraction performance,[34] based upon actual nonextraction heat rates. To some extent this followed an earlier method worked out by and used by the General Electric Turbine Division. This system also facilitated determination of over-all turbine-extraction performance from the nonextraction-turbine efficiencies obtainable from the Knowlton and Warren paper,[40] or from any other convenient source.

Power-plant engineers have at their command therefore published information from which complete and accurate studies of the relative heat consumption of any steam-turbine plant can be calculated. Knowledge of boiler performance and miscellaneous operating losses permits a close approximation of the over-all fuel consumption.

The authors are to be congratulated for carrying out a very long and laborious undertaking and can have the satisfaction of having made a lasting and fundamental contribution that should stand as long as the present steam tables maintain their acceptance and the many conditions of operation are not exceeded.

AUTHOR'S CLOSURE

The authors are gratified that so much worth-while discussion of their paper was forthcoming. The interest manifest in theoretical regenerative-steam-cycle heat rates has confirmed their opinion concerning the importance of this subject to steam-power engineers, and the need for basic data in a form convenient for applying to the solution of such problems. The discussers have brought to attention several points which can well be explained or amplified with a view to making the data more understandable and useful.

Professor Baumeister rightly states that the value of the paper rests in its utility to engineers engaged in designing and operating power plants and wishes to know whether it is proposed that the answers to several questions of detailed apparatus arrangements will be forthcoming. These answers are obviously not contained in the present paper, so that the question really is as to what is proposed for the future second part of the work. This second part has not been crystallized, but the general philosophy now existing regarding what should be done is about as follows:

The effects on performance of losses in any of the apparatus required in steam plants would be pointed out in some detail with the view to showing from past experience what should be reasonably attainable.

The fact that engine efficiencies and other factors change with steam conditions and with advances in the art of manufacturing turbines, as pointed out by Professor Baumeister, would seem to justify the development of the heat-rate tables on the basis of theoretical conditions as was done in the present paper. Thus the tabular values need not be changed (unless the steam tables are changed), and it is believed that correction factors can be worked out for different engine efficiencies so that the plant designer may use the engine efficiency which is applicable at the time of making his calculations.

It is not to be expected that such factors as can be evolved later will be sufficiently all inclusive to furnish an answer to every question; but in general it is hoped to give the plant designer enough information to permit him to assign an over-all efficiency to his plant, based upon actual or calculated heat consumption, and to show why this over-all efficiency is what it is assumed to be. When the major elements of a proposed cycle have been decided, it may then be necessary to make detailed calculations to evaluate the relative merits of minor refinements to the cycle such as changing the location in the cycle of an evaporator or of a heater-drain pump.

The data already presented also should be useful in making comparisons between different cycles, as Professor Baumeister suggests. These comparisons in practical cases require consideration of the effect on performance of many factors of an involved nature, although the net differences in the final answers may be small. A simple comparison of the theoretical heat rates will show the theoretical differences, which can be compared with the practical ones, whereby a better understanding of the reasons for discrepancies may be had.

Mr. Brooks raises a question as to the assumption made regarding the temperature to which feedwater is heated by superheated steam. This is stated in paragraph (2) of the paper under "Description." The curves in Fig. 6 are drawn from the figures in Table 1, simply to show the trend of decreasing heat rate with increasing temperature. With reference to the use of superheated steam in heaters, Mr. Brooks doubts that "it is feasible to get higher than the saturation temperature of the steam in the heater..." Actually several heater manufacturers are guaranteeing performance on the basis of heating the feedwater to a temperature several degrees above the saturated-steam temperature in the heater if the heater is supplied with superheated steam.

Commander Dusinberre, Mr. Markson, and Dr. Robinson apparently have a common idea, viz., that information concerning weight flows, as well as "parts" of complete cycles, should be made available. Commander Dusinberre has proceeded to make some sample figures and tabulations illustrating how this idea

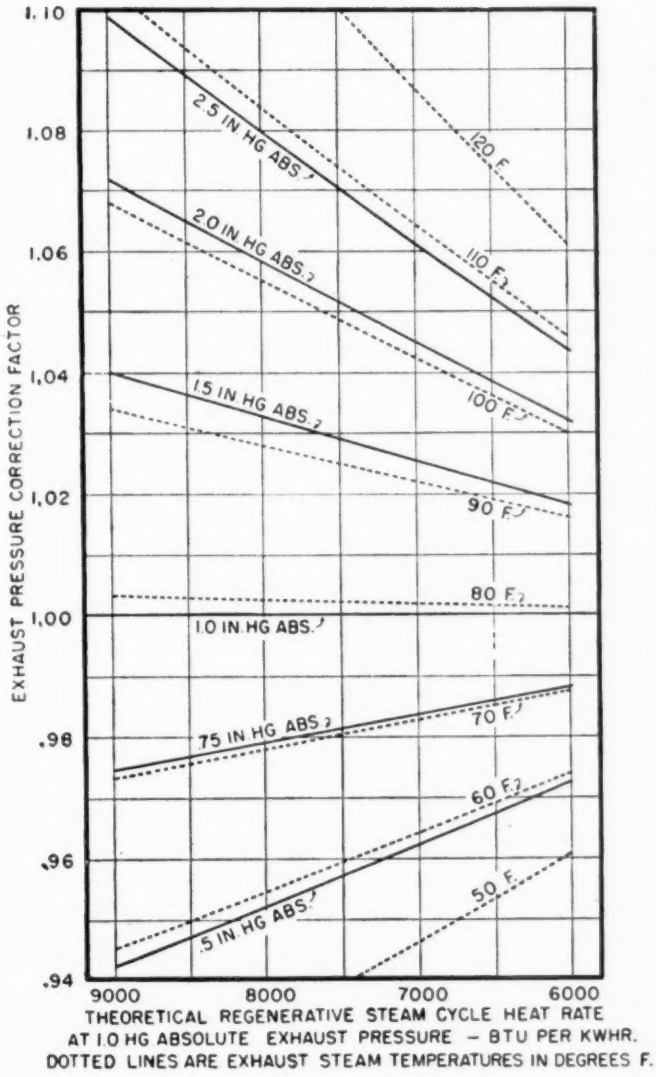

FIG. 5(*b*) REVISED CHART OF EXHAUST-PRESSURE CORRECTION FACTOR

(In the theoretical cycle, exhaust steam temperature is the same as condensing water supply temperature.)

might be carried out. The authors believe that such information, if completely worked out, would be useful. In fact, it may be the only good way of handling the reheat cycle but, at present, they are unable to do more than commend this suggestion to anyone having time to work on it.

In his statement concerning power-plant performance of River Rouge No. 1 Power Plant of the Ford Motor Company, Mr. Dulmage has made a welcome contribution to the store of information which will be needed in preparing the second paper. The authors appreciate this early co-operation. For further information about this plant, reference may be made to an article by W. W. Dulmage and C. J. Walker.[42]

Messrs. Engle and Benjamin both point out the possible value of the paper and its proposed sequel as a means of relating the actual performance of a plant to what can reasonably be expected of its cycle. Such uses are precisely along the lines of the authors' own ideas. There also may be considerable merit to the idea of rating the actual performance of a given plant upon the basis of what fairly can be expected of it, rather than upon the basis of comparison with a more modern or more complex plant.

The authors feel that Mr. Hardie has complimented them in suggesting that the heat-rate tables be adopted as an American Standard basis for appraising plant performance. His suggestion that the condensing-water temperature would be preferable to the turbine exhaust pressure as the lower boundary of the theoretical cycle is supported by the discussion of Commander Dusinberre. This suggestion appeals to the authors as well, since it serves to emphasize that in the theoretical cycle the exhaust steam would condense at the temperature of the cooling-water supply whereas in an actual cycle thermodynamic losses result from the necessity for a temperature rise in the cooling water, and a terminal temperature difference in the condenser. Accordingly, constant-temperature lines have been added to the chart in Fig. 5(*b*), which originally had exhaust pressure lines only. The revised Fig. 5(*b*) appears with this closure.

The authors had not considered the problem of appraising the performance of a mixed-pressure plant. It would seem that each section of such a plant could be appraised separately and a suitable basis of averaging arrived at. The suggested basis of fuel input may well be the most satisfactory for this purpose.

Mr. Hardie mentions the pressure loss from boiler drum to turbine throttle, which of course is not present in a theoretically perfect cycle. This is a practical loss, and presumably the actual plant should be charged with this loss, part of which occurs in the boiler and part in the piping.

Mr. Ireland has requested a basis for using a short-cut formula for computing heat rates of partial regeneration cycles on the assumption that, with the full regeneration heat-rate tables available, it would be possible to derive suitable correction factors for using a short-cut formula. In actual practice, the heater spacing is not ideal in all cases, only a small finite number of heaters are employed, and the same final feed temperature may be achieved using any number of feedwater heaters. For these reasons it does not appear that any simple set of corrections could be developed which would yield satisfactory results under all conditions when applied to the short-cut formula. If Mr. Ireland is thinking in terms of an actual turbine, the authors feel that the best way to accomplish what they believe he wants, the method developed by J. Kenneth Salisbury, referred to by other discussers, should be used, or the older methods of the large-turbine manufacturers.

On the other hand, if Mr. Ireland is thinking in terms of theoretical performance, with only partial regeneration, it is suggested that the results to be obtained from the short-cut formula with corrections could be derived rather easily by superimposing a Rankine cycle on a theoretical regenerative cycle having its initial pressure equal to that of the highest pressure bleed point. The bleed-point pressure would be the saturation pressure corresponding to the final feedwater temperature, and the exhaust pressure of the Rankine unit would have that same value. This suggestion is an application of the thoughts expressed by Commander Dusinberre and Mr. Markson. The heat rate of the regenerative portion of the cycle can be taken from the present paper while the heat rate of the Rankine portion of the cycle may be determined from published tables of theoretical steam rates.[43] The effect of partial regeneration would be covered in the correction factors of the proposed companion paper.

Mr. Meyer suggests that the calculations could be made by

[42] "Performance Test at Ford Motor Company," by W. W. Dulmage and C. J. Walker, *Power*, vol. 85, July, 1941, pp. 72–75.

[43] "Theoretical Steam Rate Tables," by J. H. Keenan and F. G. Keyes, published by THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New York, N. Y., 1938.

formulas derived from the concept: "In any cycle in which heat (dQ) is added at variable temperature T (deg abs) and rejected at constant temperature T_s (deg abs) the maximum work obtainable (W_m) is given by" etc., from which he proceeds to derive the formula. This formula is the same as that given in the paper and labeled "inaccurate." The error of this formula is shown in Fig. 3 and comes about because the formula is only correct for a "reversible" cycle, whereas the cycle used by the authors contains an irreversible process whenever the throttle steam is superheated, this irreversible process being the transfer of heat from superheated steam to feedwater, which transfer involves a definite degradation of heat.

Professor Shapiro derives an expression for exhaust-pressure correction which is the equivalent of the one given in the paper. These expressions are exact, regardless of the initial condition of the steam, as long as the exhaust is in the wet region. Therefore there is no error in using Fig. 5(*b*) and Table 1. The authors believe Professor Shapiro must have misread the text since they did not intend to cast any doubt on the usefulness of the exhaust-pressure correction factors. Professor Shapiro's full discussion of the methods of calculation of the theoretical heat rates constitutes a valuable addition to the paper. The authors agree that his "Method 2" is an accurate means of performing the necessary integration, and that, even for the highest pressure cycles, a relatively small number of intervals is satisfactory. A similar method, although with not quite as precise a determination of the feed-pump work, was used in some of the calculations made in producing the heat-rate table. Unfortunately, a few computation errors were made, so that the true value of this method was obscured. Also, small errors in determining feed-pump work made the computations slightly inaccurate at the high pressures, which difficulty seems to have been overcome by Professor Shapiro. Regarding his statement as to the accuracy of the heat-rate table, we believe the figures to be correct within about $\pm$ 3 Btu per kwhr.

Dr. Robinson's remarks concerning the desirability of having weight-flow data available apparently reflect the same viewpoint as is expressed by Commander Dusinberre. The authors do not question the potential value of such information, if it could be prepared. Quite possibly it might be the most advantageous way of handling the reheat cycle for which Commander Dusinberre wants data. If such data were prepared it also would be desirable, as Dr. Robinson points out, to have figures based upon various practical turbine efficiencies.

Mr. Salisbury's remarks, comparing the present paper with his own excellent presentation, point out the differences as well as the similarities in the two approaches to this question of theoretical and practical steam-plant performance. The authors have hopes, with Mr. Salisbury's permission, of using some of his results, in preparing the proposed sequel to the present paper. It is thought that practically all of Mr. Salisbury's work is directly applicable except that, in general, his results must be cast into a somewhat different form. This is because he has dealt with "percentage gains," built up upon the nonextraction cycle, whereas the authors intended to deal with "percentage losses" from the theoretical regenerative cycle.

The authors do not agree with Mr. Salisbury that "it may be found expedient to remove the loss due to boiler-feed-pump work." In their opinion the feed-pump work is not a loss at all in the theoretical cycle, since the pump is a necessary part of the cycle. There are a number of practical ways in which the feed pump has been arranged in practical cycles, varying from a single pump to a separate pump for each of a finite number of feed heaters. It will eventually be necessary to work out the differences between the theoretical cycle infinite-number-of-steps pump and the practical one-or-more-step pump.

The authors appreciate the comments made by Mr. Warren, which present a concise picture of the way in which it is felt these theoretical heat rates will be of use. They also appreciate his constructive interest and consistent support accorded to this project.

Mechanical Features of the Glenville Impulse Turbine

By ARNOLD PFAU,[1] MILWAUKEE, WIS.

At the Glenville Plant of the Nantahala Power and Light Company near Franklin, N. C., is the only large impulse-wheel turbine unit east of the Rockies. Its performance has established a water-wheel efficiency record for the United States of practically 89 per cent. This paper is devoted to descriptive details of the unit, its operations, and performance.

THE Glenville Plant of the Nantahala Power and Light Company is located on the West Fork of the Tuckasegee River about 13 miles east of Franklin, N. C. It has the distinction of being the only large-capacity impulse turbine east of the Rocky Mountains. With a gross head of 1207 ft, a net head at maximum discharge of 1188 ft, and a rated capacity of 30,000 hp at 1150 ft, 27,000 kva, 21,600 kw, its capacity exceeds by far that of the few small impulse turbines in the East.

The Tuckasegee River at Glenville Dam has a drainage area of 39.4 sq miles and an average annual computed flow of 135 cfs. The dam with a height of 150 ft has a net storage volume of 68,000 acre-ft. Since the turbine uses about 275 cfs at full load, this unit will operate at approximately 50 per cent annual load factor, drawing out the available storage and generating power to suit the requirements of the downriver plants most advantageously.

General Operating Details

The Glenville unit is a horizontal-shaft single-jet double-overhung impulse wheel with shaft supported in two bearings and the generator rotor located between them. The turbine is rated 30,000 hp, 1150 ft net head, 257 rpm. One shaft end is extended for coupling to exciter, pilot exciter, and to the independent generator supplying current to the motors driving the flyballs of the governors.

Being of the double-overhung type, the two water wheels, one on each shaft end, constitute two independent hydraulic prime movers, each being provided with its own governor and gate valve, so that the water on one side can be shut off entirely without interfering with the operation of the other. When small outputs of less than 50 per cent are necessary or desirable, a better wheel efficiency can be maintained. Also, the individual control of each water wheel by its own governor assures a double safety, maintaining a control of one half of the output of the unit in case the governor of the other half should refuse to act properly.

This double control, two governors for one single generator, was successfully introduced by the company with which the author is connected and has since become a generally accepted design here and even abroad, not only for double-overhung impulse wheels but also for double-overhung Francis-turbine units, the first of this latter type having been furnished by the author's company in 1913, for the 18,000-hp unit at the Halsey Plant of the Pacific Gas & Electric Company of California.

The Glenville unit is designed for a static head of 1215 ft and rated two times 15,000 bhp under 1150 ft net head at 257 rpm. The generator is rated 27,000 kva maximum, 6600 v, 60 cycles, three phase. It is designed for the full runaway speed which the rotating parts may attain, with both jets wide open under 1150 ft net head and no load on the generator. Speed-and-pressure control of the unit is maintained by the individual governing mechanism of each water-wheel side.

To avoid dangerous pressure rises and surges in the pressure tunnel, which is several miles long, with no surge tank, the change of velocity of water under fluctuating load must be very gradual. To obtain quick response to load changes, the output of the unit must be changed quickly by a corresponding change of water quantity impinging upon the buckets. The most perfect method of quick control would be simply to control the impingement of the jets and to hold the flow-controlling needles stationary, i.e., water-wasting regulation. This is prohibitive when water is to be used economically. Here provision must be made to adjust the flow according to the load demand.

Since the Glenville plant does not permit of quick changes of flow in the tunnel and pressure pipe, it is realized that load increases can be taken care of only if so gradual that no serious pressure drops will be experienced. The two needles controlling the flow are therefore set to stop the flow at an average rate of 120 sec, slowing down near closed position to a rate of about 200 sec, and to accelerate to full flow in about 100 sec. Such rate of closing movement would involve a full runaway of the unit on full sudden load rejection such as is the case when the unit becomes detached from the power system. To hold the momentary speed rise within tolerable limits, the quantity of water directed upon the buckets must be changed more rapidly.

In the older art this was accomplished by moving the needle rapidly and by opening a relief outlet as synchronously as possible to discharge the amount shut off by the needle, and thereafter to close the relief outlet at a rate to prevent undesirable secondary pressure rises in the pipe line; in other words, a "switch-over" of flow out of the needle nozzle to relief outlet. This is ideal only if the two discharges are strictly inversed at all times so that the sum of the two discharges equals the former total discharge, i.e., that the velocity of water in the pipe line is not changed.

A practically perfect method, first introduced by the author's company in connection with the 60,000-hp impulse-wheel unit at the Big Creek 2-A Plant of the Southern California Edison Company, Los Angeles, Calif., is to provide means for diverting quickly the jet from the buckets and to let the flow-controlling needle follow the movement at a rate "independent" of the rate of deflection, but in strict accordance as dictated by the pipe-line characteristics.

The various processes are illustrated in Fig. 1 (*a*) for both relief outlet and jet deflection.

Relief Outlet. In Fig. 1 (*a*) at ordinate A-$A'T$ (governor time) = 0, the flow is 100 per cent (full load of unit). The load is suddenly dropped from A' to $A = 0$. The speed rises, but the flow-controlling needle does not start to move until time B is

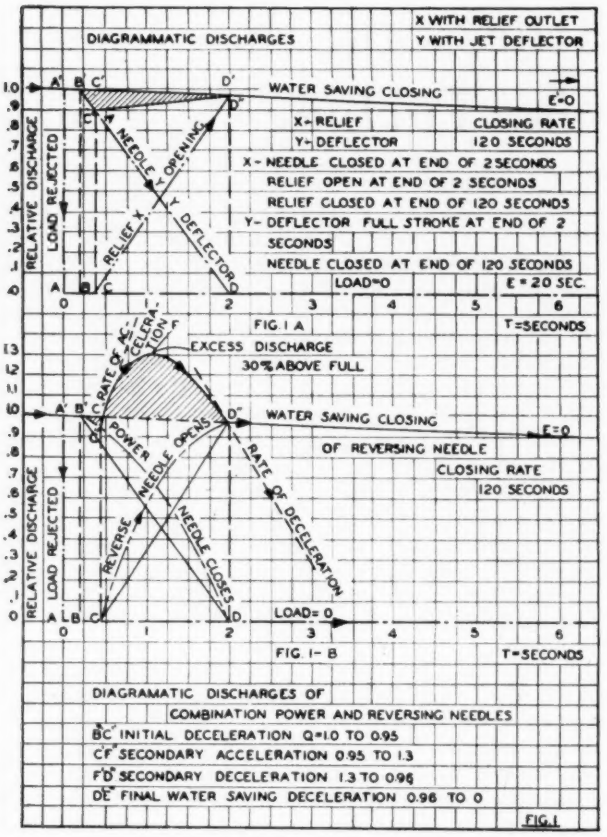

FIG. 1 DIAGRAMMATIC DISCHARGES OF COMBINATION POWER AND REVERSING NEEDLES

$B'C''$—Initial deceleration: $Q = 1.0$ to 0.95
$C''F$—Secondary acceleration: $Q = 0.95$ to 1.3
FD''—Secondary deceleration: $Q = 1.3$ to 0.96
$D''E'$—Final water-saving decelerations: $Q = 0.96$ to 0

reached. The flow through the needle is reduced along line B'-D and the flow upon the buckets is stopped in 2 sec from the beginning of load rejection. The movement of the needle acts upon the relief outlet which begins to open at time C, and its water-saving mechanism immediately starts its relative closing movement at a rate of 120 sec (from C' to E'). The delay BC, during which the relief outlet remains closed, causes a reduction of flow from B' to C'' at the full rate of closure of the needle, thereby producing a material initial pressure wave in the pipe line.

If the relief outlet has a capacity of 100 per cent of that of the needle, it opens the relief outlet wide at the time D, when the needle is closed. However, the relative water-saving movement reduces the flow to D'' instead of D'. If the discharge rates of the needle and relief outlet were linear, the resultant total discharge (being the sum of the ordinates of needle- and of relief-outlet discharges, respectively) would be as indicated by curve C''-D'', and the area $B'D'D''C''B'$ represents the change of velocity in the pipe line. It is obvious that any deviation from the straight lines B'-D and C-D'' causes even more serious changes of water velocity, as illustrated in Fig. 1 (*b*).

Jet Deflector. In Fig. 1 (*b*), the deflector is directly actuated by the governor. Therefore no additional initial delay BC is experienced. The output flow is reduced along line B'-D, and the needle controlling the flow in the pipe line is independently reduced to zero from B' to E'. The undesirable feature of change of resultant flow represented by former area $B'C''D''$ is reduced to $B'D''$. The diagram at once discloses that here the deflector movement from B' to D (taking the place of the former needle movement) can be made as quickly as is mechanically desirable.

Fig. 1 (*b*) represents the case of two reversing needles of approximately parabolic discharge characteristics, resulting in an initial deceleration $B'C''$ until the reversing needle begins to open, and changing suddenly into an acceleration $C''F$, diminishing to zero at F, where the total flow is a maximum, and changing into a deceleration from F to D'', reaching its maximum at D'', when the power needle is closed and the reversing needle wide open, and followed by the gradual deceleration $D''E'$, caused by the water-saving movement of the reversing needle to closed position at the end E' of 120 sec. Serious accidents to pipe lines and loss of life are on record caused by a faulty correlation in movements and discharge characteristics of such reversing needles.

Mechanical Features of Glenville Unit

Main Shaft. The main shaft is a hollow-bored steel forging with integrally forged flanges on each end for bolting the water-wheel runners to it. It is bossed up in the center so that the generator rotor can be brought into position over one of the flanges. It rests in two bearings of 22 in. diam, 18 ft apart. One end is arranged for flexible coupling to the direct-connected exciter.

Bearings. The total rotating weight (water wheels and generator rotor) of about 135 tons is carried in two ring-oiling pedestal-type bearings, each of 1450 sq in. bearing surface, in split, babbitt-lined shells with ball-and-socket seat, which permits of adjustment of the bearing surface in accordance with the deflection of the overhung portion of the shaft carrying the weight of wheel runner and the resultant impact force produced by the jet, which varies as the output of that side of unit varies. The two bearing shells are water-cooled, and lubrication is assured by five oiling rings which pick up the oil from the basin formed in the lower bearing housing and discharge it over the top of the shaft. Thus the normal operation is not in need of outside lubrication under pressure, but is self-contained. However, to facilitate starting the unit, when the contacting bearing surfaces may have become dry, provision is made to use oil under pressure from the oil-pressure system of the governors.

Temperature relays are provided which cause the governors to shut the unit down when the temperature becomes excessive. Excellent results have been obtained with this design of bearing, the largest being those at the Big Creek 2-A Plant with a shaft diameter of 32 in. operating at 250 and 300 rpm, delivering 50- and 60-cycle current at times, depending upon the network served.

Wheel Disks and Buckets. The forged-steel wheel disk is machined all over and is held to the forged-shaft flange by central-recess and ream-fit steel bolts with secured nuts. Twenty-one buckets of cast steel are held to the disk each by three taper ream-fit bolts with secured nuts on either end. From a point of view of mechanical strength, the design is liberal, involving only moderately high stresses of material even under maximum centrifugal force due to runaway speed, as also under conditions of rapid changes of impact force. It is not generally realized fully to what forces such a bucket is exposed, both as to amount and as to duration. At 257 rpm, a bucket passes through the jet 4.3 times per sec. When the full jet impinges, such as is the case here where the pitch is larger than the total length of intersection of the jet on the periphery of impingement, the impact force is 63,000 lb, beginning with zero value when the bucket lip enters the jet, reaching above maximum as long as the full jet impinges on the same bucket and reaching zero value again when the last particle of jet discharges from the bucket. This process takes

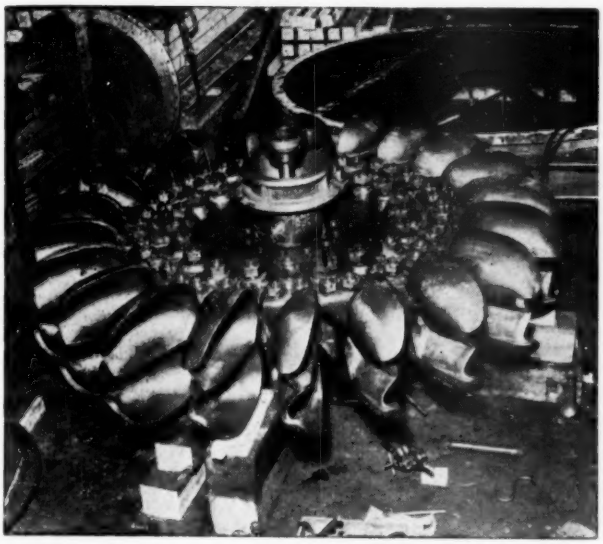

FIG. 2 SHOP-ASSEMBLED DISK AND BUCKETS FOR 10-IN-DIAM JETS

place over about 1/4 of the periphery of the wheel, therefore, in $\frac{1}{4 \times 4.3}$ or about $\frac{1}{17}$ sec.

This intense hammer blow (some practical engineers call it "a swift kick in the pants") must be resisted by the bolts holding the bucket to the disk, in addition to the steady centrifugal force of about 110,000 lb at normal speed, or about 370,000 lb at full runaway speed.

This explains the cause of serious accidents experienced early this century when buckets exploded, due to crystallization of bolts and breakage of bucket castings, and due to weakening on account of pitting because of faulty inlet and discharge angles of the bucket bowl.

Fig. 2 shows the shop-assembled bucket wheel with all bolt holes properly reamed and bolts and buckets fitted and assembled on the wheel disk. The weight of each rotating element is about 37,500 lb.

Nozzle Pipes. In the nozzle pipe, the energy of the flowing water (partly pressure and partly velocity), due to the total available net head of 1188 ft at the entrance to the nozzle pipe is transformed into kinetic energy which is contained in the jet after leaving the orifice. This process of transformation can be

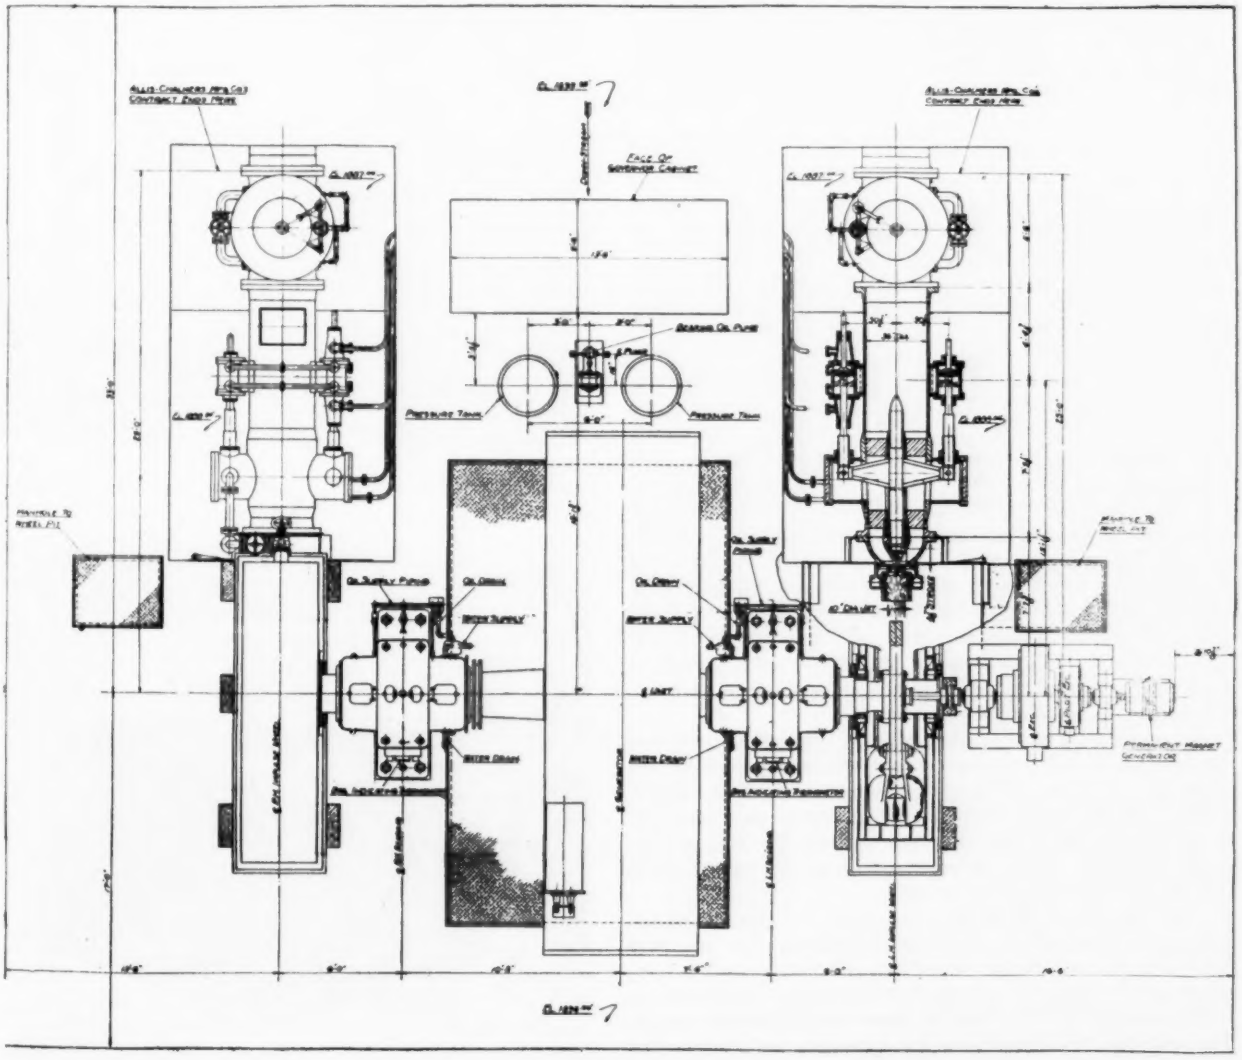

FIG. 3 PLAN OF HYDRAULIC IMPULSE-TURBINE UNIT AT GLENVILLE PLANT

accomplished more or less efficiently, depending upon the design and care of workmanship.

Let C_n be the velocity due to the net head H_n at the entrance to the nozzle pipe, and V the velocity of the jet. Thus the jet efficiency e is

$$e = 1 - \frac{M \times C_n^2}{2} - \frac{M \times V^2}{2} : \frac{M \times C_n^2}{2} \text{ or } \frac{(V)^2}{(C_n)}$$

If the jet velocity were equal to the available net velocity C_n, the efficiency of the jet would be 100 per cent. Naturally, the bucket, transforming the kinetic energy $\frac{M \times V^2}{2}$ in the jet into torque force, producing output, cannot do more than what it receives. This justifies the designer to endeavor to produce the best possible nozzle design. It at once cautions against using multiple-bend piping, such as is involved with a multiple-jet arrangement or crowded settings of the water wheel. This applies equally well to the Francis and propeller types.

The Glenville nozzles are of the patented design first used in 1927, in connection with the 40,000-hp water wheel at the San Francisquito No. 1 Plant of the Bureau of Power and Light, Los Angeles, Calif., and from which to date still issue the largest diameter of jets (14 in.) in the world.

Fig. 3 shows a plan view of the complete unit.

The nozzle pipe is made of welded steel with an inlet diameter of 36 in. for flanged connection to the gate valve. It is straight and slightly tapered, containing a four-arm spider forming the support of the needle stem carrying the steel needle tip. This needle tip is made of two removable parts to facilitate and economize repairs. The stem is provided with a crossarm, the two ends of which project into pockets on either side of the nozzle pipe where they are pivoted to plungers projecting through packing boxes to the outside where they are coupled to the piston rods of the servomotor jointly actuating the needle. The diameters of the plungers are so dimensioned that they partly offset the force tending to hold the needle tip against the orifice from which the jet issues. The downstream end of the nozzle pipe carries the cast-steel nozzle tip with renewable steel throat ring which, when the needle tip seats against it, closes the orifice tightly.

Fig. 4 shows the shop-assembled nozzles with needles, and mounted on them are:

The Jet Deflectors. These are disposed between the nozzle orifice and the rotating buckets, with a minimum space required to maintain compactness of the full jet impinging upon the buckets. The jet deflector surrounds the jet without interference when in neutral position to assure highest output efficiency. The portion surrounding the jet is lined with a renewable steel sleeve. The deflector is hinged and extended at the lower end for pivoted connections into the nozzle-pipe pit where it is coupled to its oil-pressure servomotor.

The orifice part of the nozzle pipe, consisting of the throat ring and needle tip, to a great extent affects the condition (or efficiency) of the jet, and since it is exposed to the high velocity of water issuing, it is essential that it be kept in good condition by frequent examination. For this purpose the supports for the hinges of the stream deflector can be readily moved out of the way for quick access to the orifice.

Upper and Lower Wheel Housing. Fig. 5 shows one of the housings shop-assembled. It is made of welded plate steel, suitably reinforced to minimize breathing. The lower part is completely grouted into the concrete foundation and is machined on top to form the base to which the upper wheel housing is bolted. The rear face is also machined for supporting and surrounding the nozzle pipe. A door is provided for access from the nozzle-

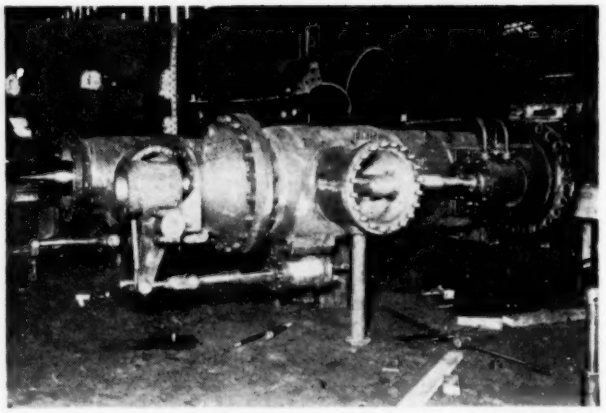

FIG. 4 NOZZLE WITH JET DEFLECTOR AND NEEDLE OPERATING CYLINDERS SET UP IN SHOP

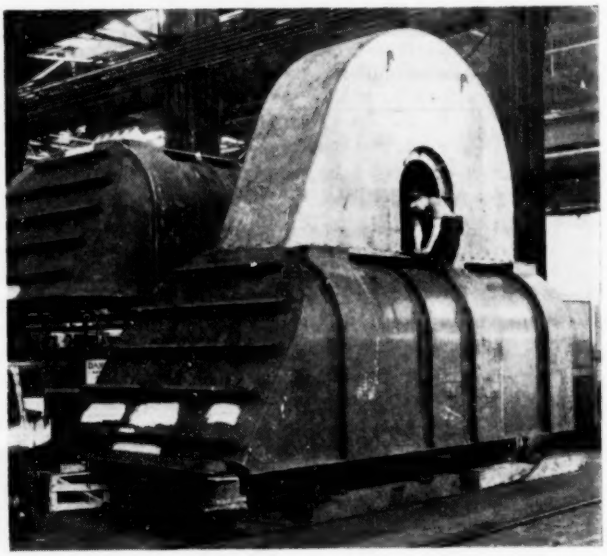

FIG. 5 UPPER AND LOWER WELDED-STEEL-PLATE IMPULSE-WHEEL HOUSINGS

FIG. 6 VIEW OF STILLING POOL

pipe pit to the front of the wheel pit. The downsteam face is inclined and heavily reinforced to be capable of receiving the full impact force of the jet when, due to runaway, the major portion of the jet passes forward without impinging upon the buckets. Proper baffles are provided in order to deflect the discharging water, rather than to throw it back against the buckets, or the orifice.

The upper housing is double-walled for stiffness and for the purpose of ventilation.

Where the main shaft projects through the housing, proper baffles are provided to prevent splash water from escaping along the shaft.

Wheel Pits. These are lined with steel on both sides, the bottom and the ceiling of the outlet.

Inspection shafts for access to the wheel pits are provided on each outer upstream end of the unit. They are covered by floor plates securely bolted to frames to avoid rattling caused by the heavy air-pressure fluctuations in the wheel pit when the jet becomes deflected on sudden load rejections.

Energy Translator. When the jet is fully deflected from the buckets by the sleeve in the jet deflector, it presses against the upper-cylinder portion of the sleeve and thus begins to spread, whereby it loses part of its impact force. This would still be so high as to cause destruction to the tailrace. Fig. 6 is a view of the stilling pool showing the water discharging when the jets are fully deflected. It was designed and built by the engineers of the Aluminum Company of America and is giving very satisfactory service. A combination of splitters is built into the end of the apron and these are assisted by the pool of water in the stilling pool itself. The splitters are wedge-shaped with the point of the wedge facing the unit, three to each water wheel, the center splitter being in line with the center line of the water wheel. This splits the deflected jet into seven parts. That part of the jet impinging against the wedgelike splitter is elevated, while the jet between the splitters and on either side of the end splitters goes out horizontally. This scheme has proved very satisfactory on full-load rejections, no water ever being spilled beyond the confining walls of the stilling pool when the full-load quantity of 270 cfs is discharged under 1188 ft net head with a velocity of about 264 fps.

Hydraulic Brake. The liberal flywheel effect of rotating parts of the two water-wheel runners and the generator rotor would keep the unit revolving for about 40 min after the water is shut off. In case of mechanical accident, this delay in coming to a stop may cause more damage. Provision is made to reduce this time materially by applying a water jet onto the buckets opposite to the direction of rotation. The brake jet is controllable by a hand-operated needle and a gate valve connected to the upstream side of the main gate valve, so that the brake can be applied even when the main gate valve has been closed.

Gate Valves. These are illustrated in Fig. 7, under actual water-pressure test in the shops with a pressure of 550 psi applied to the upstream side of valve plug. The valve, built of cast steel throughout, is of the single-seat parallel-face follower-ring type, as successfully used since 1913, for the eight 24-in. valves at Big Creek No. 1 and No. 2 Plants under heads up to 2350 ft. These are designed to be closed against the full flow of water under the maximum head. The filler ring is an extension, integral with and below the valve plug, which, when the valve is in the wide-open position, fits into the gap otherwise left in the valve housing. It thus protects the valve seat against scouring by sand, etc., passing through the valve during operation, and it serves as a guide for the plug to prevent chattering of the plug during closing or opening movement.

The valve plug is raised and lowered by a hydraulic piston and cylinder, with control valve admitting penstock pressure to the top and bottom, respectively, of the piston for closing and opening the valve.

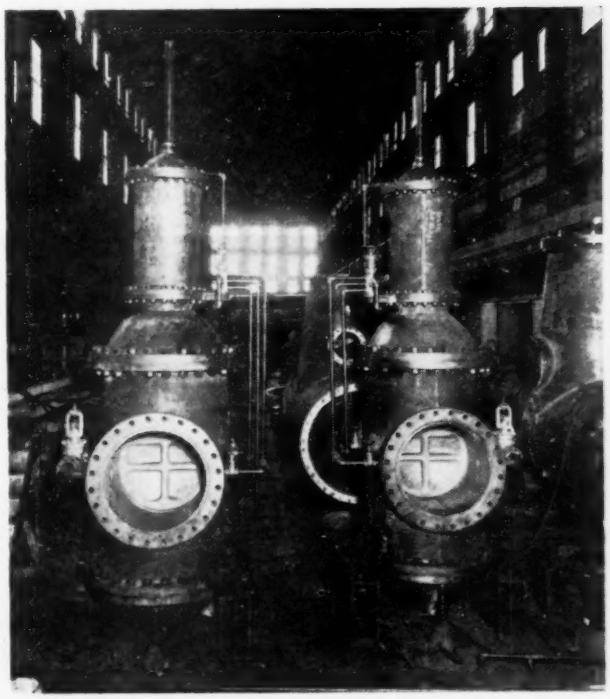

FIG. 7 TWO 36-IN. FOLLOWER-TYPE GATE VALVES FOR GLENVILLE UNIT UNDERGOING SHOP TESTS

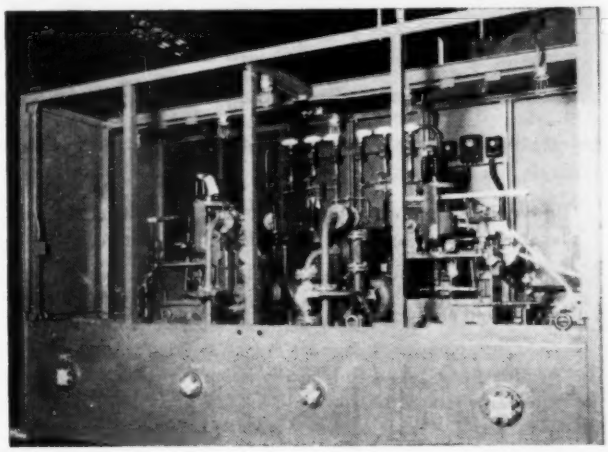

FIG. 8 REAR VIEW OF CABINET GOVERNOR FOR ONE DOUBLE-OVERHUNG IMPULSE WHEEL

Governors. As previously explained and diagrammatically illustrated in Fig. 1, speed and pressure regulation is accomplished by a combination of quick-acting water-wasting jet deflectors. Subsequent gradual movement of the flow-controlling needle is at a rate to assure protection of the pressure pipe line against undesirable pressure variations. Each water-wheel side has its own governor, with two servomotors attached to its nozzle pipe for movement of the needle, and one servomotor located below the nozzle pipe in the nozzle pit for the purpose of actuating the jet deflector.

The actuators of the governors are housed together in a cabinet near the upstream wall of the powerhouse, where the

two oil pump sets, pressure and receiver tanks are also located. Fig. 8 shows the rear of the cabinet opened up for a full view of the equipment and wiring circuits behind the front wall of the cabinet.

The principal elements of a modern governor are:

The speed-responsive part, or flyballs.

The control valve actuating the servomotor controlling the output producing flow of water.

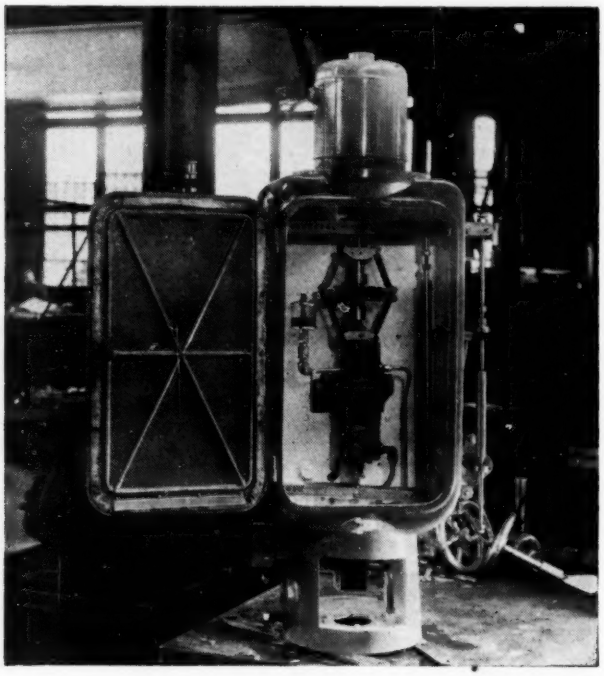

FIG. 9 SUPERSENSITIVE FLYBALLS FOR A RECONSTRUCTED GOVERNOR

The synchronizer for paralleling the unit, or shifting the load.

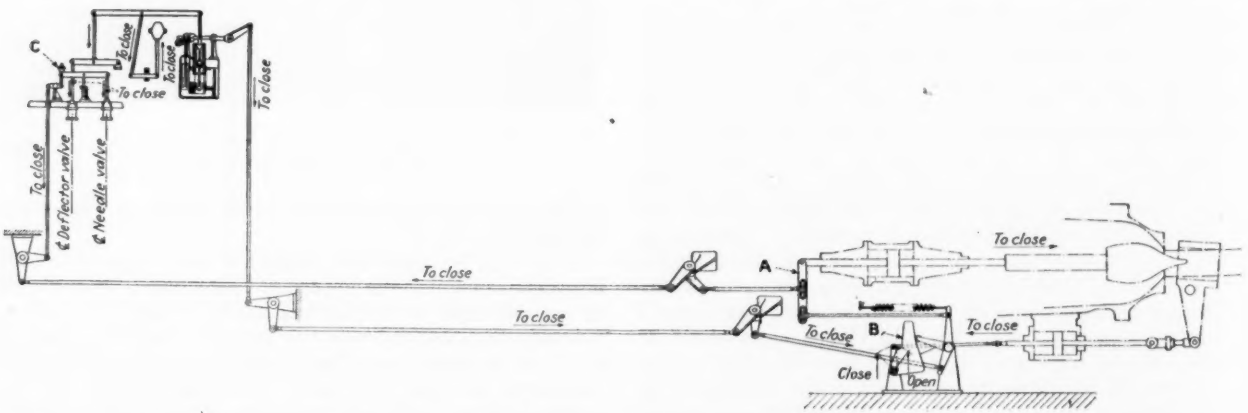
The speed droop device, for adjusting the difference between no-load and full-load speed.

The load-limiting device.

The solenoid shutdown.

The restoring mechanism which holds the control at rest at constant speed (or load).

The oil-pressure hand control.



The oil-pressure supply system.

Flyballs. Fig. 9 shows the flyballs of a modernized governor of older design, mounted in a cabinet and directly coupled to the driving a-c motor operating in synchronism with the speed of the turbine. It is of the improved (patented) supersensitive, spring-balanced high-speed design in which the centrifugal forces are directly counteracted by adjustable springs, so that only the resultant governor force is transmitted to the flyball collar, no pivoted joints being employed. The flyball collar is flexibly coupled (however, without lost movement) to a stem which rotates with the flyballs and serves as a pilot for the servomotor actuating the levers leading to the control valve. Thus the pilot describes a high-speed rotary movement which, combined with the axial movement on speed changes, requires a minimum of energy for its operation, but produces a fixed force in the differential oil-pressure servomotor actuating the leverage leading to the control valve. The speed-responsive element is thus relieved of any mechanical duty, but acts merely as a speed-responsive device, which, by means of the servomotor, at once produces a liberal force available at the slightest speed change.

These flyballs respond safely to 0.01 per cent above and below speed, so that prompt control of the output is assured, resulting in sensitive speed control with practically entire absence of tendency to hunt. The servomotor is coupled to the center of a single-arm lever, one end being adjustable by a handwheel or by an electric motor for switchboard control, starting, paralleling, or stopping the unit, and for changing the output when paralleled.

The opposite lever end is pivoted to the main floating lever, one end of which actuates the control valve, the opposite end receiving the movement from the servomotor actuating the output control of the unit. An adjustable relay-compensating oil-dashpot device is inserted into the relay connection, which permits of small droop compensation when the movement of the servomotor is slow, and a temporary larger droop on quick movement with gradual return to the smaller droop, and which is adjustable from 6 per cent to $1^1/_2$, or even 0 per cent when the unit does not operate in parallel with other alternators.

An adjustable load-limit device, either hand- or remote-

C
To close
To close
To close

electric-operated, permits of holding the output within desired upper limits without preventing complete no-load action in case of total load rejection.

The solenoid shutdown device acts upon the load-limit device for the purpose of complete shutdown of the unit in case of failure of current to the flyball motor, or for any other protective features, such as excessive bearing temperature, overload, or overvoltage.

Where no independent mechanical hand control is combined with the main servomotor, a hand control by means of oil pressure is provided in order that the automatic parts of the governor can be examined or repaired without causing a shutdown of the unit.

The governors of the Nantahala unit are performing a combination of deflector and needle movement, involving two control valves and a combination relay mechanism. This is illustrated diagrammatically in Fig. 10.

The floating lever actuated by the flyball servomotor is pivoted not directly to a control valve but to the center of a single-arm lever with a fixed point on one end and connection on the opposite end to the control valve actuating the servomotor which moves the jet deflector, the movement of which is transmitted to a relay shaft carrying a lever B with a cam against which a roller is held by a tension spring. The roller is part of a lever keyed to a relay shaft carrying two levers, one with relay connection to the compensating oil dashpot actuating the end of the floating lever for the purpose of restoring neutral or dead-beat condition.

There is another lever keyed also to the relay shaft which transmits the movement of the roller to a floating lever, the outer end A of which receives the movement of the servomotor actuating the needle or, if the latter is stationary, serves as fulcrum and thus causes a second relay movement transmitted over a double-arm lever to the control valve actuating the needle. By proper cam movement the final dead beat or neutral position of the control is such that the jet deflector touches the jet so that water is not wasted, nor is there a dead or lost active movement of jet deflector, all of which assures prompt speed control.

Since the deflector can act quickly while the needle must move slowly only by reason of the rate-limit devices controlling the flow of oil directly in the needle servomotor, as required by the long pressure pipe line, the stroke at point C may cause an excessive stroke of needle-control-valve piston. To prevent this the fulcrum of this lever is made flexible; however, always tending to restore to normal position.

By means of a handwheel at C, the relative position can be changed between jet deflector and power needle.

Likewise, the shape of the cam surface of lever B can be so formed that at small outputs the jet deflector does not clear the jet until it has to assume a certain size in accordance with the output demand.

This particular feature has proved especially valuable, as will be set forth in the discussion of the special requirements of speed control of the local power system which the Glenville unit is to take care of at times.

Flyball Drive. Current to the motors driving the flyballs of both governors is supplied by an independent generator directly coupled to the exciter of the generator. It is of the permanent-magnet principle, 2-phase with common circuit for connection to the two flyball motors.

The oil-pressure system serves each governor independently, or can be interconnected. The 15-hp a-c-motor-driven oil pumps pick up the oil from the two-compartment receiver tank directly below, and deliver it to the respective pressure tank, a check valve preventing backflow when the pump does not deliver oil under pressure. Combined with the pump is an unloader valve which opens when an oil pressure of 300 psi is reached and closes at a lower limit of about 270 psi in the pressure tank. With the unloader is combined a relay switch which shuts the motor down when unloading and starts it when oil must again be delivered to the pressure tank.

The oil returning from the governor discharges over a strainer into the receiver tank. All individual elements of this pump system are arranged to be readily accessible.

Setting of Unit Due to Flood Conditions. Fig. 11 shows the complete hydroelectric unit. It will be noted that no windows are provided at elevations below the top of the generator stator.

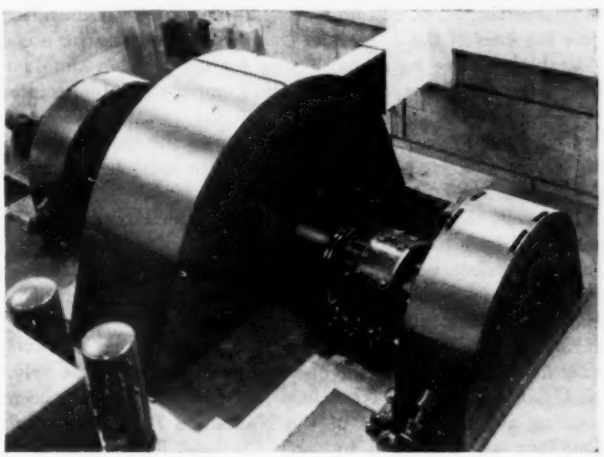


FIG. 11 INTERIOR OF STATION SHOWING TURBINE AND GENERATOR

The powerhouse is located in a gorge, and abnormal floods in the river might raise the water level so far above the floor that even the top of the generator would be submerged. This would drown the two water wheels, thereby materially reducing the output, if not rendering operation impossible. Since such floods are exceptional and of short duration only, it would be a waste of available head if the unit were placed safely above exceptional flood-water elevations. It was calculated that the kilowatthours permanently lost in normal times by this higher setting (and loss of head) would exceed the loss of kilowatthours output during the floods, with plant shut down completely. It was therefore economically feasible to locate the unit for the normal head condition, and merely shut it down during flood periods by providing tight-shutting gates at each wheel-pit outlet to keep the water from entering the wheel housings and putting them under pressure.

A system has been worked out which would permit setting the unit as high above lowest tail-water level as possible, putting the wheel housing under slight vacuum at the high head and under slight back pressure at extreme flood levels, however, without drowning the buckets. With this system the water level is held at safe distance by supplying compressed air, similar to what is now accomplished with Francis and propeller units, operated idly as synchronous condensers, so that they revolve in air instead of absorbing considerable power when revolving idly and submerged at normal speed. If the flood periods at Glenville were of longer duration it would have been economically feasible to provide for such an arrangement including auxiliary compressor equipment, which can be made automatic in case floods arrive unexpectedly.

Pressure and Speed Control. With a pressure conduit exceeding 16,000 ft in length, the critical time $\frac{2L}{a}$ at which a maximum

pressure rise of $\frac{aV}{g}$ will result is over 8 sec. Therefore, it necessitates a very gradual deceleration and acceleration of water on sudden load rejections and load increases in order to avoid pressure variations of a destructive value. Pressure control is assured by the rate of movement of the flow-controlling needles, which is fixed by admitting the oil into and out of the needle servomotors at a rate individual for each position of needle, entirely independent of the rate of governor action.

The system of the Nantahala Power and Light Company is connected through a rather long transmission line over mountainous country with the Aluminum Company's transmission line at Santeetlah, N. C. From Santeetlah the power is transmitted over the lines of the Aluminum Company of America for a considerable distance to Alcoa, Tenn., for use by the Aluminum Company. At Alcoa, the Aluminum Company's system is interconnected with the T.V.A. system.

Under these conditions, the regulation of the system will not be seriously affected when one of its large units becomes suddenly detached.

However, there are times when the Nantahala system is disconnected from the Aluminum Company's system at Santeetlah and is therefore isolated from both the Aluminum Company and T.V.A. systems. When this occurs, the system load of the Nantahala Power and Light Company amounts to a maximum of approximately 5000 kw. This remaining load has relatively wide fluctuations due to the operation of a paper mill at Sylva, N. C. Except for the Nantahala and Glenville plants, the remaining generator plants of the Nantahala Power and Light Company are too small to carry the load fluctuations satisfactorily.

The Glenville Plant was put into operation several months before the Nantahala Plant was completed.

The power company does not plan to use the Nantahala Plant for regulation of its local load due to the fact that it is a Francis-type turbine with a long tunnel and pipe line, operating under an exceptionally high head which requires slower governor-operating time, and which subjects the turbine parts to extreme cavitation and wear when operated at light loads.

It is therefore the duty of the Glenville unit to take care of the speed control when the load is restricted to the local system alone.

Under such conditions, prompter action is required than can be secured with the slow rate of movement of the needle. In other words, the water-wasting stream deflector must actively participate in the control of the momentary load changes of the isolated, small system.

When the unit operates in parallel with the Aluminum Company system, and in turn when that system is operating in parallel with T.V.A., the flywheel effect of all the rotating masses operating in synchronism is so large that even large, sudden load changes will cause only gradual changes in speed; in fact, so gradual that the slow-moving needle may be adequate to take care of it without causing the stream deflector to cut into the jet on sudden load rejections, i.e., if such load rejections do not increase the frequency more than 62 cycles.

At loads above 4000 kw per jet, the relative position of the deflector and needle is such that the deflector does not disturb the water stream issuing from the needle valve and therefore in no way influences the efficient operation of the unit.

At loads below 4000 kw per jet, the relation is such that the stream deflector remains partly in the jet, thereby deflecting some water from the buckets so as to be ready to back out of the jet promptly on load increases which the needle could not take care of by reasons of its slow rate of movement. Thus a materially better speed control is obtained for the small isolated system, although it inevitably involves a slight wastage of water at loads below 4000 kw.

Two requests of the power company had to be met:

1 That the frequency of the machine following full load rejection should be held to a minimum possible value, and that the unit should be promptly brought back to synchronous speed so as to be ready for prompt paralleling in a minimum length of time.

2 That penstock water-pressure swings, following full-load rejections and during light-load operation, should be held to a minimum.

To meet the first requirements, an overspeed switch was adjusted to close contacts at approximately 62 cycles. This over-

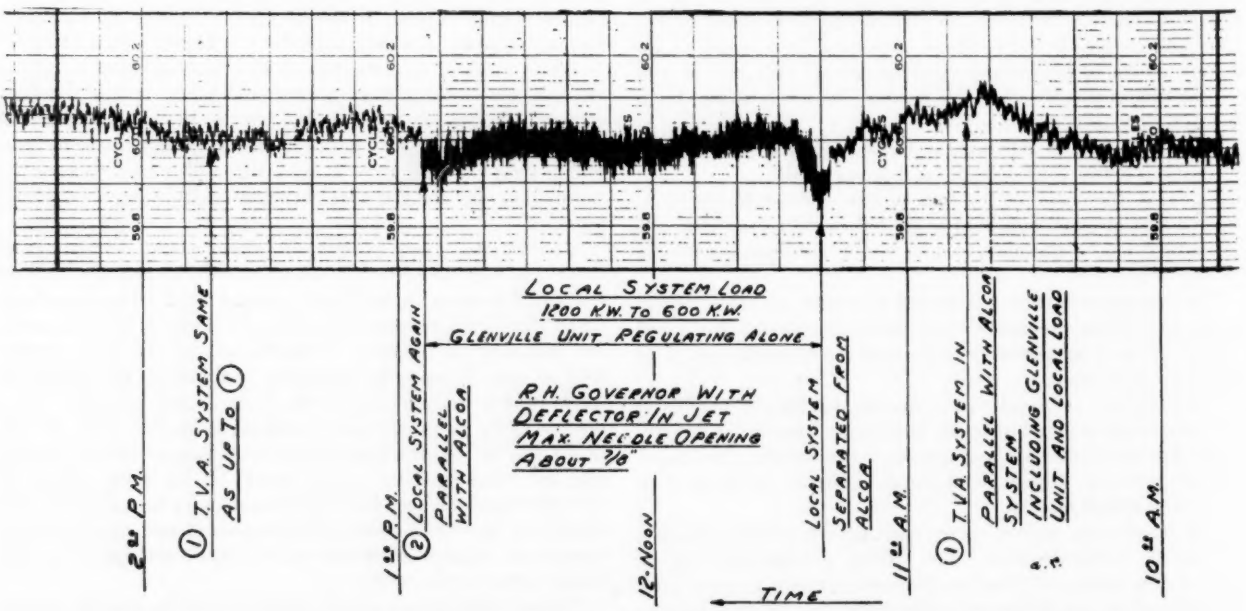

FIG. 12 RECORD OF CYCLES ON MARCH 31, 1942, UNDER DIFFERENT SYSTEM OPERATION OF GLENVILLE UNIT
(Voltage-limiting device is subsequently adjusted to release 15 sec earlier to allow voltage to return to normal in 40 sec after trip of breaker.)

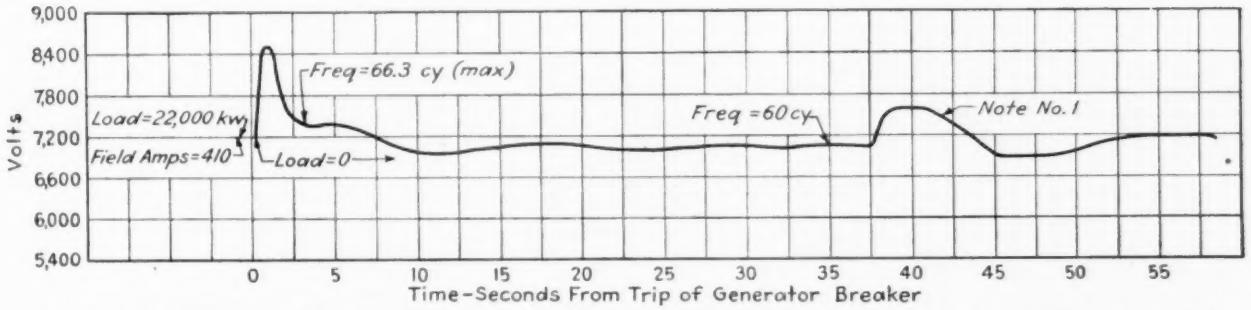

FIG. 13 CURVE SHOWING HOW VOLTAGE AT GENERATOR TERMINALS RETURNS TO NORMAL AFTER A LOAD REJECTION OF 22,000 KW

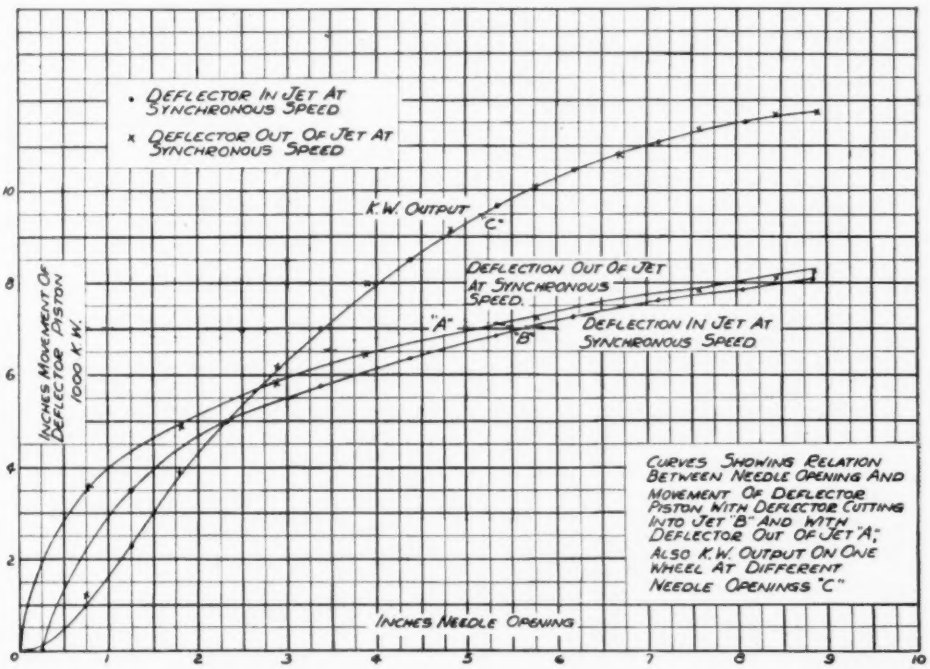

FIG. 14 CURVES SHOWING RELATION BETWEEN NEEDLE OPENING AND MOVEMENT OF DEFLECTOR PISTON WITH DEFLECTOR CUTTING INTO JET B, AND WITH DEFLECTOR OUT OF JET A; ALSO KW OUTPUT ON ONE WHEEL AT DIFFERENT NEEDLE OPENINGS, C

speed switch energizes a solenoid-operated valve to admit oil pressure to the deflector and also energizes the circuit to the synchronizing motor to operate it in the lowering direction. The synchronizing motor continues to operate until it returns the mechanism to the speed no-load position where the motor is stopped by means of a limit switch. The solenoid remains energized until the frequency returns to approximately 61.5 cycles. By means of these two devices, the latter of which was suggested by H. H. Gnuse, Jr., electrical engineer of the power company, the speed rise on rejection of 22,000 kw has been held to 66.3 cycles, as measured by a standard frequency meter, and the machine speed and voltage have returned to normal values within 35 sec, so that the unit was ready to be reparalleled with the system. These tests were made with a speed-droop setting of approximately 5 per cent.

During this load rejection, the penstock surges were very minor due primarily to the fact that, with the present adjustments, the needle never completely closes until the gate-limit adjustment has been operated to the zero position. The slight opening which remains in the needle valve very effectively prevents the customary penstock pressure surges which are obtained upon complete closure of such a valve.

Fig. 12 shows a record of the cycles on March 31, 1942. Up to point marked (1) it shows the cycles of the systems, Nantahala, Glenville, Alcoa, and T.V.A. interconnected, the Glenville unit operating with one water-wheel side only. At point (1) Glenville was detached from T.V.A. and Alcoa, to take care of the Nantahala system alone, with units at Franklin Plant and Bryson City operating on blocked governors to limit all frequency control to one Glenville governor. The load was around 600 kw with a total maximum of 1200 kw.

It will be noted that even one governor of the Glenville unit held the cycles within very satisfactory limits.

Fig. 13 is a record taken August 11, 1943, showing that voltage at generator terminals returns to normal after a sudden load rejection of 22,000 kw. The curve also indicates that the speed returned to normal 35 sec after the load change.

Fig. 14 shows the kilowatt output curve C and the inch movements of the servomotor piston actuating the deflector, curve A when the deflector does not cut into the jet under stationary needle positions, and B when it is set to cut into the jet. The points marked X on curve C apply to curve A, and those marked (·) apply to curve B. It will be noted that the outputs for the various needle openings do not vary appreciably whether the deflector cuts into the jet or not at normal speed. The adjustment, it will be noted, is so made that, at small jets (or needle

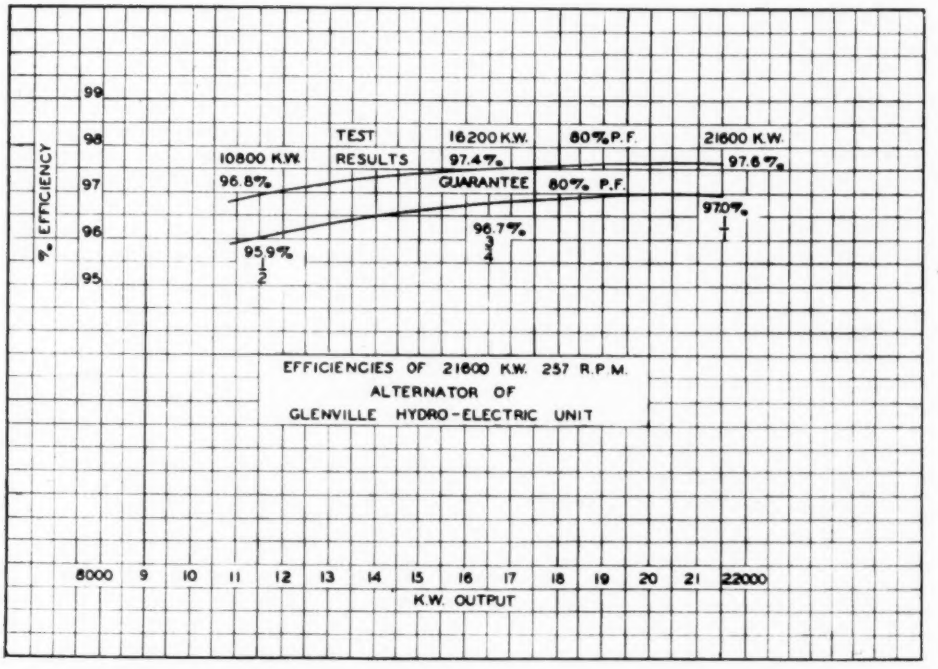

FIG. 15 EFFICIENCIES OF 21,500-KW 257-RPM ALTERNATOR OF GLENVILLE UNIT

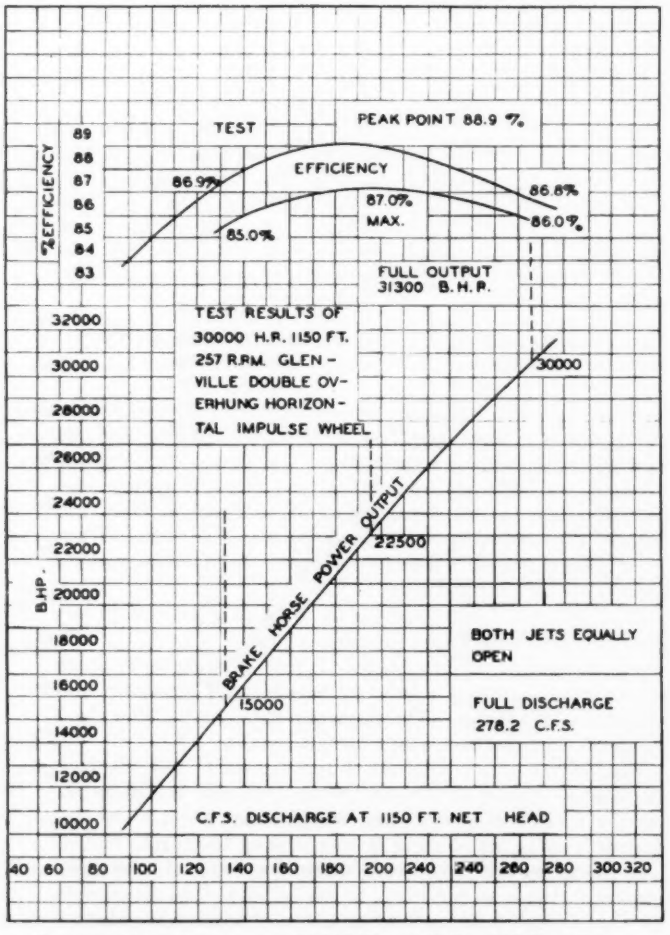

FIG. 16 TEST RESULTS OF 30,000-HP, 1150-FT, 257-RPM GLENVILLE DOUBLE OVERHUNG HORIZONTAL IMPULSE WHEEL

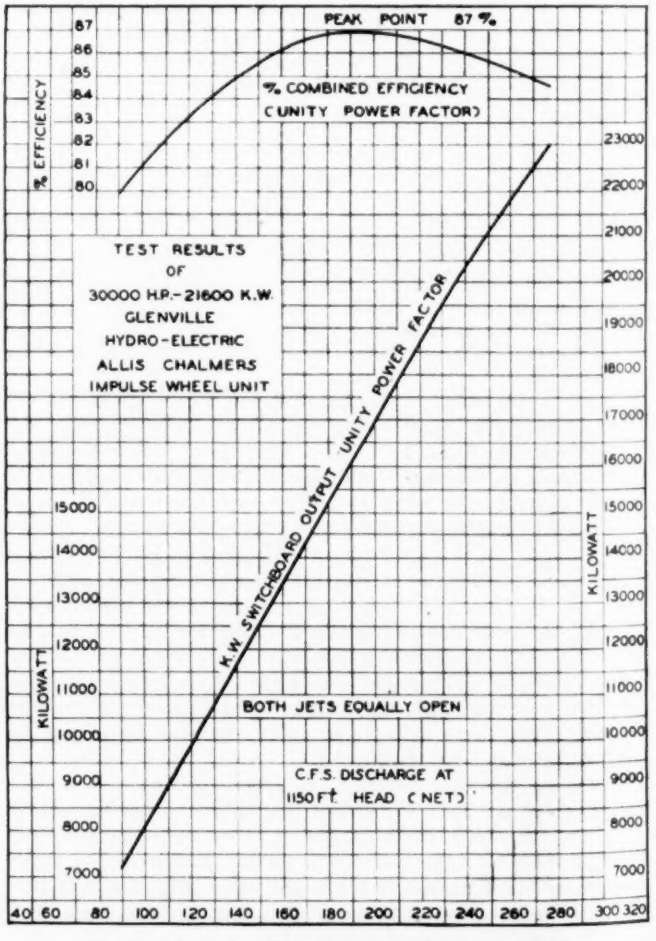

FIG. 17 OVER-ALL EFFICIENCIES OF GLENVILLE UNIT

strokes), the deflector cuts into the jet and is clear of the jet at larger needle strokes or outputs. This is desirable to insure equally close regulation on very small loads of the isolated Nantahala system.

Generator. The generator associated with this unit is rated 27,000 kva, 80 per cent power factor, 6600 v, three phase, 60 cycles, 257 rpm. The rotor is designed to provide the required 4,400,000 lb-ft² moment of inertia without the use of a separate flywheel. The poles are dovetailed into a laminated "floating" rim which is keyed to the fabricated spider. A damper winding is provided in the pole faces. The damper winding has no connections between poles but has the bars silver-soldered into the pole end plates. The stator core is made up of low-loss high-permeability silicon-steel laminations supported in a box-type welded plate steel yoke. The stator winding is of the double-layer lap-wound type, designed for minimum eddy-current loss.

A number of standard 10-ohm temperature-detector coils are embedded between coil sides. The generator is completely enclosed and is cooled by air circulated by axial-flow fans mounted on the generator rotor. Surface coolers are mounted below the generator to maintain the temperature of the in-going air to the generator at not more than 40 C. A main exciter and pilot exciter are direct-connected to the shaft. A rocking-contact-type regulator in the main exciter field controls the generator voltage.

The performance of this generator, as indicated by the tests made in August, 1942, and by the operating records is fully satisfactory. Conventional efficiency is more than 0.5 per cent above guaranteed values. Operating temperatures are well within those recommended by the standards.

Efficiency Tests

To determine the efficiencies of the entire hydroelectric unit, tests were made at the power plant, first to establish the generator efficiency to arrive at the actual brake-horsepower-output curve at the generator shaft.

The generator tests were made by purchasers' engineers and according to the A.I.E.E. Test Code.

Fig. 15 shows the guaranteed and the generator efficiencies actually obtained, indicating a substantial margin above the guarantees.

The water-wheel efficiency of the unit was determined by Dr. Norman R. Gibson's method, and in accordance with the rules of the A.S.M.E. Test Code in force.

Fig. 16 shows these guaranteed and the actually obtained efficiencies, indicating also a substantial margin above guarantees made.

Since the entire hydroelectric unit was designed and built "under one roof," so to speak, the individual test efficiencies of water wheel and of generator can be combined into one over-all efficiency from cfs discharge at normal contract net head to kilowatt output measured. These values are plotted in Fig. 17, as is also the corresponding over-all efficiencies as computed from the individual guarantees of water-wheel and generator efficiencies.

For a hydroelectric unit designed, built, and guaranteed by one single manufacturer, the "undivided responsibility" would permit of a simplification of the tests, in that a guarantee made from "water to switchboard" eliminates the necessity of establishing the individual efficiencies of the generator and turbine.

The Glenville unit is the only large impulse-wheel unit east of the Rockies, and its performance establishes a record in this country as regards water-wheel efficiency of practically 89 per cent.

Acknowledgments

The writer wishes to express his appreciation and thanks to Mr. J. E. S. Thorpe, president of the Nantahala Power and Light Company, and to his staff for the valuable assistance and co-operation rendered by contributing plans, photographs, and operating data.

Discussion

Robert Lowy.[2] Having had 25 years of experience in the construction of European Pelton wheels, the writer would like to point out certain differences between the trends of construction abroad and in this country, as follows:

1 The safety of the construction indicated in the paper is highly insured. The author himself mentions that the design, from a viewpoint of mechanical strength, is liberal. It may even be that the construction does not give a true picture of the current utilization of materials in the United States.

There was a great difference in Europe between constructions before and after the first world war; economy in the use of materials was far greater after the war.

This condition does not appear to have existed to anything like the same extent in the United States, owing to the fact that losses through the war were not as great, and there was no impoverishment. Perhaps this may change after the present war. However, we must not forget that, at the same time, impoverishment in Europe will be far greater than in America, and utilization of materials and labor in Europe will be forcibly magnified.

The construction of the Glenville plant as described is surely far safer than European installations. The principle of streamlining is also more highly developed than is the usual European practice.

2 A pertinent example is the construction of a turbine and generator for runaway speed. The price difference between a wheel which is built for a 1.8 runaway speed and for the runaway speed of only 1.2 is not very great; but, for the generator, the price difference is a multiple of the generator price. The runaway speed will in all likelihood never be reached. The European point of view is now that such constructions for complete runaway have in some way an exaggerated safety and indicate use of superfluous materials and labor. This amounts to a loss of national wealth. It would be the same as though a dam built for a 200-ft head were used for a 150-ft head. In Europe all large Pelton turbines have a special safety device which prevents racing of the turbine. This control is independent of the oil governor and also of the system of speed regulation. The safety device works hydraulically with the water pressure, sometimes with dead weight. Such constructions are indicated in a previous paper[3] by the writer.

A fundamental rule in using such safety devices is the instruction that these contrivances have to be tested either weekly or monthly. In this way operating personnel will become accustomed to having the unit running at higher speeds, limited by the safety device, and will not become alarmed in the event of racing.

Nevertheless, the generators for the Pelton plants in Europe are built up to date for the runaway speed, but owing to the safety device employed, the safety factor of the generator construction is tacitly lowered. Even with such construction, the safety of such units is far greater than that of steam turbines.

It seems there now exists an understanding among the producers in Europe to make the customer acquainted with the safety device to show that such a safety arrangement is more

[2] Baldwin Locomotive Works, Philadelphia, Pa. Mem. A.S.M.E.
[3] Yearbook of Waterpower, 1930–1931.

practical, more economical, and really provides a sufficient factor of safety. In a few years, maybe directly after the war, the construction of such turbine units to take care of runaway speed will be eliminated, and the arrangement of an efficient safety device will be all that is necessary, as in the case of steam turbines. As the price of the safety device is small in comparison with the construction for runaway speed, a real saving results. These remarks intend only to show the trend in Europe without recommending the use of them under existing economic conditions.

In studying the data given in the description of the Glenville Plant, the writer fails to find the closing time of the deflector servomotor. It would be interesting to know these relations because the speed rise by rejections of full power seems to be extremely high. The writer's experience indicates that to attain a smaller speed rise by full-power rejections is not so difficult. It is most difficult to obtain relatively small speed rise with small load rejection.

D. J. McCormack.[4] It is to be regretted that other American manufacturers have not accomplished any real development work on impulse wheels for many years past. European turbine builders have had engineers specializing on impulse turbines, and exhaustive studies and tests have been made continually to improve the results. Consequently, even 15 years ago, they were obtaining 89 to 91 per cent efficiency on field tests of impulse turbines. At that time American manufacturers thought they were achieving great results if they got 84.5 to 85.5 per cent efficiency. As a result, some of the large American installations were obsolete when they were installed. This turbine under discussion, showing 89 per cent efficiency on field test, is not in any way exceptional. If it showed 91 per cent efficiency or over, that would be notable. Seven years ago, the writer's company had field tests of 88 per cent on small units of only 2700 and 7000 hp.

Upon questioning, the author has stated that he would not take a chance with the American steel foundries, and cast the buckets solid with the disk or in a continuous ring. To date the writer's company has supplied 75 such runners up to 90 in. impulse diameter, which have stood up in service and are continuing to give fine results. Excellent castings are being produced which show up well under most rigid inspection. The construction is stronger, and a greater number of buckets can be used to obtain higher efficiencies. All buckets wear alike, so there is no advantage in replacing just one bucket. A whole new runner can be supplied for less than the cost of one set of buckets.

The author evidently does not favor the use of elbow-type nozzles. Of course, the answer to this is that higher efficiencies are being obtained with the elbow-type nozzle than with the straight-line nozzle originally developed by The Pelton Water Wheel Company, and the one under discussion which is only a slight modification of the Pelton design. However, the elbow-type nozzle must be designed properly.

E. B. Strowger.[5] The author has indicated that the pressure conduit of the Glenville unit is something over 16,000 ft long, and that no surge tank is installed. Further, the critical time of the pipe line is 8 sec. As a consequence, a long time of closure was chosen for deceleration of the flow. While the jet deflector acts to unload the wheel in about 2 sec, the needle stroke is timed to about 100 sec for full load.

The plant was tested by the Gibson method and, in view of the foregoing conditions, it may be of interest to describe briefly the application of this method and the results obtained. On

[5] Hydraulic Engineer, The Niagara Falls Power Company, Niagara Falls, N. Y. Mem. A.S.M.E.

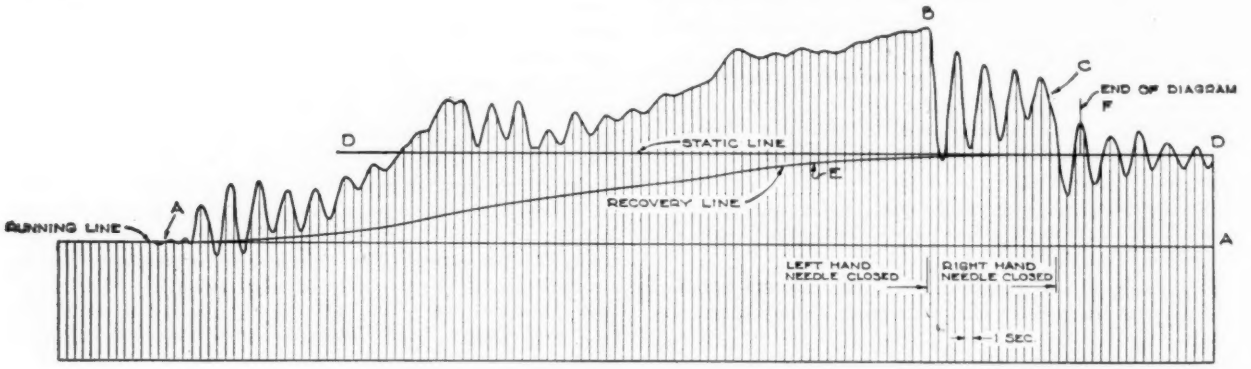

Fig. 18 Gibson Diagram 100 Per Cent Nozzle Opening
(Measured cubic feet per ser second, 280.1.)

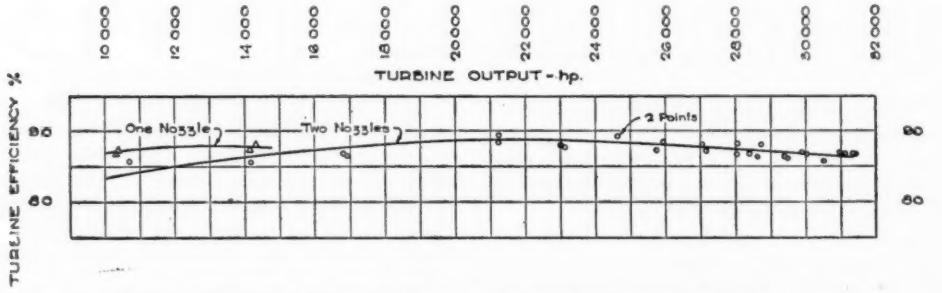

Fig. 19 Turbine-Efficiency Versus Turbine-Horsepower Curves

account of the long closing time, it was necessary to utilize a relatively long length of conduit in order to secure a pressure-time diagram of satisfactory size. The Gibson piezometers were therefore placed 378 ft apart. Using this length of pipe, the differential pressure-time diagram shown in Fig. 18 of this discussion, was obtained for the rejection of full load. The velocity in the pipe line was reduced from about 10 fps to zero during the gate closure.

The delineation of this diagram shows an area of approximately $13^1/_2$ sq in., which corresponds to a discharge of 280 cfs flowing in the pipe just before closure started. During each test run, the two nozzle openings were adjusted to the same value, and it was assumed that each wheel used 50 per cent of the total discharge. The timing of the two needles was not adjusted prior to the test to exactly the same value. For the diagram shown, the left-hand needle had a closing time of 88 sec, and the right-hand needle had a timing of 103 sec by stop-watch measurement. This can be checked from the diagram by counting the second marks from *A* to *B* for the left-hand needle and from *A* to *C* for the right-hand needle. *A*-*A* is the running line of the diagram, *D*-*D* the static line, and *A*-*E* the recovery line. The end of the diagram is at *F*.

Since the author showed the efficiency curve of the wheel plotted with cfs as abscissas, Fig. 19 is presented to show the variation of efficiency with turbine horsepower. The test points are shown on the curve which is very flat from 10,000 to 31,000 hp.

Author's Closure

Dr. Lowy's remarks that the safety factors of American waterwheel designs are materially higher than those of Europe are undisputed. It is a question as to whether the element of safety is to be invested in the unit itself, or into a safety device as an auxiliary. Today many power companies, well experienced by long years of operation of units, still prefer to witness a unit operating safely at its highest runaway speed without a safety device, because such a safety device does not guarantee absolute absence from failure even when its action is being witnessed during one test case.

Mr. McCormack's statement that field tests made seven years ago with units of his company's make showed efficiencies of 88 per cent should have been backed by a proof of authenticity equal to that of the Glenville test. It may be stated also that the author's company built impulse wheels with straight-flow needle-controlled nozzles as early as 1908, although not yet of the capacities of the world record as to physical size of the wheel at San Francisquito No. 1 plant of the Bureau of Power and Light, Los Angeles, Calif.

Mr. Strowger has answered Dr. Lowy's question by stating that the stream deflectors are moved in two seconds. This does not preclude the possibility of even a quicker rate if it should be desired.

Efficiency Analysis of Pelton Wheels

By ROBERT LOWY,[1] PHILADELPHIA, PA.

This paper is devoted to a discussion of the various flow losses in a Pelton bucket. Special attention is given to whether or not such losses are avoidable. Three phases of flow are investigated in detail, i.e., the entrance, the main flow, and the outlet. The author describes the application of a new method to study such movements. The investigation is carried out on a stationary bucket with a jet having the same entrance conditions as the jet on a rotating bucket. The influence of the lip on the entrance conditions is shown by example, and the conditions in the deflected part of the jet are indicated. The loss through the deflected jet is shown in kinetographic representation. A notable loss due to crossing of streamlines on a bucket is discussed. Finally, a list of all possible losses is tabulated.

THE efficiency of Pelton wheels heretofore built has been relatively high, and it is probable that the securing of such good efficiencies is the cause of the lack of much close study and analysis as applied to this type of unit. On the other hand, more study has been given to the reaction type of hydraulic turbines, both of the Francis and propeller type, due to the past necessity for improving the efficiencies of such units.

A stage has now been reached, however, where efficiencies of the reaction type often surpass those usually obtained from the impulse type; and it seems desirable to develop methods whereby the impulse-wheel efficiencies may be raised as the result of analyzing the various losses with a view to reducing them.

Thus it became obvious that the current simplified theory is not sufficient, and that a more exact and comprehensive examination of the flow would be necessary. The investigation of the flow of a jet on a revolving bucket is very complicated, and a complete theoretical examination is not feasible. It is possible to find certain hydraulic potential motions which have some resemblance to the flow mentioned; but these examples are relatively far from the true condition. Nevertheless, they are of great help in arriving at a better understanding and a clearer explanation of the actual phenomena.

Pelton-Wheel Nozzle and Bucket Details

The essential parts of a Pelton wheel involved in this analysis are the nozzle and the bucket. The nozzle consists of the orifice ring and the needle. Both parts form the control valve for the power-supply line. The bucket consists of two ellipsoidal half-shells connected with a common middle edge, the splitter. The outer edge of the bucket is provided with a lip which varies greatly in form for various designs. The lip results from the need to form a suitable entrance for the jet coming from the nozzle.

One of the principal differences in the general appearance of buckets lies in the depth. There are flat and relatively deep buckets. Nevertheless a practical investigation reveals that the relative depth has no determining influence on the efficiency, regardless of the specific speed.

The efficiency of a complete wheel, obviously, can be divided into efficiency of the nozzle and efficiency of the wheel itself, these parts being absolutely independent of each other.

The efficiency of a nozzle can be found by direct measurements; and it has been established that, in general, a loss of 2 to 3 per cent can be attributed to this part of the unit. A precise test of a special nozzle and needle at full opening gave the highest efficiency of 99.8 per cent. At 15.4 per cent opening the efficiency was 98.1 per cent. Material improvement of these values is not possible.

The efficiency of the wheel itself results from a great number of different losses. All these losses are relatively small, but in total they are considerable, so that the complete efficiency of a Pelton wheel reaches a maximum of 87 to 91 per cent.

Any increase in the efficiency can be obtained only by reducing, one by one, the separate losses. Therefore it is particularly essential to determine all the losses and to know how to deal with them.

This study will consider all losses in a bucket, and special attention will be given as to whether or not the loss is inevitable.

Losses in Pelton-Wheel Bucket

It has been found in many practical examples that low efficiency occurs mostly due to losses which are not known generally, and which are in some degree avoidable.

In considering the analysis of the losses, first we have those due to extraneous forces which are not dependent upon the flow. These are mechanical losses in friction in the bearings, and the air resistance of the rotating wheel. Both are inevitable and have to be minimized by proper adjustment.

Concerning the losses dependent upon the flow, we must distinguish principally three phases, as follows:

1 The entrance of the jet into the bucket, partially on the splitter, partially on the lip.
2 The flow in the bucket itself.
3 The discharge or the outflow from the bucket.

Each phase shows a loss which is necessary and which can be reduced only to a certain degree. A complete elimination of these losses is impossible. They are connected with the function of the flow itself and are in a certain sense necessary in the turbine system.

The principal loss is the discharge loss. It is necessary for the water to flow away from the bucket; and therefore some velocity head must be sacrificed to do this work. Then we have the loss due to friction on the surface of the bucket. Even the smoothest surface has some resistance, but with proper surface finish this loss can be reduced greatly. Finally we have the entrance loss, a singularly involved loss, which is dependent upon the specific speed.

These three losses are inevitable and cannot be avoided. Only arrangements with highly decreased losses are possible. The efficiency of a Pelton wheel is therefore determined by at least all these losses. It is necessary to take care of all the relevant circumstances to be able to reduce these losses, by proper adjustment, and to reach a high standard of performance.

In addition to the foregoing necessary losses, there may be other losses which appear not infrequently. Such losses are connected with the flow, but they are avoidable. Therefore an arrangement should be chosen so that such occurrences will be completely avoided, or the losses should at least be reduced as far as possible.

Study of Flow in Bucket

To evaluate these losses, we have to investigate the flow in the bucket. It should be considered principally that the flow of the jet on the bucket changes because the nozzle through which the jet flows is fixed, whereas the bucket is moving. Of course, there is always an intermittent movement at the beginning of the impact of the jet. The impact of the jet on the bucket takes place both on the lip and on the splitter. Where the impact occurs on the lip, the jet is divided into two parts. One part remains flowing on the bucket and forms the impinging jet branch. The second part, the deviated jet branch, flows past the bucket and reaches the next bucket.

If the impact occurs on the splitter alone, two symmetrical jet branches result. These two branches of the jet on the bucket will then be turned back. The impact on the splitter takes place at different points, and, furthermore, every single water filament will have a different impact angle on encountering the splitter.

The construction of the impact angle, i.e., the entrance triangle, is well known and is represented in Fig. 1. In this figure, for one water filament a, the absolute velocity V, the peripheral velocity u, and the relative velocity v are indicated. Subsequently, the complete relative paths a', b', c', for three water filaments a, b, and c, are traced, which is a well-known construction. Furthermore six positions of a bucket are represented for the following cases:

1 First contact of a single water filament
2 First contact of the half jet
3 First contact of the complete jet
4 Last contact of the complete jet
5 Last contact of the half jet
6 Last contact of a single water filament.

It is necessary, of course, to choose the number of the buckets on a wheel so that the last drop encounters a bucket and no outflow between buckets is possible.

These procedures are generally known and used in practice. They contribute to a good efficiency of the bucket, but this alone does not give absolute assurance that a high efficiency will be reached.

Nevertheless, there have been cases in which buckets designed in conformity with these considerations, and with very smooth bucket curvatures, have given mediocre results. Investigations of the running wheel and the model, with and without stroboscopic instruments, have brought forth no explanations of such discrepancies. To study such cases and to find and eliminate disturbances, the author used an original method which gave excellent results.

Use of Fixed Bucket for Experiments

This method consists of a thorough investigation of the flow on a fixed bucket, but with a jet striking the bucket at the correct relative angle, under the same entrance conditions which exist on the running bucket.

The primary objection which can be made against this method is the fact that the flow on a stationary bucket is not identical with the flow on a rotating bucket. This is, in general, correct; however, the difference is not so far-reaching that this method cannot be applied. This can be proved easily by an examination of the flow.

We can distinguish three different kinds of flow motion:

1 The relative motion of the jet and the rotating bucket.
2 The absolute motion of the jet.
3 The flow of a jet on a fixed bucket with practically the same entrance conditions as for case 1. We designate this briefly as "absolute" motion but we repeat that this "absolute" motion has nothing in common with the motion in case 2.

This particular method involves an investigation of the motion in case 3 with the reservation that case 1 should be used.

We may now examine the difference between case 1, the relative motion, and case 3, the particular "absolute" motion. Regarding the course of the flow, the difference between the motions on the various parts of the bucket is not the same.

The greatest difference shows the part of a streamline which lies in a plane of rotation. This is the case which shows the relative paths in Fig. 1 (a', b', and c'). The absolute motion on the fixed bucket would be a straight line, the tangent to the relative path, therefore identical with the direction of the relative velocity v. A streamline on a bucket will run only to a small amount in a plane perpendicular to the axis of rotation. Therefore only a small difference between tangent and curved line can result.

No difference between "absolute" and relative motion will be found for a streamline which is formed by an enforced guidance in the bucket with a cylindrical surface, the cylinder being parallel to the axle of rotation. Here the relative path and the absolute path are always identical.

All other streamlines show differences which lie between these two extreme cases. If we desire to know the specific difference in the course of the flow on a bucket, we can trace a sketch which shows in which sense and to what extent such differences occur. Fig. 2 shows, on a bucket, different "absolute" and relative paths:

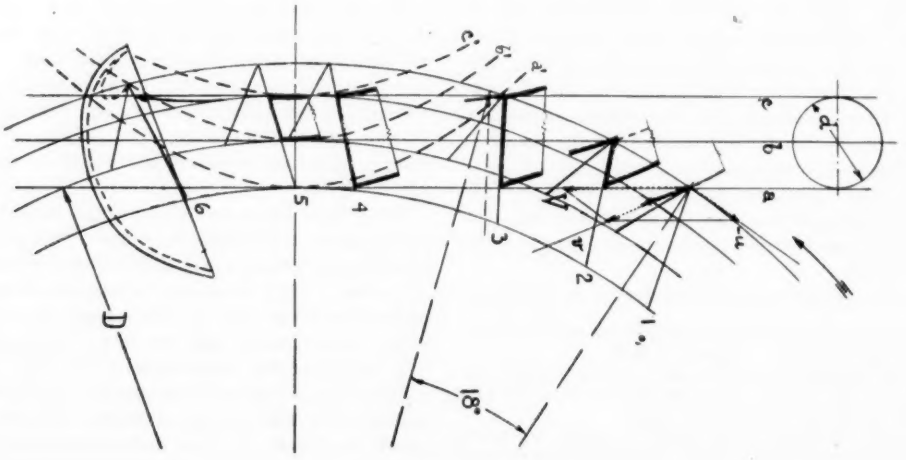

Fig. 1

The "absolute" paths are given in full lines 1, 5, the relative paths are given in dashed lines 1, 5. We conceive that the paths 1 and 5 in Fig. 2 are practically the same in both motions. The paths 2, 3, and 4 show deviation in a rotating system wherein path 3 shows the greatest deviation.

It is now essential to note that, even if relative and absolute courses of the flow are identical, the motions on the fixed bucket and the rotating bucket are not the same. This difference is, of course, due to the bucket rotation and is expressed by the value of the velocity.

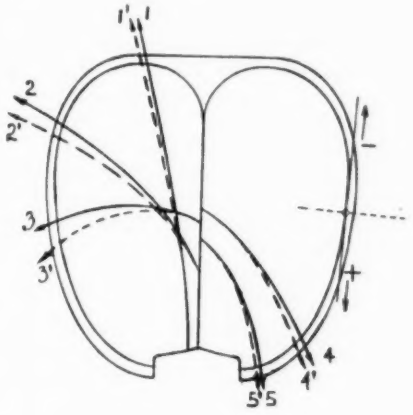

FIG. 2

In a stationary system, the velocity remains constant, if we do not take the losses into account. In a moving system with free flow, that is, with no essential pressure in the flowing liquid, the relative velocity is no longer constant but maintains the following relation according to the fundamental equation: For two points, 1 and 2, with the corresponding velocities, we have

$$\frac{u_2^2 - u_1^2}{2g} + \frac{v_1^2 - v_2^2}{2g} = 0 \quad \ldots\ldots [1]$$

where u_1 and u_2 are the peripheral velocities, and v_1 and v_2 are the relative velocities.

This is an equation which could be derived also from mechanical principles alone inasmuch as in the free flow there is no difference in pressure. The sense of this equation can more easily be understood by a simplified example. If we suppose that $u_2 = v_2$ (and this will be nearly the case with high efficiency), then also $u_1 = v_1$. Now it can be established in general that "the relative velocity in the rotating system changes in the same degree as the peripheral velocity."

We now see clearly that the motion on a bucket in a fixed system, as compared with a rotating system, has a different velocity, even if the path should be the same. If, for instance, the particle comes to a greater radius, the relative velocity increases and vice-versa. But, as we know, the difference in the peripheral velocity of a bucket is relatively small, due to the fact that the bucket for low and moderate specific speeds is small in comparison with the diameter of the wheel. Therefore, there can arise only a small degree of difference in the relative velocity.

Equation [1] provides an explanation of the mixing loss. We conceive that the relative velocity at one point of the water filament will be different from the relative velocity at another point of the water filament *c*. But both relative velocities are not connected by a relation similar to Equation [1]. This will be clear by the way in which the relative velocity was found, see Fig. 1. If the two water filaments, *a*, *c*, in the relative system, should represent only mechanically separate particles, and if the relative flow of these particles were in a manner free and independent, then the existence of different relative velocities would be possible.

But both filaments, *a*, *c*, are, in fact, not independent; they represent streamlines of a hydraulic continuity, i.e., confined flowing liquid, in which, between filaments, pressure transformations sometimes arise. The relation for this transformation can be given in a form similar to the Bernoulli equation for absolute motion. We have in an absolute system, the Bernoulli relation with

$$\frac{V^2}{2g} + \frac{p}{\rho} = \text{const} \quad \ldots\ldots [2]$$

In a relative system there exists the relation

$$\frac{v^2}{2g} + \frac{p}{\rho} = \text{const} + \frac{u^2}{2g} \quad \ldots\ldots [3]$$

It is important to know that such a connection exists between the velocities of a closed stream in a relative system. The constant can be regarded as similar to an energy capacity and remains, for a closed system, invariable. It is essential to understand that, in the present case, the single filaments do not have the same energy capacity, due to the fact that the relative velocity is not even at the same radius.

To explain this, we can make a comparison with a reaction turbine using water at different pressures. We conceive that in one runner this cannot be done without losses. If we try to use water at two different pressures in one runner, we receive a mixing of both pressures with a loss in energy. It is, in fact, necessary that an exchange in the energy capacity take place between the various water filaments on the bucket.

To show these relations in a practical example, consider Fig. 1, as the diagram for a wheel with the following data:

Head		1000 ft
Jet velocity	$V = \sqrt{(2gH)} =$	252 fps
Water quantity		24.2 cfs
Jet diameter	$d =$	4.2 in.
Wheel diameter	$D =$	59.6 in. = 4.97 ft
Power		2380 hp
Wheel speed	$n =$	450 rpm
Ratio	$D/d =$	14.2
Specific speed	$n_s =$	3.87

Now examine Fig. 1, position 3, "first contact of the complete jet," and we have the following velocities for the border filaments:

Peripheral velocities	113.5 fps	129.4 fps
Relative velocities	148.5 fps	133.0 fps
The corresponding heads are:		
For peripheral velocities	201 ft	261 ft
For relative velocities	345 ft	276 ft

The energy capacity measured in feet, as difference, is therefore 114 ft and 15 ft.

The jet on the surface of the bucket should present, in relative motion, a hydraulic continuity, with uniform energy capacity in every filament. But this is not the case. Therefore an energy exchange between the different filaments has to take place, owing to the fact that all filaments on the running wheel do not start with the same energy capacity.

The loss consists in the appearance of vortex motions between the various water filaments with an equalization of the different energy capacities, i.e., a mixing loss.

However, there is no need for a complete equalization of the energy to take place. If two filaments should be separated, then the closed system would be disturbed, and every filament could

remain separated with its own capacity, and no further mixing loss would occur.

This difference in energy capacity increases essentially with greater specific speed, that is, if the diameter of the jet is relatively larger in comparison with the diameter of the wheel. In this case, the influence of these appearances on the efficiency of the wheel is very unfavorable.

In case of an investigation of a stationary bucket, there is no mixing loss, the water impinging on the bucket with the same speed throughout. This fact consequently results in a difference between relative and "absolute" motion.

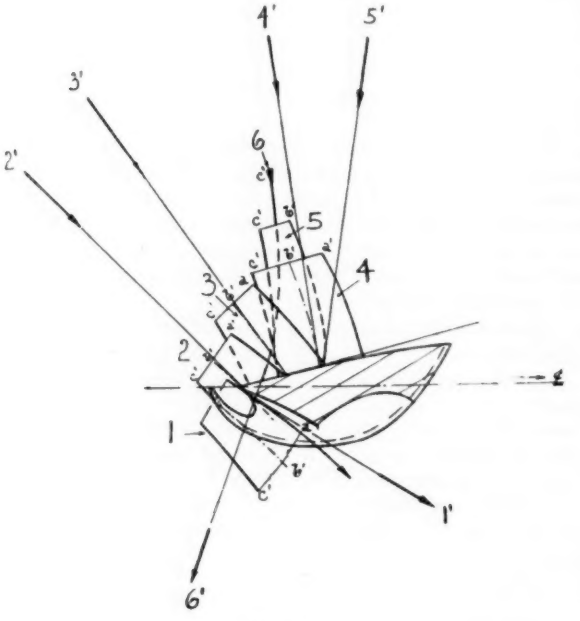

FIG. 3

Consideration and reflection show now that all these divergences and velocity differences are not so far-reaching that the general character of the flow would be changed. In fact, appearances in a stationary system are practically the same as in a rotating system.

By such means, it is possible to make an investigation of the flow on a stationary bucket, and this contributes deeply to the knowledge of the flow, as has been found by experience with this method. If desired, and as sometimes may be necessary for scientific investigations, it is also possible to rectify exactly the motion on a stationary bucket to obtain a precise reproduction of the flow in a rotating system. For practical purposes, however, an exact rectification is not necessary. Besides, we know that the flow of a jet on a surface takes place with a spreading effect, with an increase of the width. Then the outer water filaments of the surface are no longer parallel. The calculation could be made only for the filament which represents the center of gravity. But the side deviation of the border streamlines cannot be computed. The calculation is therefore from the beginning not very helpful.

We have defined the "absolute" motion as a flow on a bucket which shows the same entrance conditions as the flow in relative motion. In Fig. 3 the different positions of the impact of a jet on a stationary bucket are designated. This construction is developed from Fig. 1 which shows the same bucket in its six different positions. In the same way, in Fig. 3, we have six different positions for the jet on the stationary bucket.

It now becomes possible to form a simple arrangement to bring a nozzle into such position that the jet will have the same entrance conditions as in the relative motion. Such a testing arrangement was used for trial performance, and it was not difficult to make all necessary measurements.

The investigation of the flow on a stationary bucket seems to call for an arrangement where these various directions of the impinging jet will be secured; but it has been established that this sharp connection between jet and bucket is not necessary.

We know principally that the position of the impinging jet on the bucket is dependent upon the peripheral velocity, i.e., number of revolutions. With a change of the peripheral velocity, for instance, during speed regulations, or as a result of differences in pressure, a change of jet-impact conditions must take place. The flow should be regular without disturbances for a range of angles on the impinging jet; and therefore it is not advisable to make the investigation only for the computed main positions.

It is indeed practical to mark the main directions of the impinging jet on the bucket by painting. Nevertheless, the investigation will also embrace directions which are not far from these computed directions. In this way the investigation will be enlarged and will be made wider in scope than if merely fixed by the normal entrance conditions.

Cavitation and Bucket Efficiency

Now what can be proved by such an investigation on a "fixed" bucket? There are two principal factors which can be studied: The problem of cavitation and the problem of efficiency. Concerning the efficiency, we distinguish, as before, three phases of the flow, and consider first the discharge.

The best efficiency of a wheel will generally be reached if the value of the relative exit velocity is nearly identical with the value of peripheral velocity, or if the absolute exit velocity is perpendicular to the peripheral velocity. It is obvious that the absolute velocity has to be as small as possible, because the velocity head of the absolute exit velocity is a real inevitable loss, as previously mentioned.

To explain these relations, Fig. 4 shows all the relations at the discharge for a filament. We see in this figure that the absolute exit velocity consists of two components. The component perpendicular to the brim of the bucket is useful, inasmuch as this velocity carries the water away from the bucket. The second component which is directed parallel to the brim of the bucket and gives practically no help in discharging water is practically useless and should be eliminated completely, if possible.

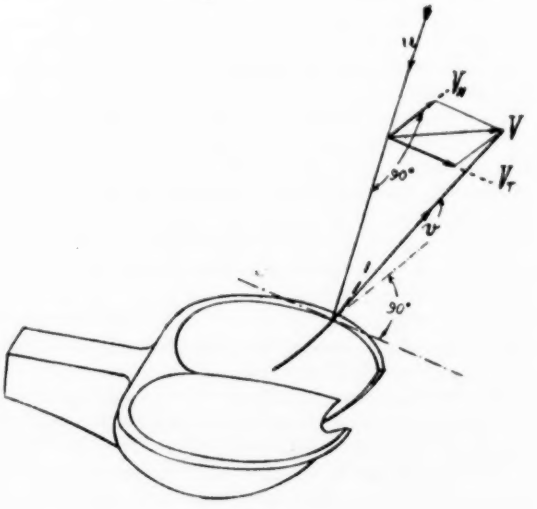

FIG. 4

We know that there is always a spreading of the jet on the bucket. Then the filaments on the border will always contain useless tangential components. Therefore a spreading with very inclined border lines should be avoided as far as possible. On the other hand, it should be borne in mind that the relative motion on the bucket is in a certain way different from the "absolute" motion on the fixed bucket. It is just this tangential component at the discharge which forms a principal difference between the two motions (Fig. 2).

Let us consider now the "absolute" flow on a fixed bucket, and imagine that we have found and tabulated the effective relations for each jet position. The tangential component of the exit velocity can be positive in some points, that is, directed outward, perhaps in some points negative (see Fig. 2). To arrive at a relative motion on the bucket, it is necessary to make the corrections with an additive positive tangential value; this means that points which show, in the absolute motion, an extreme negative tangential exit component will have an amelioration of the discharge on the rotating bucket. A flow on a fixed bucket, which shows a great positive tangential exit velocity, will suffer a deterioration in the case of the rotating bucket. In this case, a change of the bucket will be advisable, to reduce the tangential exit loss.

The examination of the discharge on the bucket is therefore reduced in finding the exact direction of the discharge velocity, especially with reference to the brim of the bucket. It is obvious that all positions of the jet under the corresponding impact angle should be investigated.

With these trials, it is necessary to determine that the jet coming from a bucket does not interfere with the preceding bucket.

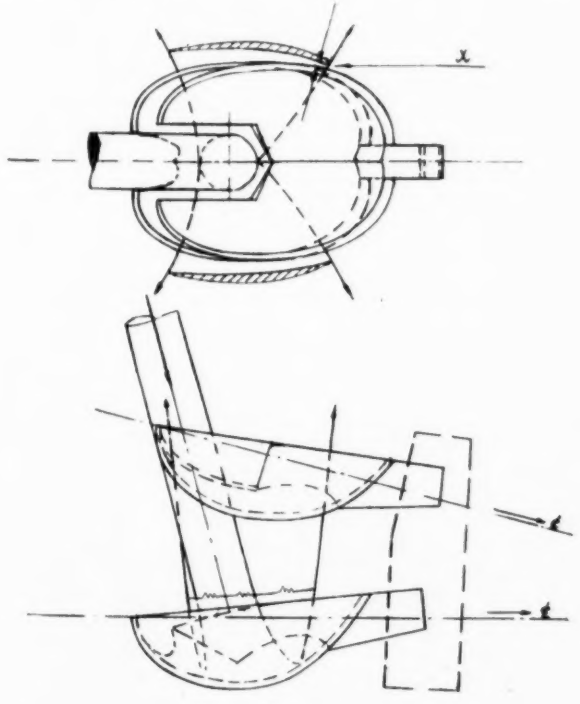

FIG. 5

There is a simple way to make all investigations in one by using a dummy bucket, Fig. 5. This dummy bucket has a far greater cutout than the normal bucket, so that the jet can be brought into the correct position with reference to the test bucket. In Fig. 5, the jet coming through the dummy bucket impinges on the test bucket, with nearly the same entrance conditions as on the rotating bucket. The discharge of the jet is, by this arrangement, clearly visible and easy to register.

In this way, it is possible to make exact measurements concerning the discharge of the jet. These measurements can be essentially simplified if two similar graduations are used on the test, and on the dummy bucket. It is also possible thereby to find the smallest clearance between jet and the preceding bucket, in this case the dummy bucket (see Fig. 5).

It is necessary to remark that a slight touching of the preceding bucket by the flow can be tolerated without sacrificing the efficiency, but such a condition can easily cause cavitation at high heads.

The inclination of the bucket relative to a radial line on the wheel should likewise be investigated. It is well known that there exists for the bucket a certain position with the highest efficiency. By changing this inclination slightly, there is almost no influence on the efficiency. On the stationary bucket, it will be found that by changing the inclination, a change in the discharge at the inner and outer part of the bucket brim will result. The discharge on the side of the brim remains practically unaltered.

Trials on a stationary bucket have proved, further, that the discharge from the bucket is not alone dependent upon the outlet form of the bucket, i.e., the brim itself, but also on the manner of the entrance relations. In this way, the splitter and the lips form a deciding factor for the discharge.

The investigation of the lip is now necessary in a twofold manner. We are interested in a correct form with reference to the discharge relations, that is, for the impinging branch of the jet. We are also interested in knowing what will happen to the deviated jet branch.

On Pelton buckets, there are now different forms of lips. The simplest form is that of an edge perpendicular to the splitter. Other forms have evolved by forming a bucket as a double ellipsoidal shell and by a cutout in the front of the bucket, the cutout being a surface of rotation with the center in the rotation axis. Another cutout is made with a cylindrical surface with its axis in the average path of the jet, and various other forms are also possible.

Thus quite diversified forms of lips may result, each form having certain advantages and disadvantages. The investigation of such lips gave such wide variety of results that it was practically impossible to classify them.

It was decided therefore to clarify the problem, and to study, first of all, the impact of the jet alone under simplified conditions. A series of tests was made to investigate the impact of a jet on specific plates under conditions similar to those arising in the bucket. This is practically equivalent to the arrangement of a lip with an edge perpendicular to the splitter.

EQUIPMENT AND TEST PROCEDURE

The testing equipment for this purpose is shown in Fig. 6. Testing plates are brought into a circular jet at different positions, Figs. 7 to 12, inclusive.

A description of the procedure is given, first, with an attempt to classify the measurements. The results in connection with the bucket will be discussed later. The results which were obtained with two test plates are shown as A and B, Fig. 7; Figs. 8 and 9 show the jet impinging on the plate A. Plate A was selected from a number of others as the most favorable arrangement. The thickness of plate A is very small, being only 6 per cent of the jet diameter. Experience has shown the importance of a clear distinction between the front part δ_f and rear part δ_r of the edge angle δ. The values of these angles are designated in Figs. 7 and 8.

The deformation of the deviated jet shows surprising forms. In Fig. 8 we see the form of the jet in two cross sections by using an

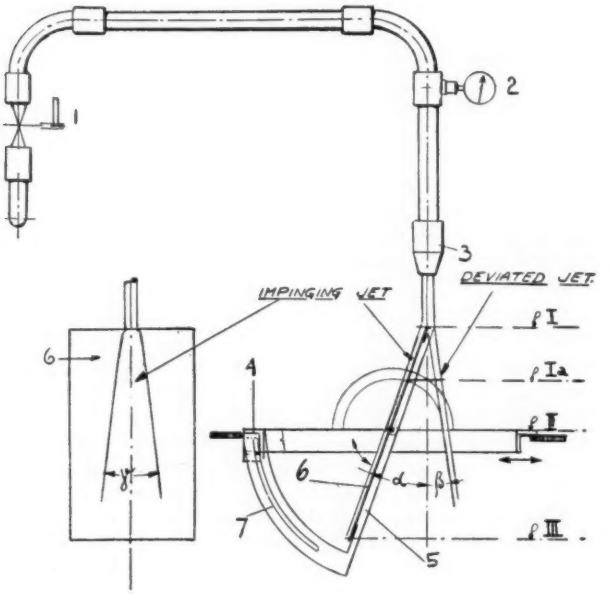

FIG. 6

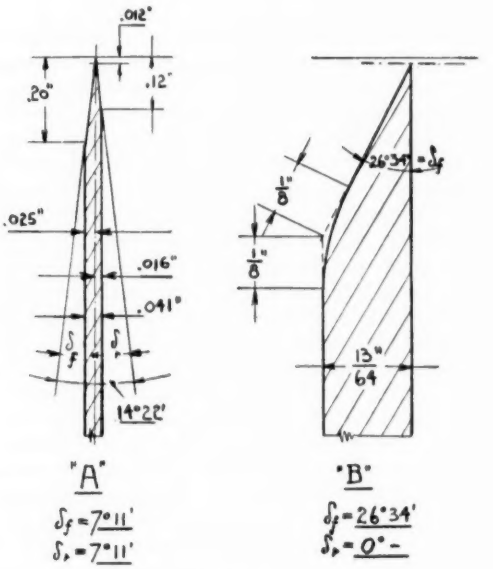

FIG. 7

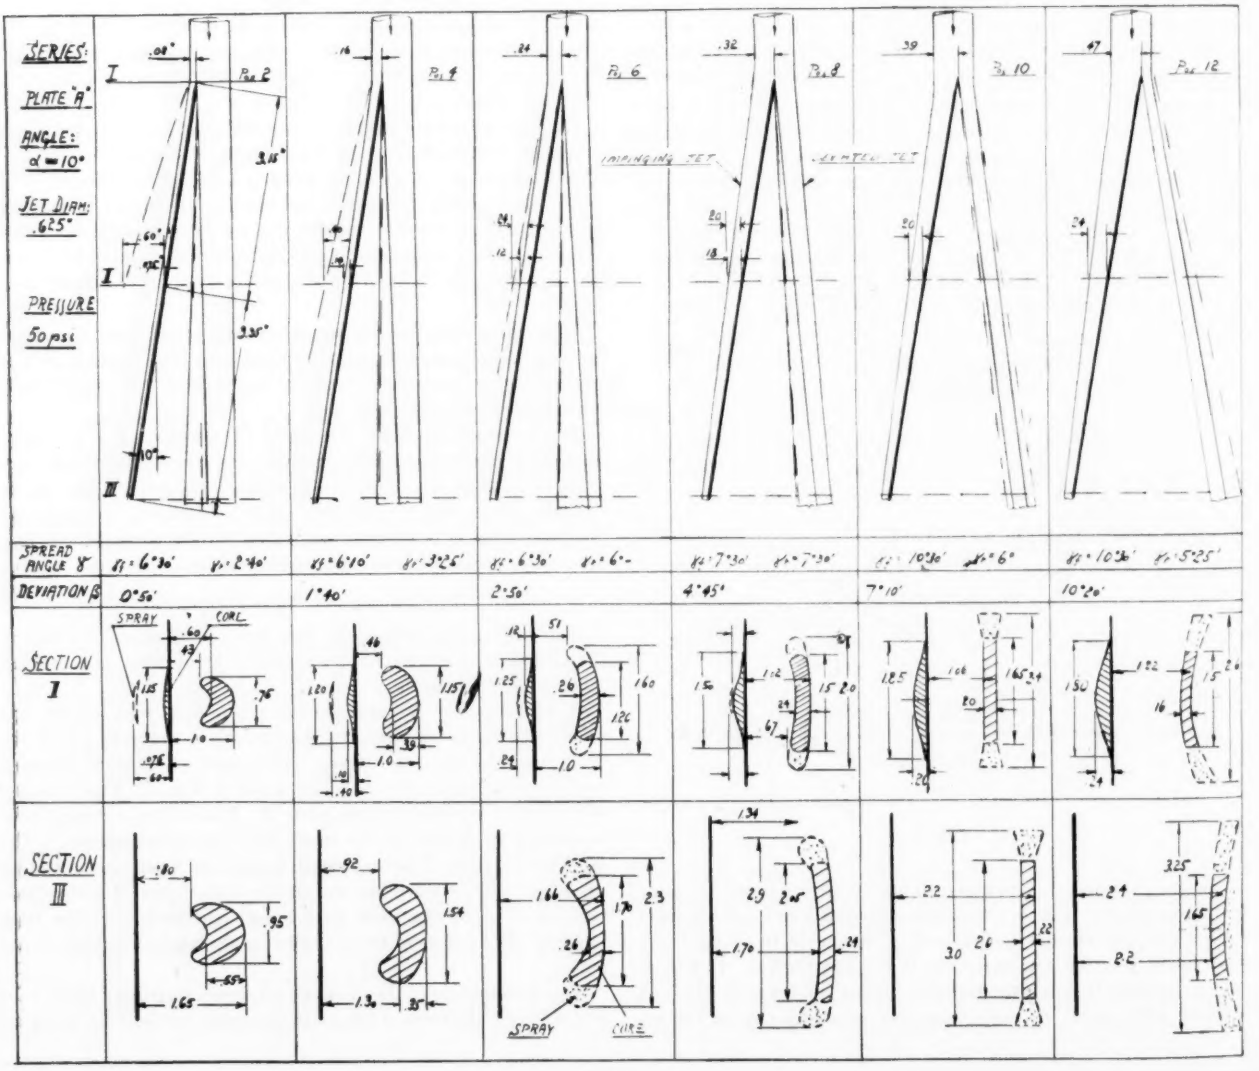

FIG. 8

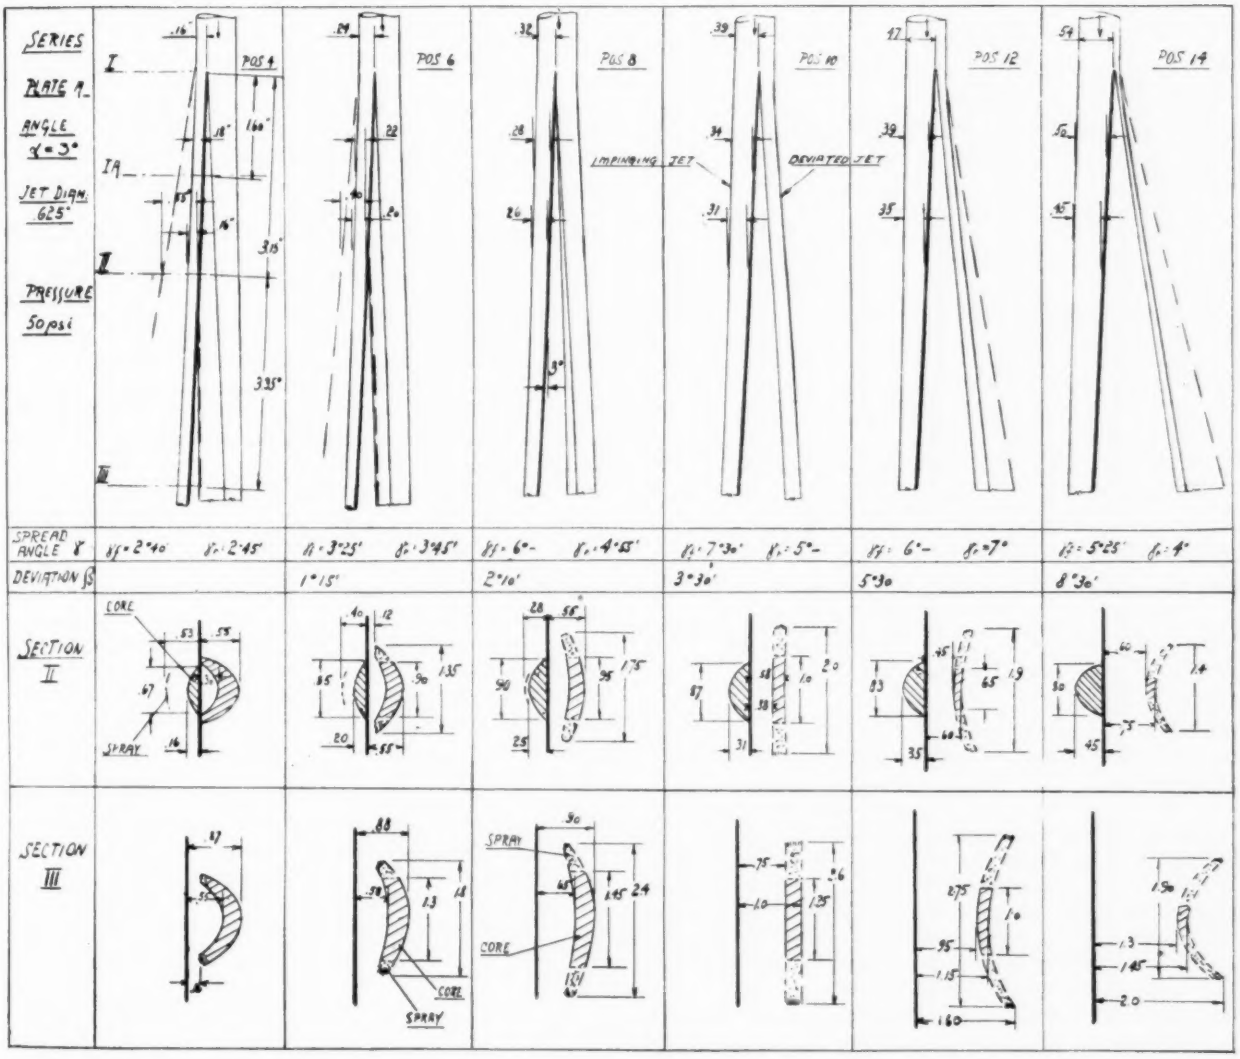

FIG. 9

impact angle of $\alpha = 10$ deg. The plate placed under this constant angle of 10 deg was shifted sidewise. The positions 2–12 in Fig. 8 correspond to the partition of the jet in its two branches, i.e., the impinging and the deviated jet. If the deviated jet is relatively large, (positions 2–6) from which it follows that the impinging jet branch is small, the cross section of the deviated jet is crescent-shaped, concave against the plate. With larger impinging jets, the crescent-shaped form changes to a flat rectangular cross section. With extremely small deviated jets, their cross sections will be curved in the direction opposite to the foregoing, i.e., convex against the plate. The deflection of the deviated jet will be greater with smaller jet. (Angle β is the angle of deviation.)

It should be mentioned that the cross section consists of two different parts; the core, which is practically filled with liquid, and the spray, which consists of numerous single separated water threads. The spray is developed extensively at a greater distance from the impact point, and, at certain positions of the deviated jet, the spray is at the point of impingement.

In addition to the deformation of the jet in the direction of deviation, there is also a spreading of the jet perpendicular to deviation. Both the impinging and the deviated jet spread on the plate, particularly with smaller thickness. (γ is the angle of

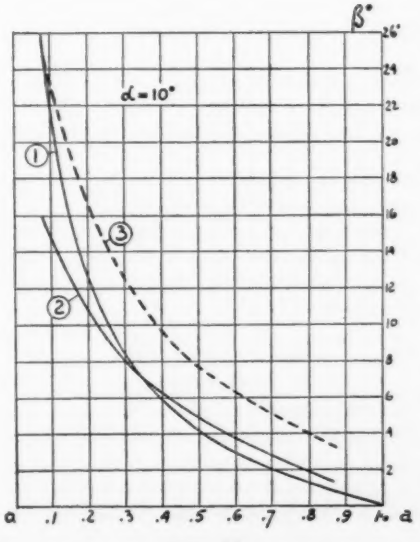

FIG. 10

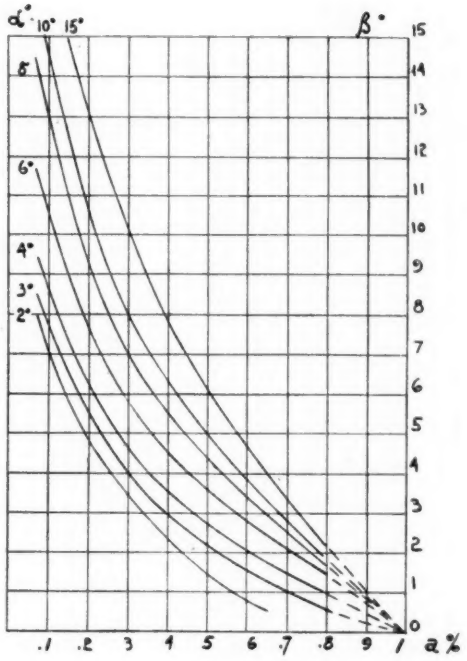

FIG. 11

spreading.) The angle of spreading of the impinging jet (γ_f), and the angle of spreading of the deviated jet (γ_r), should be clearly distinguished.

The plate was investigated at numerous impact angles. Fig. 9, for example, gives the appearances for an angle of 3 deg. The principal difference in these cases (angle 10 deg Fig. 8, and 3 deg Fig. 9) is that the curvatures of the cross sections are far more pronounced at 3 deg than at 10 deg. The cross section of a large jet deflection at 3 deg impact angle shows a cavity. The side ends of the deviated branch adhere to the plate; and under such conditions, cavitation is practically inevitable.

Figs. 8 and 9 indicate the angle of deviation β, i.e., the angle of the deviated jet, in relation to its initial direction. This angle can be calculated theoretically with relation to the reaction, and the following equation gives the value

$$a = \frac{1 - \cos \alpha}{1 - \cos (\alpha + \beta)} \quad \ldots\ldots\ldots\ldots\ldots [4]$$

In this equation α is the impact angle; β the angle of deviation, and a is the per cent area of jet deflection. (The complete jet has 100 per cent area and the impinging branch, the area $1 - a$ in per cent.)

Fig. 10 indicates the dependency of the deviation β as a function of jet deflection a for 10 deg impact angle. Line 1 gives the theoretical calculations according to Equation [4], and line 2 gives the measurements with plate A, according to Fig. 8. The values are not completely identical, but it is impracticable to discuss the differences here.

Results of Tests

In general, it has been established that the connection between deflected and impinging jets is uniform. Fig. 11 gives a complete diagram for plate A which shows all the deviations from 2 deg to 15 deg impact angles for all impinging jet areas.

As previously mentioned, plate A was selected from a variety of test plates. For example, in order to indicate the effects on another plate, Fig. 12 shows the conditions with jet impinging on plate B (Fig. 7). This was one of the first plates examined and has been developed from the lip forms used ordinarily.

In relation to the difference between plates (see enlarged sections in Fig. 7), the following comments are in order: While plate B is extremely thick in comparison with plate A, this alone does not constitute the essential difference. The edge angle on plate A is far smaller than on plate B. Moreover, the front edge angle δ_f on plate A is identical with the rear edge angle δ_r, whereas plate B has no rear edge angle at all.

By comparing the figures for plate B with those for plate A, it becomes evident that the results obtained with plate A are superior to those in the case of plate B. Both the impinging and deviated jets at plate B show disturbances which are not feasible under any conditions. To clarify these relations, the deviation for plate B under 10 deg impact angle is also noted in Fig. 8.

The principal differences in the impact conditions between plates A and B can best be defined as follows: Small impinging jets on plate B are not feasible, as the impinging jet will be deflected and sprayed.

With the same impact angle, the deviation for plate B is far greater than for plate A. The spreading of the jet is less favorable on plate B and is more developed.

A plate thinner than plate B, but with the same characteristic form, produces results analogous to plate B, with other limiting factors.

At this point, the influence of these investigations on the flow on a Pelton bucket should be discussed. We conceive from Figs. 8 to 12, inclusive, that the jet upon encountering a bucket has a tendency to deflect, this being forced to take another path, as presumed by the simple theory with the single water filament.

It is obvious that the relative paths a', b', c', in Fig. 1, are correct only in so far as they represent that portion of the jet which has not been deflected. The movement of that part of the jet which will be deflected is extremely complicated owing to certain cross sections being influenced by various deflections.

To make these relations as clear as possible, an attempt was made to develop a kinetographic representation. This has been accomplished in Fig. 13, by showing the wheel in a series of successive positions.

To simplify the representation, certain abstractions and suppositions were made as follows: The wheel should have 20 buckets (center angle 18 deg) similar to the case of Fig. 1 (buckets M, N, O). The lip of the bucket should have an edge, according to plate A, perpendicular to the splitter, so that the liquid will be caught up directly in the plane perpendicular to the plane of reproduction. The jet should be divided unequally (for practical reasons) into single segments. Their origin is as follows: The wheel will be presented in successive positions 10–20 (to 2 deg apart), affording uniform revolution.

The cross section 11 of the jet is determined by the end point of the bucket N in position 11 of the wheel. If bucket N arrives at position 12, the cross section 11 of the jet arrives simultaneously at the position indicated. In position 12, the end point of the bucket N determines the position of the cross section 12 in the jet, and so on.

This arrangement gives no uniform partition for the jet, but simplifies the representation. It is obvious that bucket O arrives at the location of bucket N in the successive ninth position. Positions 11 and 19 are identical.

The inclination of the lip was chosen of such a form that in the extreme position the relative velocity is exactly the direction of the lip entrance. It is assumed that if the lip enters into the jet, there will be a tendency toward deflection only for the critical cross section of the jet. The movement is now unsteady and it is therefore impossible to compute the exact influence on particles which are not in immediate proximity to the lip. A further sim-

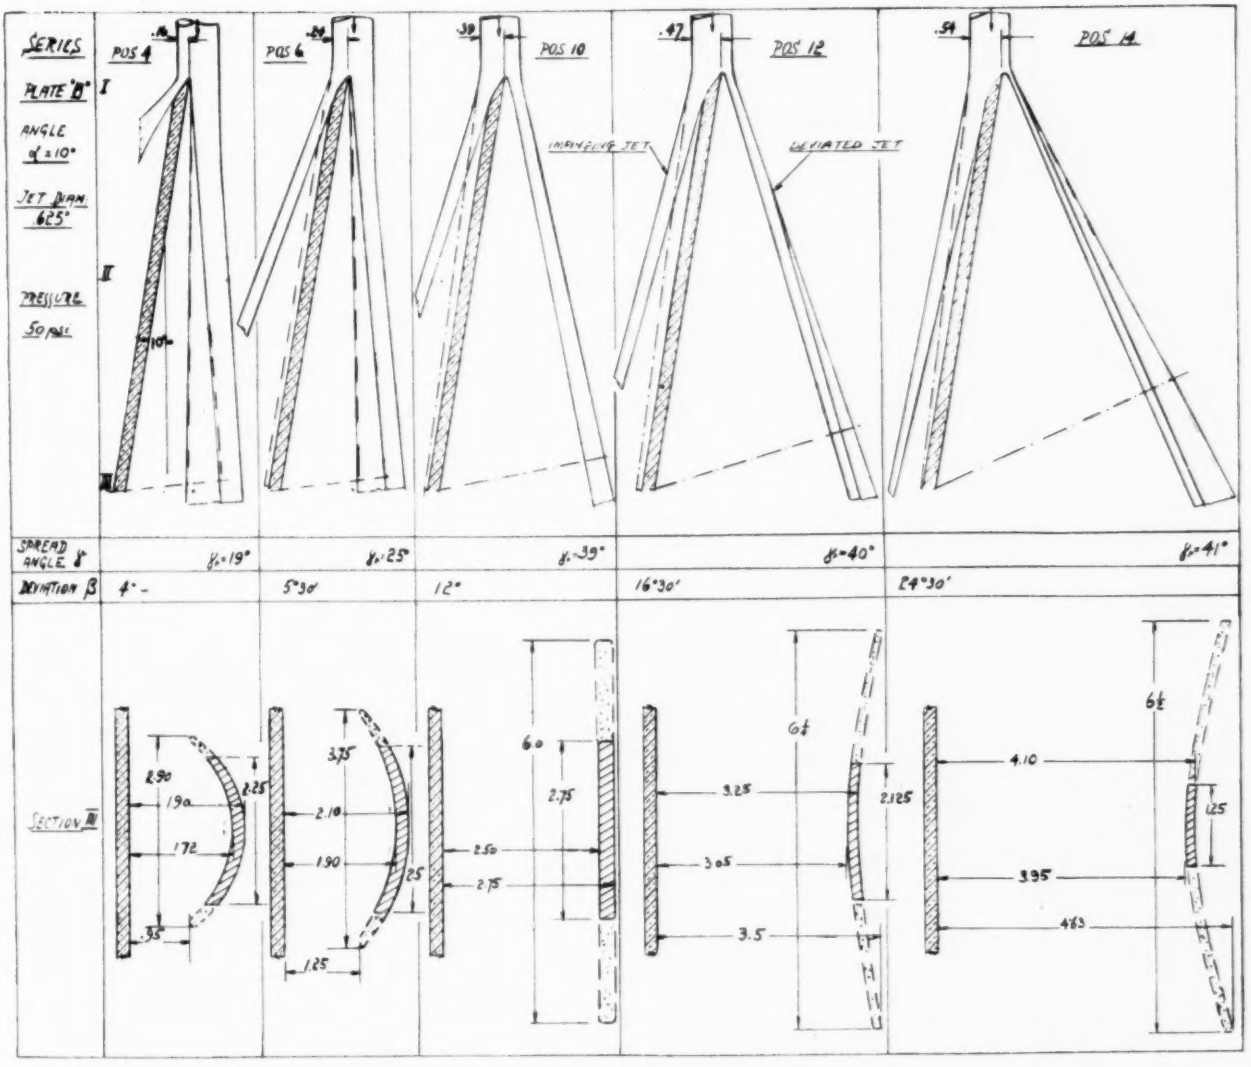

FIG. 12

plification can be made by disregarding the appearances of the width. We can therefore abstract the spreading and change of the cross section of the deviated jet. We assume further that the angle of deviation β in the relative system can be transferred unchanged in the absolute system. Therefore we co-ordinate to the influenced cross sections a deviation of the direction of the absolute speed according to the diagram, Fig. 11.

The affected cross sections of the jet are therefore not moving in the original direction; on the contrary, they will have individually different directions.

The kinetographic representation of the jet parts which form the admission for bucket M was made in this manner.

Fig. 13 represents a succession of positions of the three buckets M, N, O, and the relative position of the jet segments. Each second segment of the jet is hatched in the direction of motion. This figure represents clearly momentary positions, and it will be seen how a part of the jet between the cross sections 14–19 will be deflected so that it will not reach bucket M.

To find the loss, the volume of the part which does not reach the bucket is computed and divided by the volume of the jet per pitch length. The loss was found to be 5.8 per cent, which is excessive. An improvement can be effected in part by a greater number of buckets, and partly by increasing the wheel diameter.

These considerations have been abstracted from the form of the deflected jet. It has been established, Figs. 9 and 10, that there is a spread resulting in the form of the deviated jet being more or less rectangular, the longer side oblique to the splitter. It should be borne in mind that the deflected jet will be caught by the following bucket so that it will now be an impinging jet. The impact of such a rectangular jet on a bucket is certainly not favorable. The outer water filaments are likely to splash directly on the bottom of the bucket, guidance through the splitter thus being lost.

It is impossible to effect any material improvement of these particular conditions by changing the splitter. The lip, on the other hand, should be modified to avoid the appearance of such deviated and compressed jets. This is, in fact, the reason for the existence of special lip forms.

Relative to the impinging jet, it can be established that there is proper guidance only if the edge angle of the lip is very small. Sizable edge angles are inclined to produce a complete spray of the impinging jet. It has been demonstrated, furthermore, that the spread of the impinging jet is quite small if the impact angle is likewise small. It would be advantageous to arrange a bucket

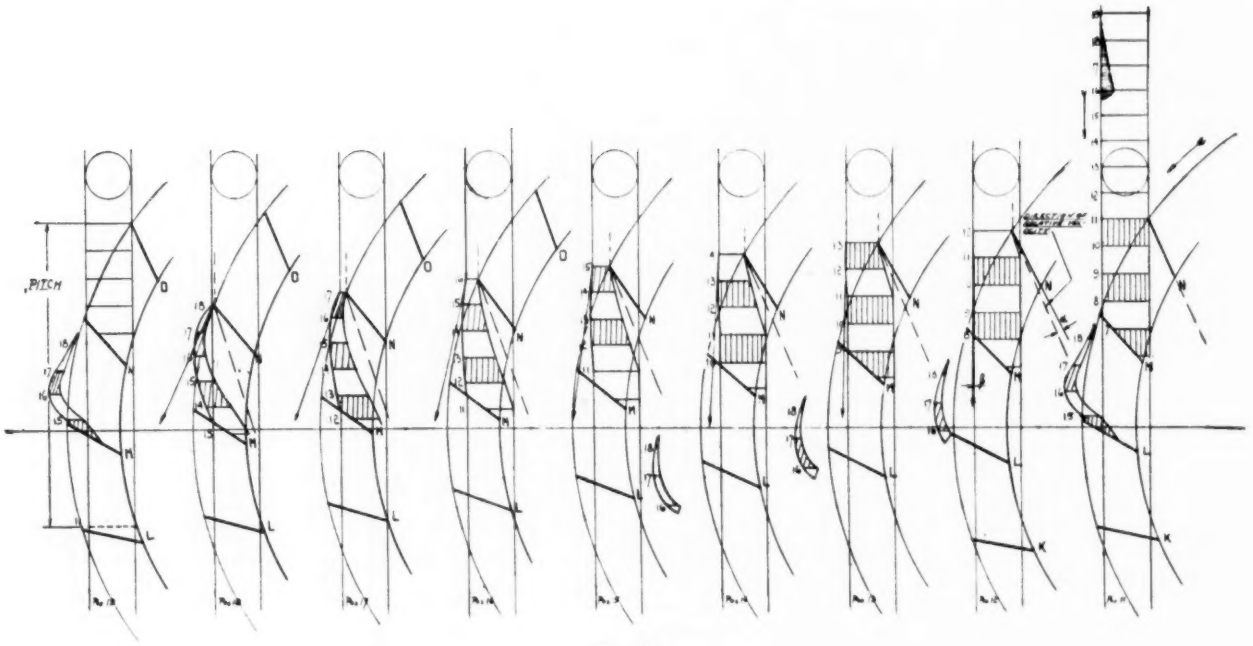

FIG. 13

so that small impact angles would be produced, but there are two reasons why this should not be done, as follows:

1 A very small impact angle at a given peripheral velocity results, at a greater peripheral velocity, in a jet impingement on the underside of the lip. This should be avoided because it decreases the efficiency.

2 Cavitation will inevitably be produced with smaller impact angles at higher heads.

On the other hand, a small edge angle on the lip is difficult to maintain, because such an edge will not stand up under high heads. Further, an uneven edge invariably causes cavitation; and it is therefore necessary to make the wall of the lip adequately thick.

It is obvious that the straight lip form does not give very favorable results (see Fig. 13). There are, however, various methods, forming other lips without the disadvantages just outlined.

As mentioned previously, the variety of the lips is so far-reaching that it is impossible to find a combination which can be regarded as best in every respect.

It develops that the method with the stationary bucket makes possible the study of all questions and problems connected with the form of the lip.

It has been said that the discharge on the Pelton bucket is influenced to a great extent by the entrance conditions, that is, by the form of the lip and of the splitter. We know now in what sense the lip is working, and that through the lip edge a spread of the impinging jet results.

The splitter also causes a spreading of the jet, and it can be stated generally that the spreading will be increased with greater splitter angle. Both edges, the splitter and the lip edge, have therefore a combined influence on the impinging jet. The form of the bucket should be a natural transition without sudden rupture in the curvature of the surface.

We assume that losses at the entrance are produced chiefly with the deflected jet, while losses at the entrance of the directly impinging jet are very rare, with suitable arrangement provided.

The losses of the deflected jet consist in not reaching the following bucket and in an impinging of a compressed jet on the adjacent bucket. By this means, the influence upon efficiency,

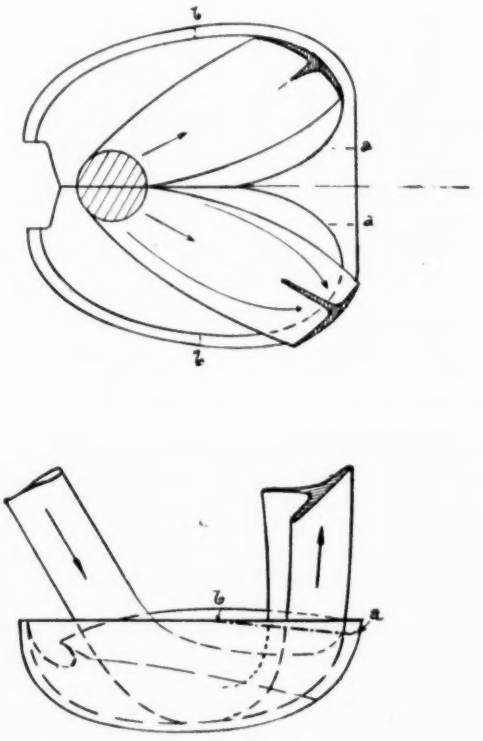

FIG. 14

both at the entrance and the discharge, can be established, resulting in considerable reduction of losses, if not completely eliminating them by proper arrangement. The final consideration is the possibility of avoidable losses during flow on the bucket itself.

It seems improbable that such losses could exist; however, with the method described, a hydraulic loss was found which caused further efficiency decrease. A runner which was built for a plant

according to a previous model did not show the efficiency expected. The bucket had smooth curvatures and had only slight differences in comparison with the model, which should have increased the efficiency.

Upon testing the bucket in the fixed position, this bucket showed a singular form of discharge. The cross section of the discharge was not flat or a more or less rectangular strip. On the contrary, it had a T-shaped form, Fig. 14.

It was established that this T-shaped cross section was produced by two streams, both originating on the splitter and working against each other. This was a steady appearance on the bucket, starting from a certain impact angle.

It was obvious that under such circumstances the discharging water came into strong interference with the preceding bucket. In this case it was possible to improve the efficiency largely by altering the discharge edge of the bucket alone. The bucket part on the rim between the points a and b (Fig. 14) was cut away as marked with dot-and-dash lines. However, a better correction would have involved a change in the curvature of the bucket.

Further investigations proved that such T-shaped discharge is not uncommon. In this case, the T-shaped form was a steady one, in another case it was found that such T-shaped form was produced by the continued succession of jet parts impinging under different angles.

These conditions can be studied easily in the case of the fixed bucket. It is doubtful whether it would have been possible to see them on a revolving wheel.

Upon becoming acquainted with the facts and knowing where to give our attention, it will be possible, with proper arrangements, to see these conditions on a revolving wheel with stroboscopic instruments.

Finally, there should be mentioned, among the avoidable losses, a disturbance which arises from the outflow, but which has its real cause in the enclosing housing. Sometimes the discharging water impinges against the walls of the housing or elsewhere and is deflected, after which it returns to the wheel, and in this way the power of the turbine is reduced.

In certain cases, the discharging water will be taken by the air rotating with the wheel, thus producing similar disturbances.

These losses cannot be traced back to the flow on the turbine; but they have their cause in the specific construction of the turbine itself, i.e., housing, air passages, baffle-plate arrangement, etc.

To avoid such conditions only one rule has to be observed. The outflow of the water from the bucket should be completely free of foreign matter which would interfere with the outflow; and it is advantageous to make arrangements whereby the outflow tendency can be increased.

Having established the relative outflow conditions on a bucket, it is possible to estimate the absolute flow and to decide whether interference is to be expected, and if such conditions exist, how to deal with them.

TABLE 1 ANALYSIS OF PELTON WHEEL LOSSES

1 Nozzle:
  Friction in nozzle and on needle
2 Wheel:
  (a) *Mechanical losses:*
    1 Friction in bearings
    2 Air resistance of turning wheel
  (b) *Hydraulic losses:*
    (a) Unavoidable losses
      1 Entrance; mixing loss
      2 On bucket; friction of flow on bucket
      3 Discharge; normal discharge loss
    (b) Avoidable losses:
      1 Entrance; deviation of jet on lip with outside pressing of jet parts. Spray-formation compression of jet parts with unfavorable impact on adjacent bucket
      2 On bucket; crossing of two streams; disturbances
      3 Discharge; tangential discharge; interference with preceding bucket; deflection of discharged jet on wheel housing and disturbances resulting therefrom.

With the method of the fixed bucket, the author has been enabled to study the flow on the bucket and to analyze the losses which determine the efficiency of the wheel. It is natural that this method alone is not sufficient to determine the efficiency which can be established only by testing the performance of the wheel. The losses on the bucket having been established, it is practical to summarize them for further investigation, as in Table 1.

Discussion

S. Logan Kerr.[2] This paper is of particular interest to the writer, as it fell to his lot to make a research investigation of some unhappy results of impulse-wheel performances when he was still in the hydraulic-turbine industry. Now after an absence of some 7 years, keeping meanwhile the position of "sitting on the lid of the Hydraulic Turbine Test Code Committee," the perspective attendant to a detached view of the "art" may be helpful as a contribution to the discussion of this paper.

Some 15 or 16 years ago, the writer had the privilege of visiting the plants of the principal manufacturers of turbines in Europe. They were most co-operative and put at his disposal much information which showed their superior performance, individually and collectively, with special attention to their improved performance in relation to the state of the art in America.

It was also his privilege to have entreé into the plants of the users of these superlative turbine units. Much "sales talk" was deflated thereby. But some things defined the debunking process; one in particular was the efficiency of impulse wheels.

Such "impossible" arrangements as a vertical shaft unit with a test efficiency of 90 per cent (with a penalty clause in the contract and a certified copy of the test results), and horizontal units of medium and large size that attained efficiencies of 88 to 91 per cent, seemed to be greatly at variance with reported "ceiling efficiencies" of 85 to 87 per cent in American practice, to say nothing of the horrible examples that slipped into the middle "seventies."

What was the answer to these major differences in performance?

There were many answers to that question given in writing, in polite conversation, and sometimes in conversation that was not so polite. Perhaps this view in retrospect will serve to bring the discussion of this controversial question down to a sound basis of an open-minded consideration of engineering and technical aspects and leave out completely the side issues of personal opinions and commercial issues, tradition, and other obscuring factors. Let us examine some fundamentals:

1 What is the efficiency of an impulse turbine? Is it not measured on the same basis as all other hydraulic prime movers as set forth in the A.S.M.E. Power Test Code for such equipment? Or should there be some other basis? The writer's committee[3] is vitally interested in knowing.

2 What elements determine the performance of an impulse turbine? Here we find an essential difference between the reaction turbine and the impulse turbine. In the reaction turbine, we have a single combined unit which permits various deviations in the individual elements that affect each other but can be compensated for in the design basis used.

In the impulse turbine, however, we find two units, the nozzle, and the bucket in series. The jet discharged by the nozzle must be solid and free from dispersion and distortion or else the most perfect bucket in the world cannot produce acceptable efficiencies. If the most perfect jet is impinged on a bucket not suited to it, the bucket cannot develop its best performance.

[2] United Engineers & Constructors, Inc., Philadelphia, Pa. Mem. A.S.M.E.

[3] Committee 18, Hydraulic Prime Movers, A.S.M.E.

We are then faced with two requirements: An efficient nozzle, delivering a solid compact jet to the bucket; and an efficient bucket capable of receiving it and converting this energy to the best possible degree.

4 The author gives a careful analysis and discussion of the elements of loss in the buckets upon receiving a good homogeneous jet of water from the nozzle. The writer recommends this paper; it merits careful study. It is the work of a distinguished engineer and scientist. Think well before taking issue, and then take issue only when full and accurate information to refute this exposition in part or in whole has been developed.

5 Make sure that the nozzle is free from rapid accelerations followed by retardations of flow; be sure that abnormally high velocities are eliminated from the approach passages of the nozzle; be sure that abrupt and unnecessary changes in direction are avoided in the nozzle and the approach to the nozzle; in brief, be sure that the most efficient bucket that can be designed has a good, solid, high-efficiency jet impinging upon it and can start its own work with a chance to contribute without impairment to the maximum over-all efficiency of the unit as a whole.

6 When these objectives have been attained, then test the scale model under conditions where there is sufficient turbulence to simulate accurately the behavior of the jet under full-scale velocity conditions of the design head, not the available test head for the model.

7 When these conditions have been thoroughly studied and complied with, then many of the mysterious discrepancies between the impulse-wheel laboratory work and the field performance will disappear, just as they did many years ago on the reaction turbine when the basic fundamentals of the relation between the model and full-sized-unit performance were reduced to an academic problem of slide-rule computation.

The impulse turbine has still to overcome the obstacles of insufficient relationship between experimental laboratory and full field performance, both as to the degree of efficiency attained at the maximum point and the ability to reproduce in the field the performance attained in the laboratory as to shape of curve and as to many other characteristics.

L. F. Moody.[4] It will be generally agreed that the Pelton wheel, while it has been developed into a thoroughly reliable and satisfactory prime mover, still has ample possibilities for further improvement. To hold that it has reached its ultimate state and that the room for betterment is too narrow for profitable investigation would represent a defeatist attitude not justified by analysis. Gains in efficiency of the order of some 5 per cent or more are easily conceivable. and when translated into values of generated power would justify intensive research.

As pointed out by the author, Pelton-wheel efficiencies have lagged considerably below those of reaction turbines; and it should be remembered in making this comparison that the installation efficiency of a Pelton wheel, which is the figure to be compared with the reaction-turbine performance, should include the head lost in the free fall from the buckets to the tail water, an element which is included in the reaction-turbine figures. Future development may show the practicability of regaining this loss, in spite of mechanical objections such as the closed outlet with shaft seals, ejector means for taking care of air accumulations, and float control of the water level.

The listing (Table 1 of the paper) of hydraulic factors involved in the Pelton-wheel action emphasizes the complexity of the flow in the bucket and the unattractiveness of attempting a completely theoretical analysis. In the hydraulic field, we have been long converted to the experimental method in attacking such problems. A mere comparison of over-all results with progressive changes in design is, however, a slow process, and a method of isolating parts of the problem and attacking them separately is greatly to be desired. The author's method of research should be of real value in giving us a deeper insight into the nature of the flow in the Pelton bucket.

Probably many have thought of using stationary buckets in experimental research on these wheels, or have actually made such experiments. The writer must admit, however, that before reading this paper he was inclined to think that conditions in the running wheel would be so different from those in the experiment that the results would be of doubtful value. The author shows convincingly that the differences are actually of a low order of magnitude; and that by the use of a dummy bucket, cut away to permit the jet to enter the preceding bucket at the correct relative direction, a close approximation to actual conditions can be secured. The author has thus introduced a new technique which should be of marked value in this field.

Without some method of this kind, it is difficult to know where to start in trying to improve bucket design; with the use of this method many unknown phenomena in the flow can be brought to light, the flow conditions can be determined at least qualitatively and directions of improvement shown.

The author has mentioned that not only can sources of loss of efficiency be detected, but that cavitation tendencies can also be discovered in some cases. One possible source of cavitation not included in the paper is the presence of a vortex core in the jet, which upon impinging on the bucket would produce all the essentials of cavitation.

The writer takes the opportunity to urge that more study be directed to Pelton-wheel cavitation and that statistical data be collected, as was done by the National Electric Light Association some years ago for reaction turbines, to show the general trend of the tendency toward pitting as a function of specific speed. With such data, we could plot curves of the Thoma cavitation factor sigma with respect to specific speed. For Pelton wheels having free discharge into the atmosphere, the static draft head term H_s disappears from the formula $\sigma = \frac{H_b - H_s}{H}$; giving simply $\sigma = H_b/H$, the ratio of the height of the barometric water column, at the elevation of the plant, to the effective head. With definite experience data plotted in this way we could more intelligently judge of the range of heads and speeds limiting the Pelton-wheel field.

Author's Closure

The author greatly appreciates the generous comments from such well-qualified sources as Mr. S. Logan Kerr and Prof. L. F. Moody.

Mr. Kerr states concisely the general principles which are absolutely necessary to obtain high efficiencies in Pelton wheels. Lower efficiencies in Pelton wheels can be attained very easily. One proof is that the old impulse wheel was built even a century ago in a primitive wooden form, sometimes with 75 per cent efficiency. This circumstance might be the reason for a certain superficial similarity between test and field arrangement. This neglect of nozzle arrangement and housing formation explains discrepancies between test and field performance.

The author agrees entirely with the remarks of Professor Moody, especially need of statistical survey concerning the cases of cavitation of Pelton wheels. It is obvious that cavitation is unavoidable in all kinds of turbines under certain conditions at a relatively high speed which is desired for economical reasons, and we urgently need to establish these limitations in order that cavitation may be avoided.

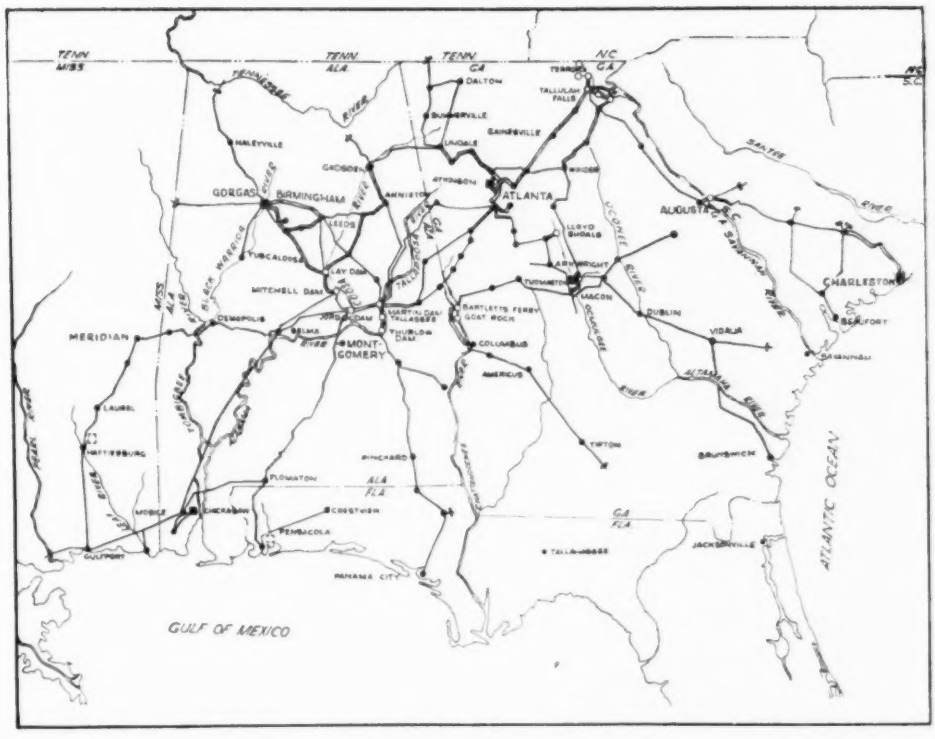

FIG. 1 EXTENT OF TERRITORY SERVED BY SOUTHEASTERN GROUP OF THE COMMONWEALTH & SOUTHERN CORPORATION

Range of Operation of Steam Plants in a Combined System of Steam and Hydro

BY A. T. HUTCHINS[1] AND HOWARD DURYEA[2]

The balance between hydro- and steam-plant power generation on the southeastern group of The Commonwealth & Southern Corporation during the postdepression period and later the period of peak war demands is explained in this paper for an understanding of the system's approach to the installation of steam plants. The discussion includes such data as area of the system, loads, plant capacities, and such pertinent factors as ratio of steam to hydro generation, the relation of steam to hydro capacity, etc. The unit principle is used in the steam-plant installations, i.e., one boiler supplies all steam requirements for one turbine unit. Details of the boilers, auxiliary equipment, operating experience, and results attained are comprehensively treated.

THE problem of fitting large and efficient steam units into utility loads during the depression years from 1930 through 1935 on the larger systems of the country has been much discussed. On the southeastern group system of The Commonwealth & Southern Corporation many of the steam plants were idle for long periods, and this was accentuated by the existence of hydro capacities that were relatively large in proportion to the total load. Seasonal changes in river flows necessitated wide variations in steam-plant loading to supplement hydro generation when flows were low and to utilize hydro generation and avoid wasting water during high flows. Postdepression and particularly the present high war loads are in sharp contrast to the foregoing conditions, as they require maximum continuous output from the more efficient steam plants and greatly increased generation from higher-cost plants.

EXTENT OF SOUTHEASTERN GROUP OF SYSTEM

The discussion of such operations is obviously more interesting if there is a general understanding of a system, its area, loads, and plant capacities, together with other pertinent factors, such as ratio of steam to hydro generation, the relation of steam to hydro capacity, etc. The small map, Fig. 1, has been prepared to show the extent of the territory served by the southeastern group of The Commonwealth & Southern Corporation. Because of lack of space it does not show all existing steam and hydroelectric plants, nor all of the transmission lines and substations.

[2] Co-Ordinator of System Power Supply, The Commonwealth & Southern Corporation, Birmingham, Ala.

Contributed by the Power Division and presented at the Spring Meeting, Birmingham, Ala., April 3–5, 1944, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

The data presented in this paper refer to the system shown in Fig. 1, corrections having been made for periods prior to 1940, when Tennessee Electric Power Company was included in this group. The present system includes South Carolina Power Company, Georgia Power Company, Alabama Power Company, Gulf Power Company, and Mississippi Power Company, listed in order from east to west. Again moving from east to west, the rivers supplying water to hydroplants are the Savannah, between Georgia and South Carolina; the Tallulah and Chattooga, whose confluence forms the Tugalo in northeast Georgia; the Oconee and Ocmulgee in north central Georgia; the Flint and Chattahoochee in southwest Georgia; and the Tallapoosa and Coosa in Alabama. Located as these rivers are in the southern foothills of the Appalachian range and above the fall line, they afford advantageous sites for hydro plant developments, starting with elevations of 1846 ft above sea level at the Burton site on the Tallulah River in northeast Georgia, with progressively lower elevations as one moves southwest.

Fig. 2 shows total load, expressed in million kilowatthours

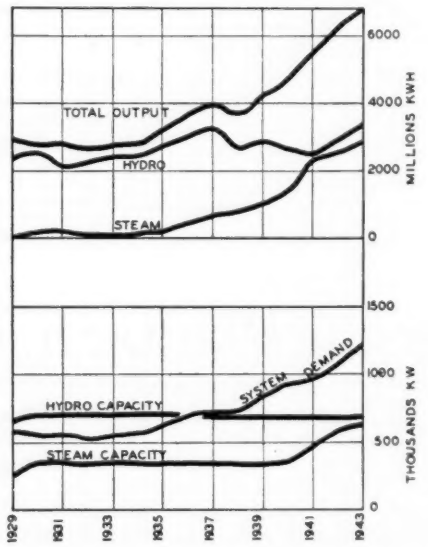

FIG. 2 TOTAL ANNUAL LOAD ON SYSTEM, RELATION OF HYDRO AND STEAM GENERATION, PEAK HOUR MAXIMUM DEMANDS, AND INSTALLED CAPACITY OF STEAM AND HYDRO POWER

annually, together with hydro and steam generation, and also peak hour maximum demands expressed in kilowatts, together with installed capacity of hydro and steam sources. Purchased energy is not shown because of lack of space and consequent confusion. The system has purchased large amounts of energy from outside sources, and the co-ordinated companies have purchased by-product generation from industrial concerns. For a few years one of them operated a plant to supply steam to an industrial customer, and thus secured a block of by-product energy. Purchases are based on requirements to supplement steam and hydro sources, availability, and relative cost.

In discussing the graphs, Fig. 2, depression loads are apparent from 1929 through 1934, followed by moderate increases in 1937. Loads near the close of 1937 and 1938 decreased, following which they again increased and assumed the present sharp upward slope characteristic of war production.

The lower section of Fig. 2 shows that there have been no increases in installed hydro capacity since 1930, and that steam capacity also remained practically constant from 1930 through 1940. This condition reflects the depression loads and the eventual loading of both hydro and steam plants until the war loads approached the existing capacity, about 1939, and resulted in the construction of additional steam facilities.

Fig. 1 shows the location of six hydro plants in extreme northeast Georgia; three on the Chattahoochee River above Columbus, Georgia, three on the Tallapoosa River, and three on the Coosa River in Alabama. In each of these groups the plants are in series so that water released from the upper plants is successively used by those below.

The total capacity of run-of-river plants is around 375,000 kw and that of the two principal storage groups is 350,000 kw, making the total installed hydro capacity some 725,000 kw. However, the annual generation is roughly two thirds from run-of-river plants and one third from storage plants. The total equivalent energy in storage is 450,000,000 kwhr, with some additional 15,000,000 kwhr in run-of-river ponds.

Referring to Fig. 2, curve "Steam," it will be noted that the output from steam plants was very low for the first 10 years shown. In fact, the composite plant factor for the steam capacity, as shown in the lower part of this figure, is approximately 10 per cent for this period. As previously mentioned, a load drop occurred in 1938, following which the sharp uptrend beginning in 1939, started a new era of steam-plant construction and operation in marked contrast to the previous periods. In 1939, the first unit of those shown in Table 1 was purchased and its initial operation, together with that of other added units, is given.

TABLE 1 STEAM PLANTS ADDED TO SYSTEM

Plant	Unit no.	Kilowatt rating	Throttle pressure, psi	Steam temperature, deg F	Revolutions, rpm	Generator cooling	Initial operation
Arkwright	1	40000	850	900	3600	Hydrogen	April, 1941
	2	40000	850	900	3600	Hydrogen	May, 1942
	3	40000	850	900	3600	Hydrogen	Nov., 1943
Chickasaw	1	40000	850	900	3600	Hydrogen	April, 1941
	2	40000	850	900	3600	Hydrogen	Mar., 1943
Atkinson	2	60000	425	750	1800	Air	Sept., 1941
Gorgas	5	60000	850	900	3600	Hydrogen	Dec., 1943

Although generating and transmission facilities, as well as distribution systems, are owned by the operating companies in the several states, planning studies for additions, design engineering, and subsequent direction of operations of power sources are coordinated by a service company mutually owned by the operating companies. The personnel of the service company for the southeastern group is located in Birmingham. By means of the co-ordination effected by the service company, the ultimate aim that power-producing facilities be most advantageously located, designed, maintained, and operated so as to produce the maximum amount of energy at lowest cost, and that each of the operating companies shall benefit therefrom is attained. In other words, all power-producing facilities are operated as a single group to provide capacity and energy for the total load. This method of operation takes advantage of all diversities of loads, stream flows, unit outages for inspection, maintenance, and emergencies that may occur between the individual operating companies' systems, as well as within the systems of each of them. Any action that materially reduces the area served and the facilities available to produce power would tend to lessen the economic value of the group.

SYSTEM RANKS HIGH IN PERFORMANCE

An indication that the size of this system tends toward economy in operation is its performance in comparison with other systems east of the Mississippi River. Of a load of 89 billion kwhr east of the Mississippi River in 1940, 44 per cent was generated by seven large generating and transmission systems that have been developed and operated under common ownership similar to the southern group of The Commonwealth & Southern Corporation. These seven systems generated an average of 4430 kwhr per kw

of dependable generating-plant capacity. This system stood third among these seven groups with a generation of 4413 kwhr per kw of dependable generating capacity.

The remaining load east of the Mississippi River was developed by a large number of smaller companies and systems. For the same year, these companies generated 3590 kwhr per kw of dependable generating-plant capacity. This is a rather striking comparison when it is realized that in this respect the seven systems under common ownership showed an increase in use factor of 23 per cent, as compared with the other systems.

Three factors undoubtedly contribute to these results:

(*a*) Diversity of peaks reserves the surplus capacity.

(*b*) Better planning, due to engineering staffs made practicable with size of operations.

(*c*) Greater use of interchange agreements where dispatching is handled by one co-ordinated organization.

The operation of all generating plants and the interchange of energy between companies within the group and with adjoining concerns is under the supervision of a central supervisory group of the service company, who work with the load-dispatching forces of the individual companies. Hourly load estimates for the entire group are maintained constantly and are projected into the future to provide hourly load schedules for hydro groups and steam units during critical daily and week-end periods. Arrangements are made to load and unload steam units so as to utilize, supplement, or conserve hydro flows; provide for outages for inspection, maintenance, and emergencies of steam and hydro units; insure sufficient free hydro-regulating capacity for tie-line control, spinning reserves, and minimum flows when and where required. Arrangements are made to receive energy from outside sources, to make deliveries to them, and to synchronize these transactions with hydro and steam operations on the system.

Unit Principle Used in Steam Plants

Since the short time peaks of load throughout the year are carried by the hydro plants, the units installed, as shown in Table 1, were all designed on the basis of carrying prescheduled loads. The extensive transmission system, interconnecting the load areas with their steam plants, makes conditions ideal for use of the unit principle of design, in which one boiler supplies all the steam requirements for one turbine. One exception among the units shown in Table 1 is unit No. 2 at Plant Atkinson, where there was some capacity available in existing boilers. Because of the importance of the load in the local area a cross connection was made between the steam lines of the two units at the Chickasaw Plant. It may be noted here that at the Gorgas Plant the steam conditions for No. 4 unit are 425 psi and 750 deg and No. 5 unit 850 psi and 900 deg, and no pressure-reducing and desuperheating equipment was installed.

The early plants in the 900-psi class were designed for 900 psi in the boiler drum and 850 psi at the turbine throttle. The design of superheaters to secure 900 F total steam temperature resulted in approximately 50 psi drop across the superheater at full load. When operated with a margin of 30 psi under popping pressure, and 20 psi drop through valves and piping, the pressure at the turbine approached 800 psi. In 1939, the requirement for safety valves designed to operate between 900 and 1500 psi was realized, and the purchase of the safety valves for the first boiler of the units, listed in Table 1, was delayed until such a valve was offered. Since that date boilers in this class have usually been built for 950 to 1000 psi at the boiler drum. This has resulted in securing the minimum of safety-valve operation.

All of these units in the 900-psi class are designed for four-stage extraction for feedwater heating, one heater being the direct-contact type arranged for very complete deaeration of the feedwater.

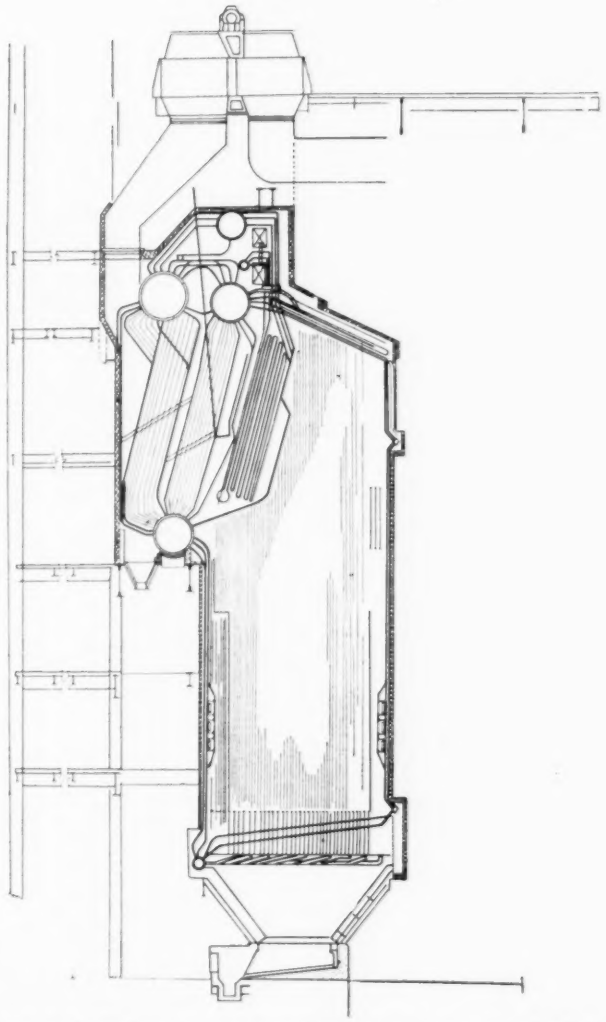

Fig. 3 Cross Section Through Steam Unit Rated at 400,000 Lb Per Hr, at 950-Psi Drum Pressure

Feedwater temperatures are approximately 375 F. Obviously, with the unit system, availability of the boiler for continuous operation over long periods is highly essential. Conventional types were selected and furnace design provided for reasonable heat liberation on the basis of four waterwalls and a dry ash pit.

Fig. 3 is a cross section of a unit rated at 400,000 lb per hr, 950 psi drum pressure, and 900 F. Three of these units were installed. The furnace of this unit has fin tubes on four sides and is tangentially fired with twelve burners, three at each corner. These three boilers and all others built with the units in Table 1 are each equipped with three pulverizers.

Fig. 4 is a cross section of one boiler built for the same capacity and steam conditions and differs primarily in the furnace bottom and the side-wall tubes. This arrangement of the furnace bottom is intended to be safe against damage to the hearth tubes from falling slag, which occurred in the other design, and also affords better protection for the dry-ash pit. The wall tubes are tangent tubes, 3 in. OD on $3^1/_8$-in. centers, which are connected to the headers with a forging which joins two tubes to a $3^1/_8$-in-OD nipple, which in turn is rolled into the header. Obviously, this results in a cooler furnace, which has proved to be less subject to slagging.

Fig. 5 is a cross section of a boiler built for the same steam con-

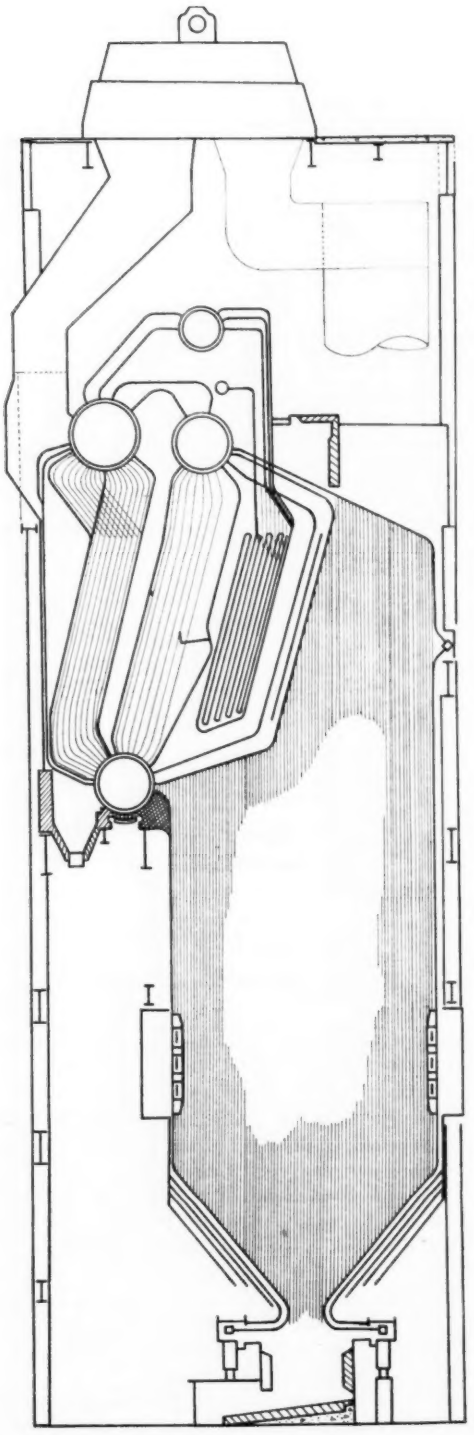

FIG. 4 CROSS SECTION THROUGH BOILER SHOWING VARIATIONS IN FURNACE BOTTOM AND SIDE-WALL TUBES

ditions but with a capacity of 600,000 lb per hr. The wall tubes and furnace bottom follow the pattern of Fig. 4; the design embodies an economizer and omits the dry drum. Similar to those just mentioned, this boiler is tangentially fired and all five units represented by Figs. 3, 4, and 5 are equipped with the regenerative-type air preheaters.

Fig. 6 is a cross section of another boiler of the 900-psi class and 400,000 lb per hr capacity. This unit is fired with six circular burners which are fitted with rings for burning gas, has a relatively large economizer and tubular air preheater. This unit has been in service only a short time, and it is too soon to report on several features of operation based on inspections, but tests show that carry-over from this boiler is a fraction of 1 ppm at rated load and with boiler water having from 340 to 835 ppm dissolved solids. This unit is installed with the primary-air fan ahead of the pulverizers, and comparative results will be studied with interest.

The reason for the selection of boilers with economizers designed to secure 2 to $2^1/_2$ per cent increased efficiency above that for the boilers, shown in Figs. 3 and 4, becomes evident when it is noted that these are the most recent units, will be assigned a more nearly base load, and the price increase was relatively small.

All of these units are arranged with by-pass dampers for control of superheat temperature, so that from 60 per cent to 100 per cent rating 860 F total steam temperature may be maintained. These dampers are manually controlled and for the type of load carried this has proved satisfactory.

Although one might not select the tangentially fired furnace for burning gas as fuel, a number of these have been fitted with gas

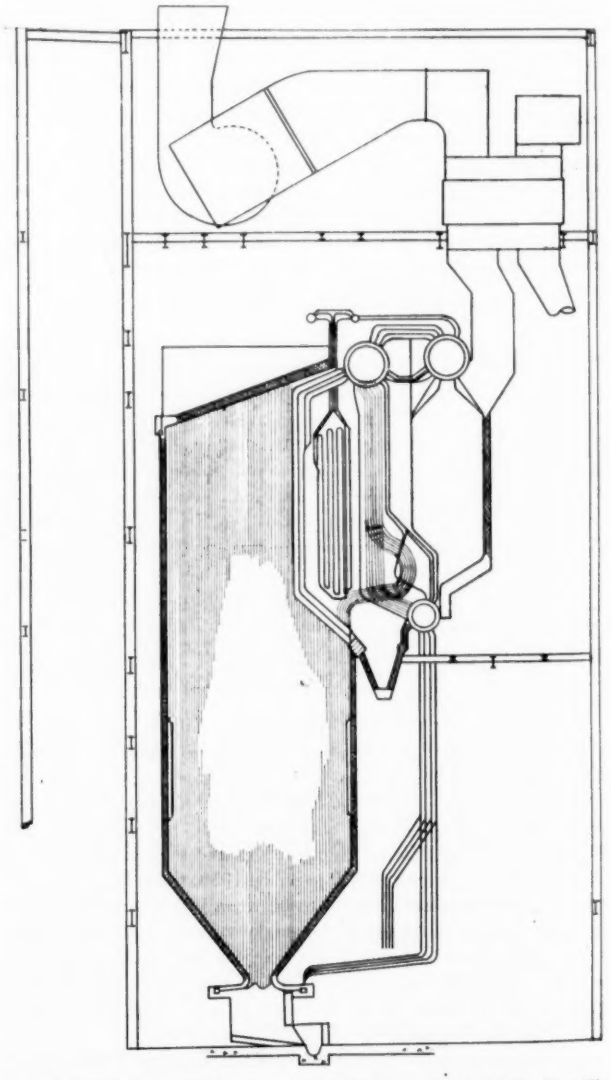

FIG. 5 CROSS SECTION THROUGH BOILER HAVING 600,000 LB PER HR CAPACITY

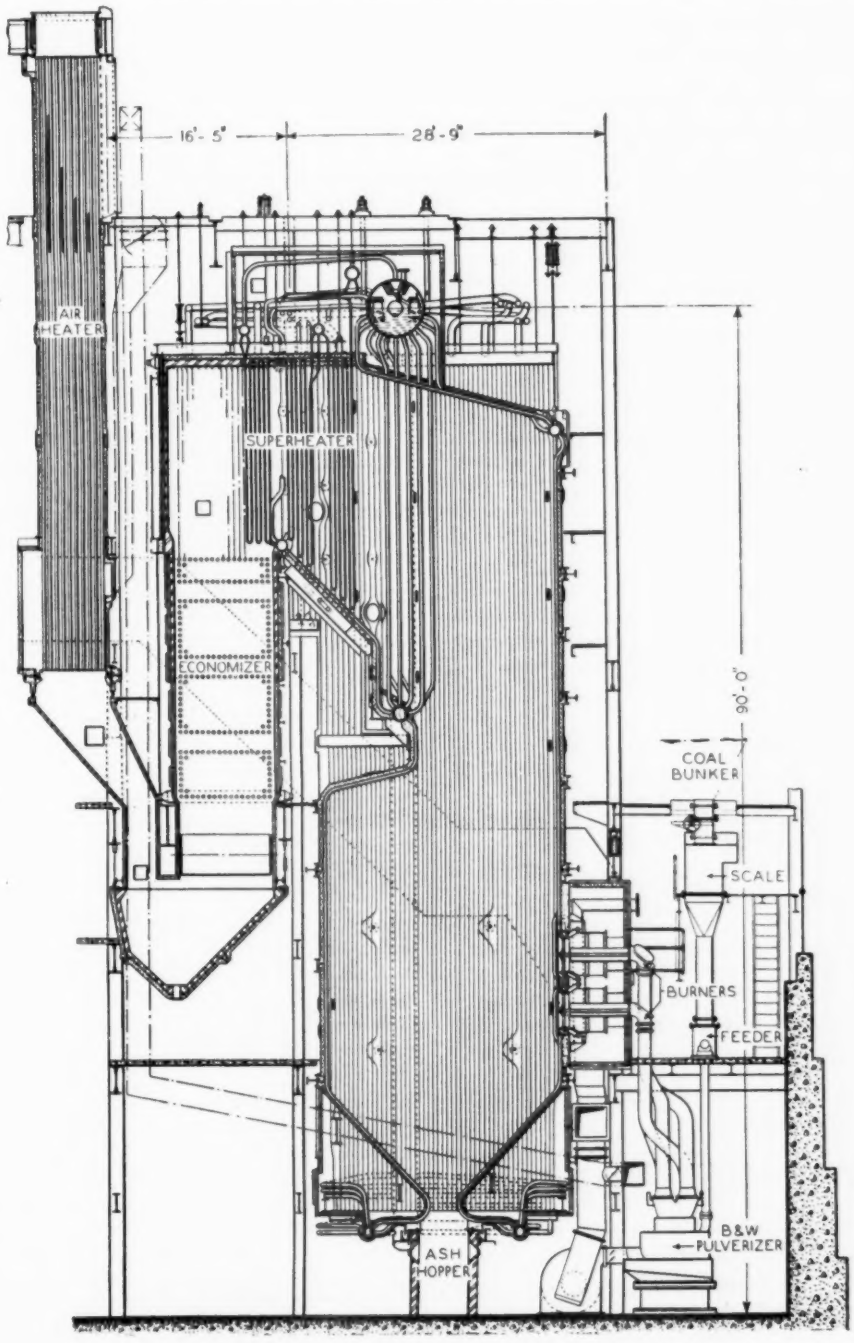

FIG. 6 CROSS SECTION THROUGH BOILER OF 900-PSI CLASS

burners and are performing fairly well. It is interesting to note that during summer months off-peak or "when available" supply of gas to plants Arkwright and Atkinson has approached 2 billion cu ft per month. The availability of burners and pulverizers installed with these units has been practically 100 per cent with no emergency outage. For the first 150,000 tons per mill, when pulverizing coal having a grindability of 45 to 50, there have been no replacements with the exception of exhauster-fan blades.

OPERATING EXPERIENCE WITH STEAM UNITS

In studying the performance of modern boilers, it is perfectly evident that the difficulty with handhole gaskets had caused considerable outage and particular effort was made in improving the design of previous units to reduce the extent of waterwall headers to an absolute minimum and thus eliminate handholes with their plates and gaskets. This was carried to the point of necessitating extremely long tubes, which were fabricated by welding, and required special arrangements for shipping. The cross sections of all these boilers clearly show this feature in the wall tubes. It is evident that a failure in one of these long tubes calls for repair by welding and this has been done successfully.

A study of the superheater of any of these boilers shows how

important it is that all portions of these tubes be free of faults and that no solids shall be deposited by the steam. In all cases tubes are made up with welded joints and at the outlet-header nipples are welded in and stresses relieved before shipping. None of these superheaters is drainable and great care must be taken to see that all condensed steam is evaporated before the tubes are subjected to gases at normal operating temperatures. One failure in the superheater of one of these boilers and of similar installations has been experienced, due to the presence of water in certain tubes, thus preventing the flow of steam and consequent overheating. In regard to the time element to secure safe starting, it may be noted that in general the elapsed time between the first indication of pressure rise in the boiler drum when starting from cold and the time for closing vent valves on the superheater outlet when steam is being supplied to the turbine is approximately $2^1/_2$ hours.

Other failures of superheater elements include erosion, due to leaking baffle, and one case of corrosion. The case of corrosion occurred near the upper end of the superheater element on the inlet side, and since there is no evidence of high temperature it must be assumed that the failure was due to oxygen attack which had been concentrated due to condensate flowing into the tube, or during the shutdown period when this element of the tube was nearly filled with water. This is mentioned because of the emphasis which it places on the necessity either for completely filling the superheater elements with water properly treated, or completely drying these elements when the unit is out of service. This latter is not easy of accomplishment.

Automatic combustion control providing only for the control of fuel and air to the pulverizers, secondary-air supply, and induced-draft-fan operation has been highly satisfactory.

With one exception the pumps for these units are all motor-driven with constant-speed motors, and the feedwater-control element consists of a single valve. Something over 2 years of service from one of these valves, which is provided with good hydraulic characteristics, has resulted in an almost perfect record, and the valve is now reported as being tight enough for shutoff purposes so that the boiler may be banked with a full pressure on the pump side of this valve. In contrast with requirements for boilers supplying steam at a rapidly fluctuating rate where three-element control is used, these valves operate from drum level only. By using a direct-contact heater for deaerating the feedwater and as a storage supply ahead of the boiler feed pump, one high-pressure closed heater has been eliminated. On the other hand, power for pumping increases somewhat, and we have found that pure water at 320 F attacks the steel in the pump more rapidly at points of high turbulence than at 235 F so frequently used. The cure for this has been coating such areas with a high-grade alloy metal or some recirculation of boiler salines.

Although the history of these units is not long enough to be conclusive in regard to carry-over, No. 1 unit at Chickasaw and No. 1 unit at Arkwright were each inspected after 2 years of operation and were found to be relatively free of blade deposits. In fact, this condition was such that continued operation throughout another year would have been satisfactory in this respect. The subject of carry-over embraces boiler performance, quality of feedwater, and finally quality of steam. To secure feedwater with low content of dissolved solids, make-up is secured from evaporators and special attention given to securing tight condensers.

Since the various manufacturers' recommendations were used in securing condenser tubes to the tube sheet, two methods were used. In one case, tubes are rolled at both ends, elongated by heating before rolling-in, and bowed slightly to take care of expansion. The other method calls for rolling at one end and packing at the other end of the tube, which was highly polished to avoid dragging the packing due to any movement caused by expansion. Both methods have proved highly satisfactory.

Starting with high-grade condensate secured from these condensers, water is supplied direct to the boilers without addition of chemicals but with thorough deaeration. Chemicals are supplied individually to each boiler through a chemical feed pump, and the initial operation of all boilers used the well-known phosphate treatment. Enough sodium sulphite was used to maintain from 10 to 15 ppm in the boiler water in order to take care of any residual oxygen or that picked up during shutdown periods. It may be noted here that the record of sulphite used in the case of 450 lb pressure and 850 lb pressure shows a considerable discrepancy, the easiest explanation being that in the higher pressure some of the sodium sulphite is broken up. About 15 or 20 ppm PO_4 in solution is maintained in the boiler water and pH of approximately 11. Under these conditions it was found that the first three boilers installed accumulated a considerable amount of fine black magnetic oxide in the boiler water. This oxide was present in quantities sufficient to cause considerable concern, and it should be noted here that the cure for it was considerably delayed due to the necessity of maintaining all boilers in operation. Some variation in boiler-water treatment was undertaken but without conclusive favorable results. Although no boiler failures have resulted from this type of corrosion, its prevention will be eagerly sought.

Turbogenerators and Fuel-Storage Methods

It will be noted from the data in Table 1, that six of the seven turbogenerator units installed in the last 4 years are equipped with hydrogen cooling for the generators. This has been highly satisfactory, hydrogen use has been less than specified by the manufacturer, and the control equipment has been trouble-free.

All of the 3600-rpm units in this group were built after the developments which provide for mounting the stator iron within a fairly rigid frame so that the 7200-cycle vibration, which has been objectionable in some earlier designs, was practically eliminated. The performance of the exciters on these units has been fairly satisfactory. The manufacturers supplied each turbine with pressure-relief diaphragms on the exhaust casing and automatic throttle closing in case of high back pressure, so that none of these units was equipped with atmospheric relief valves. This equipment has proved satisfactory on these and one 1929 unit.

At the time these plants were being designed, the use of tractors with bulldozers and carryalls for storing and reclaiming coal was gaining favor rapidly and after a test at Plant Atkinson, this equipment was put into use at the four plants: Atkinson, Arkwright, Chickasaw, and Gorgas. The advantages of using this equipment for storing and reclaiming coal are the wide range of operations permissible, low first cost, and the ability to store coal to any height of pile, as much as 30 to 40 ft. Over 200,000 tons have been stored in one pile with this equipment. Furthermore, the dense packing resulting reduces spontaneous combustion to a minimum; in fact, there have been no fires in such piles.

It is impossible to go into detail of all operating characteristics of these units, but it may be said that all changes in equipment worked out through co-operation with the manufacturer during the design of these plants have been quite satisfactory.

The longest forced outages have resulted from the damage to one superheater, previously noted, and the delay in putting two generators into regular service due to hot spots developing in the stator iron, which called for extensive rebuilding by the manufacturer. Erosion of induced-draft fans has caused repeated short outages, and plans are now under way for installing dust collectors ahead of these fans at one plant.

Shortage of manpower has prevented compilation of data to determine closely the performance of these units; such checks as have been made show they are surpassing design performance.

The Co-Ordinated Operation of Hydro and Steam Capacity in Electric Power Systems

By G. W. SPAULDING,[1] BALTIMORE, MD.

Two decades or more ago, numerous technical papers were written on the then popular subject of hydro *versus* steam power, but more recent discussions, presented both in society journals and in other engineering publications, have emphasized the advantages of the co-ordinated use of hydro *and* steam. These later papers have explored and charted that wide range of existing conditions where co-ordinated operation of hydro and steam will be more economical than use of either alone; and today the general principles involved in such co-ordinated operation are understood and applied in many regional power systems. In the first part of this paper, the historical development and the present status of co-ordinated operation in a specific regional power system are reviewed. This is followed by discussion of a possible approach to the use of pondage at run-of-river hydro plants as part of the system reserves, such use being predicated upon the probabilities of noncoincidence of maximum system loads, minimum river flows, and severe forced outage of steam capacity.

THE highly diversified industrial area in the Middle Atlantic States, including New Jersey, Delaware, Eastern Pennsylvania, Maryland, and the District of Columbia, is served by seventeen electric utility systems with power-generating resources of over 4,500,000 kw. The individual operating systems of the area, controlled by more than a dozen independent interests, have through the last decade been interconnected by high-voltage transmission lines to form an integrated regional system. Effective co-ordination of operation of the combined hydro and steam resources of this region has been established. The four companies operating in the southern portion of this area completely co-ordinated their hydro and steam operations over 10 years ago, while three of the larger companies in the northern portion began such operation at an even earlier date. Interconnection between the northern and southern parts of the area began about 1931, and over-all co-ordination has subsequently developed. Very recently, interconnections have been strengthened between the northern end of this regional power group and other regional systems in New York State and through them with power systems in New England.

Co-operative studies on a regional basis were initiated in the late 30's. These studies were gradually expanded to assure fullest utilization of the hydro and steam resources in the carrying of increased loads, in the scheduling of maintenance, and in meeting emergency outages of equipment. As a consequence, the production of power at the more economical steam-generating stations, in general without regard to location or company ownership, has resulted in operating economies and more effective utilization of available generating capacity. In addition to the co-ordinated scheduling and operation of capacity, there has been a continuing interchange of energy on an economy basis which has made possible, in the last 2 years, substantial conservation of much needed coal and fuel oil and in relief of fuel transportation.

[1] Vice-President, Pennsylvania Water & Power Company.

Contributed by the Power Division and presented at the Spring Meeting, Birmingham, Ala., April 3–5, 1944, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

REGIONAL LOAD AND CAPACITY CONDITIONS

This regional power area is predominantly urban in character. The electrical-load requirements are typical of what might be expected in metropolitan areas in which are located large and diversified industries. The power resources of this area consist of approximately 85 per cent steam capacity and 15 per cent hydroelectric capacity. Of the effective hydro capacity of about 670,000 kw, nearly 90 per cent is installed in run-of-river plants along the lower reaches of the Susquehanna River, about 10 per cent is supplied from storage projects in the Delaware River drainage basin, while the balance is made up of numerous small hydro installations.

Since there is no upriver storage on the Susquehanna, the plants on this river are essentially run-of-river plants, the pondage at the plants being relatively small in comparison with installed capacities. The Susquehanna is subject to wide variations in natural flow. The flood stages of the river usually occur in the spring of the year, and the resultant reductions of head and capacity rarely adversely affect system capacity requirements, but the experienced low flows in the late summer, fall, and winter do have an important effect on the system capacity requirements. It is in the treatment of this capacity situation that this large interconnected group of utilities may be different from other power systems.

There has been co-ordinated hydro and steam operation in certain of the interconnected systems through varying forms of power contracts for over three decades. Because of this fact, most of their steam-capacity installations have been designed for sustained or base-load operations, that is, the turbines and more particularly the boilers have been designed and rated for operation for 12 or more hours a day, which operation is required with low river flow when the peak portion of the load is carried by the hydro plants. On other power systems in the area, experiencing generally the same daily and seasonal load shape, but with relatively less hydro capacity, the steam capacity has, through the years, been designed to carry a large portion of the daily peak loads, normally of short duration, and cannot be operated at maximum output for sustained periods. In co-ordinated operation, the normal limitation of this peak steam capacity must be recognized.

Under present-day conditions, with high-load-factor wartime loads, and absence of sharp evening peaks resulting from extension of daylight-saving time, and, until recently, curtailment of lighting in coastal areas, it has been necessary and desirable to use all steam capacity on a more or less sustained basis. This means that those plants designed for peak operation must now be operated for longer periods at reduced loading. The sharp peak loads, or what is left of them, are scheduled to be carried by hydro under critical capacity conditions.

ESSENTIAL FACTORS IN A CO-ORDINATED REGIONAL POWER SYSTEM

There are obviously several essentials to the complete and

full co-ordination of the combined generating facilities of a regional power system, in addition to the necessary physical facilities, particularly when the various operating systems in the power region are controlled by independent interests. These are as follows:

1 The first essential is the availability of power contracts or interconnection agreements between the several companies of the area which are sufficiently flexible to cover the wide range of required operation. Fortunately, there were such flexible interconnection agreements in this regional area, dating back at least 5 years. There must, of course, be an incentive for co-ordination, and this can best be provided within the framework of the power agreements.

2 Considerable operating experience is necessary before the fullest advantage from co-ordinated operation can be obtained. Our co-operative studies were expanded in both scope and detail in the light of experience gained during the several years preceding the present increased war loads, such experience establishing not only the basis for determining the amount of capacity gained from co-ordinated operation, but also the routine planning and scheduling of operation and of maintenance.

3 A procedure for day-to-day direction and control of co-ordinated operation is essential. Experience has indicated, when other essentials are provided for, that the maximum advantages can be obtained without a top regional power dispatcher, so long as there is a co-operative effort on the part of the several system dispatchers to work in the interest of over-all operating economy. This co-ordinated operation, which has been of such material aid in the war effort in this regional area, has been accomplished without encroachment upon the individual responsibilities of the many operating companies.

Joint Operating Problems Not Difficult to Handle

The operating problems of system frequency control, time variation, and tie-line controls have never been difficult, largely because of the capacity of the interconnecting transmission network. This consists primarily of two high-voltage 220-kv transmission systems, themselves interconnected by a grid of double-circuit 66, 110, and 132-kv lines. There are no automatic frequency controls or tie-line loading controls on the regional system. The responsibility for frequency control is assigned, from time to time, to one of the five larger systems.

Telemetering is used extensively in the several dispatching offices to give indications of tie lines, system loads, and station generations.

Problems of policy are considered by a "Steering Committee," consisting of the top operating executives of each operating company in the region, but experience has indicated that once the general principles are agreed upon, frequent meetings of this Steering Committee are not necessary. The detailed operating and accounting problems are handled through so-called "Operating Committees," on which each company or group of companies is represented by operating men.

One of the purposes of the continuing co-operative studies is the determination of the maximum firm hydro capacity available from the run-of-river hydro plants when operated as a co-ordinated part of the regional system capacity. Our problem was not one of determining whether hydro or steam capacity should be provided to serve the increasing system load, but rather how much more war load could be carried on the regional system by complete co-ordination of the three large run-of-river hydro plants and the available steam capacity. These hydro plants are owned by different utilities and, although geographically close together, are electrically connected with different parts of the regional system. While there were found to be minor limitations in the power that could be interchanged over the regional network, particularly between the northern and southern sections, these limitations did not impose any serious restrictions on the complete utilization of the available power resources. A detailed discussion of some of the general factors that enter into our studies of firm hydro capacity may be of interest in connection with further considerations of the economies of run-of-river hydroelectric developments.

Hydro Installation

There are four run-of-river hydroelectric plants within a 50-mile stretch in the lower reaches of the Susquehanna River adjacent to tidewater. Data on these plants are given in Table 1.

The operation of run-of-river hydro plants in a hydro-steam system has been frequently explained, and it is sufficient here to call attention only to the low ratio of hydro to steam capacity in this regional system. Under normal operating conditions, the Safe Harbor pond can be used for weekly regulations of low flows; but there are other conditions under which such operation is either not desirable or not possible. In general, the use of the Safe Harbor pondage differs for three possible conditions of operation, as follows:

1 When there is ample system capacity, i.e., an excess of reserve capability, the Safe Harbor pond elevation is scheduled to provide for most economical use of hydro energy on the combined system load. The use of pondage is so scheduled as to have the forebay at top elevation Monday morning.

2 When, because of low river flow or reduced steam reserve capability, the capacity situation appears critical, the Safe Harbor forebay is maintained as near top elevation as possible, at least during the first part of the week, in order that maximum pondage will be available in the event of forced loss of steam capacity, i.e., for emergency use.

3 When, because of low river flow, coincident with loss of steam capacity due to forced outages, there is a deficiency in steam-generating capacity on the system, i.e., an emergency exists, the Safe Harbor pondage may be drawn on to obtain the needed energy from the three lower plants. It should be recognized that the only alternative to such operation would be to curtail system load. As soon as steam reserves are again available, hydro generation is curtailed to restore the forebay to normal.

Load Shape and Maintenance Requirements

The 15-min integrated peak loads for each week in a wartime

TABLE 1 HYDRO PLANTS ON LOWER SUSQUEHANNA RIVER

				215		606000	17000000

[a] Energy that can be generated from useful pondage, including both generation at site and at downstream plants.

and a prewar year are shown in Fig. 1. The critical capacity conditions might be expected, from these data alone, to occur in December. In an all-steam system that conclusion would be obvious; but in a hydro steam system without storage, where hydro capacity varies from month to month depending upon river flow and reaches minimum values about September, the late summer loads may be the most critical. Maintenance requirements and condensing-water temperature effects on steam capacity also must be considered in this connection.

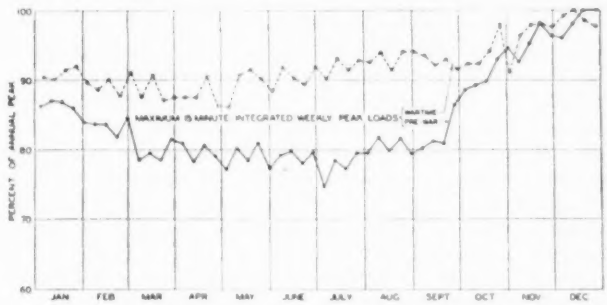

FIG. 1 ANNUAL LOAD SHAPES OF REGIONAL POWER SYSTEM

The valleys in the prewar annual load curves of the regional area and to a lesser extent in the wartime load curve, together with the seasonal variations in the amount of available hydro capacity, control to a large extent the scheduling of steam-unit maintenance; but because it is normally possible to schedule most maintenance at times other than the expected time of occurrence of system peak load, maintenance usually has little or no effect on system capacity requirements.

RIVER-FLOW EXPERIENCE

For many years, computations of firm hydro capacity have been based upon the most adverse river flows then of record, determining for such flows the hydro capacity that would be firm on maximum expected loads with pondage used over some specified period of time, determined by the assumed length of simultaneous forced outage of steam reserves. The improbability of the coincidence of all these conditions has led to a growing feeling that such assumptions are extremely "conservative."

The wartime need for using maximum-capacity resources gave added impetus to several earlier studies relating to the applicability to capacity computations of river flows somewhat greater than the minimum flows of record, but still coincident with the maximum system peak loads, and to the use of Safe Harbor pondage over a shorter period of time, which in turn is related to more recent experience on the probable length of simultaneous forced outages of steam units.

Prior to the increase in load resulting from war, the minimum weekly flows of record for each month were used in capacity computations; but currently the effective hydro capacity is computed for river flows that can be expected to be equaled or exceeded in about 93 per cent of the years (based upon flow records from 1891 to date). For the river flows thus selected for each low-flow month, the effective hydro capacity is determined for the maximum weekly load estimated for that month, with pondage used on a weekly cycle of drawdown and refill. This hydro capacity is then combined with steam capacity, adjusted for circulating-water temperatures, and for scheduled maintenance in arriving at the minimum total effective system capacity for that month, i.e., for load-carrying capacity and for system reserves. The excess of this computed capacity over the estimated system load is the capacity available for reserves and for new loads; the latter being of particular interest to the companies themselves and to the government agencies responsible for the location of war industries.

In the foregoing procedure, there are certain hydro resources which have not been fully evaluated. Additional hydro capacity is available for something less than 93 per cent of the time, resulting from river flows in excess of those used in capacity computations. Such capacity is valuable for the release of steam units for maintenance work in addition to that scheduled in advance, and much maintenance of this nature has recently been necessary. Additional hydro capacity is also available from the short-time use of pondage, when required by the simultaneous forced outage of a large number of steam units, even with stream flows lower than those used in capacity computations. The extent to which a system would be willing to rely on such capacity as firm would be influenced by the forced outage record of its own or similar steam-generating equipment, and upon the amount of other reserve capacity then available on the system.

Perhaps someone will eventually evaluate and properly combine all the pertinent factors by the application of a probability theory. As this theoretical solution now seems impracticable, an attempt has been made to approximate the possible use of pondage in the light of the forced-outage experience of steam-generating equipment, the ideal objective still being that a combined hydro and steam system should have substantially the same degree of reliability as an all-steam system.

FORCED-OUTAGE EXPERIENCE OF STEAM CAPACITY

Forced or emergency outages of steam turbines and boilers are of relatively infrequent occurrence; and only over a period

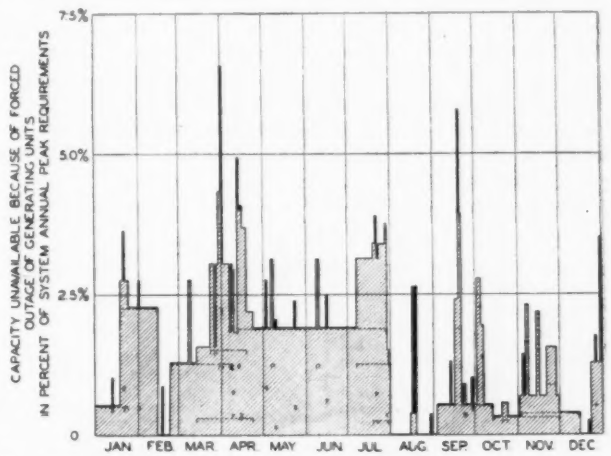

FIG. 2 ACTUAL FORCED OUTAGES OF GENERATING CAPACITY, 1943
(Exclusive of all scheduled outages or losses of capacity due to causes outside of the generating plants.)

of years could a system accumulate sufficient data to determine reasonably well the average forced-outage probabilities of its generating units. These probability factors may differ between systems in which there are different types of units or different operating requirements and maintenance practices. Although conclusions regarding either detailed differences or similarities in the probability factors must await collection of additional data, the general fact that simultaneous outages of a large number of generating units are infrequent and of short duration seems to be well established. This fact is fundamental in the determination of required system reserve capacity and the possible use that can be made of pondage.

The term "forced, or emergency outage" is sufficiently descriptive so that no precise definition is here required. We are interested only in the outages of facilities which have a bearing

upon the capacity resources of the power system, and we are not here concerned with scheduled outages for inspection, where such outages can be scheduled in advance.

It will be noted in Fig. 2 that a number of fairly long steam-unit outages were experienced on the regional system in 1943. Three of these prolonged outages existed concurrently on April 1, at the time of the largest total forced outage of capacity during the year. Yet, more than one half of this total simultaneous outage only lasted from 1 to 3 days. In spite of these several long outages, the average forced-outage time for this year was somewhat better than might have been expected from our own earlier experience; but such variations would be quite normal in year-to-year operation of any system.

Most of the individual and all of the more serious simultaneous outages, shown in Fig. 2, were of short duration. The absence in this one year of long severe simultaneous outages of capacity does not prove that such outages cannot exist, but the probabilities are decidedly against them. Data for earlier years generally confirm those shown for 1943, and give weight to the opinion that severe simultaneous forced outages of steam capacity are infrequent and of short duration. This point is important in connection with the use of pondage as firm capacity.

Use of Pondage for Short-Time Capacity

The pondage, which system operations have indicated as usable by the lower Susquehanna River plants, is equivalent to 17,000,000 kwhr. This is nearly $2^1/_2$ times the weekly hydro energy available from the lowest 7-day average river flow recorded in the month of December. Some portion of this pondage might be used (not to be confused with normal weekly use of pondage where the forebay is returned to top elevation on each Monday morning) as system reserve capacity on those infrequent occasions when severe multiple forced outages exist coincident with peak week loads and minimum flows. Such pondage operation is illustrated in Fig. 3, for the conditions assumed in capacity computations in contrast with conditions more likely to be met in actual operation.

The diagram at the left in Fig. 3 shows the assumed simultaneous outage of steam capacity equal to the ordinate Y. The energy made available by use of only 40 per cent of the available pondage, during the first 5 days of a period beginning Monday morning, would permit hydro capacity to replace an amount of steam capacity equal to the largest steam unit on the system (135 mw), or to the aggregate capacity of several smaller units. This capacity is indicated by the dimension X. (It is here assumed that there would be sufficient installed capacity at the hydro plants to permit such operation, which, however, is not presently the case.) By the following Monday morning, X capacity, out of the total forced out, is assumed to be returned to service. At that time about 60 per cent of the stored energy is still available as pondage, and this condition would be maintained until additional amounts of steam capacity are returned to service to permit gradual refilling of the ponds. The pondage will also be refilled in part as higher river flows are experienced or lighter system loads are encountered, both of which will have an appreciable influence, since it had been assumed from the beginning that such use of pondage coincided with maximum weekly loads and minimum river flow.

The diagram at the right in Fig. 3 assumes simultaneous outage of steam capacity such as was experienced by this system during the middle of April, 1943, the maximum of the simultaneous outage again being equal to Y capacity. In both diagrams the hatched areas indicate the capacity X and X_1 that could be obtained by drawing down the ponds of these three run-of-river hydro plants, while the cross-hatched portion represents capacity, which had been forced out at the beginning of the period but is returned to service, and the approximate time to bring the forebay back to top elevation. A comparison of the assumed and the more probable outage condition indicates that the assumption shown at the left is, indeed, conservative in the light of forced-outage experience; but it is an approach to the use of pondage for at least a portion of the system reserve.

It is necessary to emphasize that the amount of hydro capacity which may be available from drawdown cannot be considered as replacing the entire system reserve requirements. Obviously, it is impossible for pondage to be used as protection

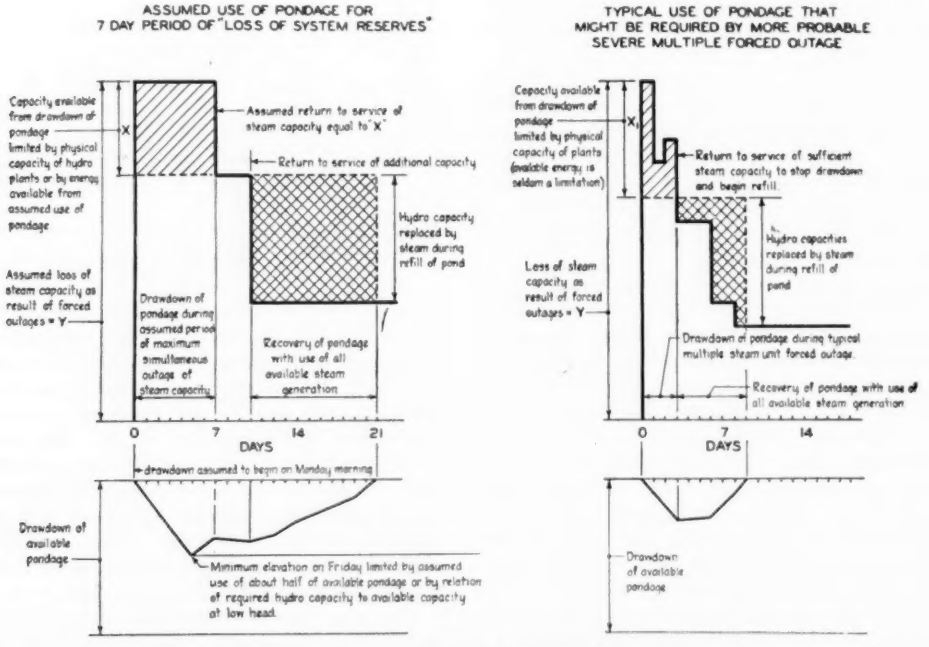

Fig. 3 Use of Pondage as Reserve Capacity

against all outages of steam capacity, for these are almost continuously existent; in low flow the available pondage would soon be exhausted as opportunities for refill would be inadequate. Neither could pondage provide protection against errors in load estimates which must be made several years in advance, nor could it provide capacity to cover scheduled maintenance where required during the peak load period of the year. However, under normal conditions, pondage might be considered for about one third of the total required system reserve.

Under present-day conditions, with necessity of meeting war loads with less system reserve than would be provided in normal times, together with the realization that any new loads added in the area might likely be of high load factor, it has been felt that the use of pondage should be limited in capacity estimates to that used on a weekly recovery cycle. It is appreciated that there is in storage, hydro energy available as emergency reserve.

Conclusion

The co-ordinated operation of all the interconnected utilities in this regional system, initiated by the utilities themselves for economic reasons even before the war clouds in Europe gathered, has proved of immense value in meeting electric-power demands of the national war effort. There has been considerable satisfaction in the realization that the saving of critical fuel and its transportation has been accomplished, and that the area has been able to absorb increased war loads because of such co-ordinated operation on a regional-system basis.

Evaluating Importance of the Physical and Chemical Properties of Fly Ash in Creating Commercial Outlets for the Material

By C. M. WEINHEIMER,[1] DETROIT, MICH.

The paper presents the reasons for emphasizing the physical properties rather than the chemical constituents in outlining an investigational program for fly-ash disposal and outlines the procedure followed in determining the potential consumers of this material. The results of a laboratory and field investigational program are presented and various methods and equipment for modifying the ash to meet special requirements are discussed. Commercial markets and other possible uses for fly ash are discussed together with the handling equipment and the storage facilities necessary in using bulk fly ash. Finally, certain conclusions are presented regarding the general problem of fly-ash disposal.

ANY company which operates pulverized-coal-burning equipment so located that collection of the fly ash is desirable and has available low-cost, adjacent land on which to dump it, is indeed fortunate. The company with which the author is associated is now in that enviable position; the long-time outlook, however, may not be so favorable. It is with this thought in mind that it has been considered advisable from time to time to sponsor work having as its purpose the development of revenue-producing outlets for fly ash. It is self-evident that any fly ash disposed of at a profit is not only a source of revenue in itself but at the same time eliminates disposal charges. It is conceivable that the profit derived from the sale of a portion of the fly ash might cover the cost of disposal of that portion for which there is no market.

In approaching the fly-ash-disposal problem, it can be considered that the value of the material lies in its physical and chemical properties, or in its chemical constituents.

The best hope for a satisfactory outlet seemed to be in capitalizing on the finely divided state in which all fly ash exists, and the major part of the investigational work was conducted with this property in mind. Nevertheless, it was felt that a certain amount of information on the chemical characteristics of fly ash would be necessary in order that we might talk intelligently with prospective customers, and, therefore, rather extensive chemical analyses were made of fly ash "as collected" and of a number of sieve fractions. In this connection it is well to make a distinction between chemical composition and chemical properties.

Laboratory Investigation

A laboratory program was undertaken, the object of which was to determine how fly ash compared physically and chemically with the materials that the ash might replace. Some of the physical and chemical properties and chemical constituents of fly ash are presented in Tables 1 and 2. Although most of this information is of a commonplace nature and is self-explanatory, a few of the properties, together with some not shown in the tables, warrant a brief discussion.

Physical Properties

Particle Size. In dealing with a material as fine as most fly ash, it is usually desirable to know more about the particle-size distribution than it is possible to learn from a sieve analysis. There are numerous ways of determining particle size in the subsieve-size range and a few of them as applied to fly ash will be discussed.

It was found that different technicians, using the hydrometer method, described by Biddle and Klein,[2] and the same suspension medium, could arrive at reproducible results within 5 per cent. However, when different suspension mediums were used, a wide divergence in results was obtained. The detailed results of this investigation are shown in Table 3.

Subsequent results obtained, using a Roller particle-size analyzer, indicate that the surface area ranges from 3500 to 4100 sq cm per g. Apparently, better dispersion is obtained when air is used for the suspension medium rather than water or kerosene.

In order to avoid the necessity for determining particle-size distribution by any one of the methods suitable for such determinations in the subsieve size ranges, in case such equipment was not available, an investigation was made of the possibility of making sieve analyses and obtaining the distribution of the finer particles by means of curves on logarithmic-probability paper. With the procedures used in this investigation, air elutriation and dry sieving, the results were not very encouraging.

Color. The color of fly ash is affected to a great extent by the carbon or coke particles. Even in those ashes that contain only a very small amount of carbon, the color is still some shade of gray. The results reported in Tables 1 and 2 show that the carbon content is much higher in the coarse than the fine-sieve fractions, yet the finest-sieve fraction with approximately one half the carbon content of the original material is reported as having the same color as the original material. In another case, where the carbon content was reduced to a little over 1 per cent, the color was distinctly gray. An explanation of this phenomenon is found in the fact that color is influenced to a greater extent by surface area than by weight. Thus in spite of the lower percentage by weight of carbon in the fine-sieve fractions, the surface area is probably much greater and the coloring effect more pronounced.

Fig. 1 shows two materials mixed in such a manner as to demonstrate this principle. These bottles contain mixtures of light and dark powders. The percentages by weight of the two powders is the same in each case, but the dark powder in the dark-appearing sample is of a much finer particle size than the dark powder in the light-appearing sample.

siderable verbal if not written discussion about the physical structure of fly-ash particles. From visual microscopic examinations of the ash itself and a study of photomicrographs, it is possible to make the following statements:

The carbon exists as irregular, porous, cokelike particles. The noncombustible particles generally have a spherical shape. A portion of the noncombustible particles, although apparently a small percentage, are thin-walled hollow glass spheres. Most of the dark-colored particles are cokelike material. The other dark-colored particles ordinarily spherical are believed to contain most of the iron compounds. Photomicrographs in Figs. 2 and 3 clearly show the physical condition of certain size fractions of fly ash and also how the condition is affected by burning out the carbon.

Thermal-Insulation Properties

The knowledge that some of the particles of fly ash are hollow glass balls invariably brings forth the idea that the loose ash

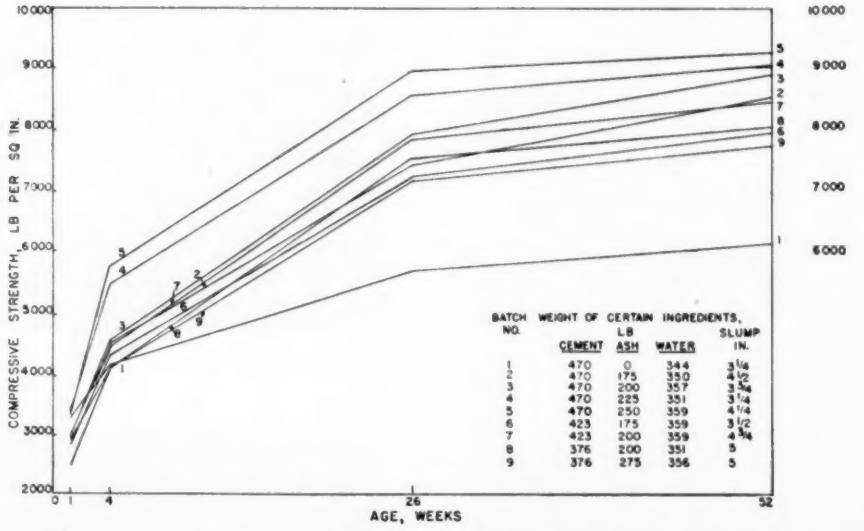

FIG. 4 EFFECT OF VARIOUS CEMENT AND ASH CONTENTS ON COMPRESSIVE STRENGTH OF SLAG-SAND-ASH CONCRETE

should make a good thermal insulator. These hollow spheres are very friable, however; hence it is quite probable that a great many of them are broken in the course of normal handling. In spite of this apparent weakness, it was decided to obtain the thermal conductivity value k, Btu per sq ft per hr per in. thickness per deg F, for bulk fly ash. The values obtained in the investigation ranged from 0.74 at 75 F mean temperature to 1.04 at 356 F mean temperature. Apparently the k value is appreciably affected by the degree to which the ash is consolidated. This is clearly illustrated by the following data:

Density, lb per cu ft	46.7	47.5	50.1	50.0
Mean temperature, deg F	74.9	75.0	74.6	76.0
k value	0.740	0.768	0.863	0.868

A test made on an 8-in. wall of Cottrell block 5 ft square revealed the following information:

Type of insulation	U[a]
None	0.383
Rock wool	0.159
Bulk fly ash	0.179

[a] Over-all conductivity coefficient corrected to a 15-mph wind velocity.

In a number of houses constructed of Cottrell block, fly ash has been used as insulation with apparent satisfaction.

Inasmuch as widespread use of fly ash as a loose insulation material would not be made without information on its hygroscopic properties, a limited amount of work was done in this connection. With a surrounding atmosphere having a relative humidity of approximately 36 per cent, it was found that the ash absorbed 0.15 per cent of its weight in 20 min. The rate of absorption decreased rapidly after the initial period and at 160 hr had reached an equilibrium state at 0.48 per cent.

TABLE 4 RESULTS OF AN INDUSTRIAL SURVEY OF FLY-ASH DISPOSAL

Industry	Material previously used	Can ash be used—Technically	Can ash be used—Commercially	Remarks
Acoustic				
dum dum	Slag dust	Questionable	Yes	Too light in weight
Agriculture				
fertilizer	Spent sand	No	No	Too fine; spent foundry sand delivered for $0.40 per ton
Soil-amendment agent	Unknown	Yes	Yes	Probably would not produce any revenue
Alumina	Bauxite	Yes	No	Uneconomic under present conditions
Building block:				
Cement block	Cement	Yes	No	Detroit market demands light-colored block
Cinder block		Yes	Yes	Improved quality of block
Cottrell block		Yes		
Glazed block		Yes	Yes	Glazed, colored tile for decorative work
Building brick:				
Fired	Clay	No	No	Unsatisfactory product
Sand lime	Sand	No	No	Unsatisfactory product, dark color
Ceramic industry:				
Drain tile	Clay	Yes	No	No improvement in quality of product and cost of manufacture increased
Hollow tile	Clay	Yes	No	
Flower pots	Clay	Yes	No	
Concrete:				
Transit mixed	Cement	Yes	Yes	Improves quality, reduces cost
Cinder ash		Yes	Yes	Lightweight concrete
Floor tile:				
Asphalt tile	Clay	Yes	No	Shipping distance too far. Color limitation
Foundry:				
Core sand	Sand	No	No	Too fine; makes a dense core
Parting sand	Limestone dust	Yes	Yes	Aluminum and magnesium foundries
Facing sand	Sand	No	Yes	Softening point too low for steel
Hot tops	Calcined clay	Unknown	No	Believed to be unsatisfactory
Gaskets	Clay	Unknown	Yes	Believed to be unsatisfactory
Paint	Extender	Questionable	Yes	Lacks covering power; difficult to disperse
Paper	Clay	No	Yes	Color, no matting properties
Plastics	Diatomaceous earth	Questionable	Yes	Poor quality of product
Polishing:				
Buffing compound	Pumice	No	Yes	Does not produce desired finish
Tooth paste	Whiting	No	Yes	Too hard
Portland cement:				
Raw material	Clay	Questionable	Yes	High alumina content is objectionable
Purification:				
Water filter	Sand	Questionable	...	Market small; properly graded material required
Oil	Fuller's earth	No	Yes	Does not produce clarification
Filter aid	Diatomaceous earth	No	...	Does not function as such; wrong type of particle
Zeolite	Zeolites	Yes	No	Small fraction satisfactory; low capacity
Putty:				
Furnace cement	Whiting	...	...	No information was obtainable
Sash putty	Whiting	Questionable	...	Dark color objectionable
Caulking compound	Asbestine	Questionable	...	Dark color objectionable
Road:				
Asphalt	Limestone	Yes	Yes	Lower cost
Concrete	Cement	Yes	Yes	Lower cost; improved product
Oil aggregate	Limestone	Yes	Yes	Lower cost
Roofing	Filler	Unknown	No	No market
Roofing	Slate granules	No	Yes	Too fine
Rubber	Clay	Questionable	Yes	Seems to have possibilities
Soap mechanic's	Pumice	Unknown	Yes	Small market; dark-colored soap
Thermal insulation:				
Insulating cement	Calcined clay	Yes	Yes	Improved product
Loose fill	Mineral wool or vermiculite	Yes	No	Can be used only in the cells of masonry building blocks

Since the thermal insulating value k is very sensitive with respect to the unit weight, the maximum compressibility of the bulk fly ash is important. Again, there are a number of variables, such as original condition of the ash and dimensions of the test specimen, that must be considered in interpreting the results.

Using a cylinder 13.54 in. diam (1 sq ft) and 1 ft high, it was found that with rodded ash the over-all height could be reduced 1.10 in. under a total load of 300 lb. With aerated ash, this reduction increased to 2.15 in. These results indicate that even under a loading of 300 psf, the unit weight would not be more than 48.5 lb per cu ft. If no vibration were present, this might be so, but unit weights of 54.7 lb per cu ft have been produced by vibration alone without any external pressure. On the basis of these data, it appears probable that loose ash in a wall or similar container would acquire a unit weight of at least 50 lb per cu ft.

Chemical Properties

As previously stated, most of the investigational work dealt with the physical properties of fly ash. All of these have been reported and the unusual properties discussed. Earlier in the paper a rather elaborate chemical analysis of fly ash was presented. Fly ash has a few chemical properties, independent of the chemical composition, that warrant discussion.

Certain types of materials are known as "pozzolanas." A "pozzolana" can be defined as a siliceous material that, although not cementitious in itself, contains constituents that at ordinary temperatures will combine with lime in the presence of water to form compounds that have a low solubility and possess cementing properties. Since volcanic tuffs, burnt clays and shales, and pumicite are pozzolanas, it is logical that fly ash should have pozzolanic properties inasmuch as all these materials have a similar chemical composition and have been subjected to a

calcination temperature. Evidence that fly ash is a pozzolana is shown in an indirect manner later on in the paper where concretes containing fly ash are discussed. If increase in compressive strength of concrete is a measure of pozzolanic activity, then the results, shown in Fig. 4, clearly demonstrate that this fly ash is a pozzolana or has pozzolanic properties.

Sales Program

Following the accumulation of these rather complete data on the properties of fly ash, a canvass was made of the potential users located within the area of economic shipment. If possible, a personal call was made to discuss the matter with both the purchasing and technical departments. If information was requested on specific properties of fly ash that had not already been obtained, an attempt was made to furnish it to the prospective customer either by work in our own research laboratory or by sponsoring investigational work in an outside organization. If there was any possibility of substituting ash for a material being used by the customer, a sample of ash was provided. Often these interviews resulted in requests to supply ash in a modified form. Wherever possible this was done. The methods employed to provide the processed ash will be described in detail later. A subsequent attempt was made to learn the results of the experiments using the ash. Sometimes, however, it was impossible to get any worth-while information. The results of this sales program are given in Table 4. The conclusions to be drawn are as follows:

1 There are only a few industries that can use the quantity of ash produced by a large steam power plant.

2 The only reason for attempting to develop the small-consumer market is for greater diversification of sales and to improve the yearly load factor inasmuch as the requirements of the large consumer are apt to be very seasonal.

3 In general, the ceramic industry is not an outlet for ash because ash does not improve the product and clay can be delivered in the plant at a cost below that at which it would be possible to supply ash, except under unusual circumstances.

Modifying Processes

Sometimes it appeared that a prospective customer might be able to use ash if it were modified in some way. The usual requirement was that certain coarse fractions or certain chemical ingredients be eliminated. These cases led to investigations of commercial ways for modifying the ash by some process.

Air Classification. It was found that, by passing ash through an air classifier, a filler material could be obtained which would meet the physical requirements of the rubber and plastics industries. The results of air classification are shown in Table 5.

In doing this work no adjustments were made to the air classifier other than those possible on standard equipment. It is believed that possibly a larger recovery of fines in one processing could be obtained with a small amount of experimentation in adjustments. It should be noted that (1) the fines of Run A meet the physical requirements for rubber and plastic fillers, (2) the tailings of Run A meet the physical requirements for asphalt filler, (3) the fines of Run B meet the requirements for asphalt filler, and (4) inasmuch as the tailings from Run B contain approximately 20 per cent carbon, they might be returned to the furnace as fuel. Since these tailings represent less than 15 per cent of the ash produced, it is doubtful that the dust-collecting equipment would be overloaded by the additional burden.

Carbon Removal. Freedom from carbon is a requirement in many instances, chiefly because of the color effect mentioned previously.

Several ways of removing carbon or reducing the carbon content were investigated but none was found to be satisfactory from both the technical and the economic viewpoints. While none of the modern flotation methods was investigated, some elementary work on this type of processing was done in the laboratory, based on information from Germany, in which it was claimed that the carbon content, which was high in the case discussed, could be reduced by a flotation method using an oil-water emulsion. Our limited work indicated that (1) with carbon contents of approximately 10 per cent no carbon reduction was obtainable, (2) the loss of the flotation medium was excessive, (3) the final product would not have been satisfactory for the intended use even had the carbon content been satisfactory.

The production of carbon-free ash by the continuous-ignition process proved to be technically possible but not commercially

5	5	400	21.82	33.84	21.44	0.38	98.30

[a] Time of digestion varied from 15 min for the smallest quantity of solution to 30 min for the largest quantity.
[b] Chromic acid.

practical. Using an externally fired, rotating, inclined kiln, it was possible to reduce the carbon content from approximately 6 per cent to less than 0.5 per cent. The kiln was operated at approximately 1500 F, and the output was 25 lb of ash per hr. It was found that the introduction of a small quantity of air at low velocity greatly aided the carbon reduction. However, the high fuel cost and limited output possible from this type of equipment prohibit its becoming commercially useful. Approximately 1500 lb of ash were processed in this equipment.

Another attempt was made in the laboratory to remove the carbon by mixing air and ash, both of which had been preheated, in an externally heated chamber. For operating temperatures up to 1800 F, it appears impossible to reduce the carbon content below 2 per cent with this arrangement of equipment.

Further efforts were made to remove the carbon by solution methods. While a number of acids could be used as the reagent to perform this function, our work was limited to the use of cleaning solution (chromic acid). The results are given in Table 6. These results show that, in addition to carbon, other ingredients, probably iron, are removed by this treatment. The fact that the residue retains its white color even after heating to 1800 F in an oxidizing atmosphere, further substantiates the conjecture that the iron compounds are removed. Because of the high cost of processing and the substantial loss of material by this digestive process, it is believed to be uneconomical to treat fly ash with acids for carbon removal.

A final attempt to remove the carbon was made using a contact potential separator at the U. S. Bureau of Mines. Starting with a material containing 7.32 per cent of carbon, two passes through the separator produced a material containing only 1.3 per cent of carbon. The yield of low-carbon material was approximately 55 per cent of the ash charged. Combining certain fractions of high-carbon material and reprocessing them would undoubtedly increase the yield of low-carbon ash without substantially increasing the carbon content. This method appears to offer the possibility of producing a low-carbon and extremely fine material in one processing. In spite of the low carbon content, the material still possessed a light-gray color which is in distinct contrast to the buff-colored material of similar carbon content produced by burning the carbon. This process seems to have definite commercial possibilities for producing a low-carbon fly ash.

Iron-Compound Removal. The general chemical composition of the ash indicated that it could be used as a raw material in the manufacture of glass if the iron compounds were removed. With this in mind, various processes aiming to reduce the iron content were investigated, but none was found which accomplished the purpose.

As previously mentioned, under the process for reducing the carbon content by treating the ash with chromic acid, the iron as well as the carbon was removed. The cost of treatment in this process made such processing economically unsound even if the process yielded a satisfactory material. A subsequent laboratory investigation disclosed that solution methods using hydrochloric, sulphuric, and chromic acids failed in all cases to reduce the iron content below 6 per cent. The original material contained 9.10 per cent iron in the form of an oxide.

Failing to produce a material of low iron content by the solution method, commercial magnetic-processing equipment was investigated. In no case was it possible to produce a material with an iron content of less than 5 per cent.

On the basis of the equipment and processes now available it appears impossible to process fly ash to produce a material containing less than 1 per cent iron which is the maximum permissible for use in the glass industry.

Commercial Markets

As a result of this extensive amount of laboratory and field investigational work, what can be stated regarding the prospects of developing commercial markets that will yield some revenue and use sufficient tonnage to take a substantial portion of the fly-ash production?

Concrete. That certain fly ashes improve the quality of concrete is no longer a debatable question, and the real problem in the use of them in this field is one of economics and sales resistance. In order to obtain data on the value of fly ash in concrete made with the cements and aggregates available in the Detroit area, considerable laboratory and field investigational work has been conducted. This work, part of which was previously discussed, confirmed the findings obtained by other investigators that fly ash has pozzolanic properties.

The chief benefits to be derived from using fly ash in concrete containing pebbles, crushed slag, or stone as the coarse aggregate are (1) greater long-time strength, (2) improved workability, (3) greater resistance to attack by ground waters, (4) lower permeability, (5) lower cost, (6) less bleeding.

Pebble-sand and slag-sand concretes containing fly ash and cinder-ash concrete have been used satisfactorily on a number of projects of the author's company.

The type of concrete and manner of use are as follows:

Type of Concrete	Use
Pebble-sand-ash	Roadways, building structures, machine foundations, cable ducts
Slag-sand-ash	Roadway
Cinder-ash	Lightweight concrete

The fact that the use of fly ash in pebble-sand concrete makes possible a decrease in cement content without sacrificing strength is clearly shown in Fig. 5. As would be expected, because of the

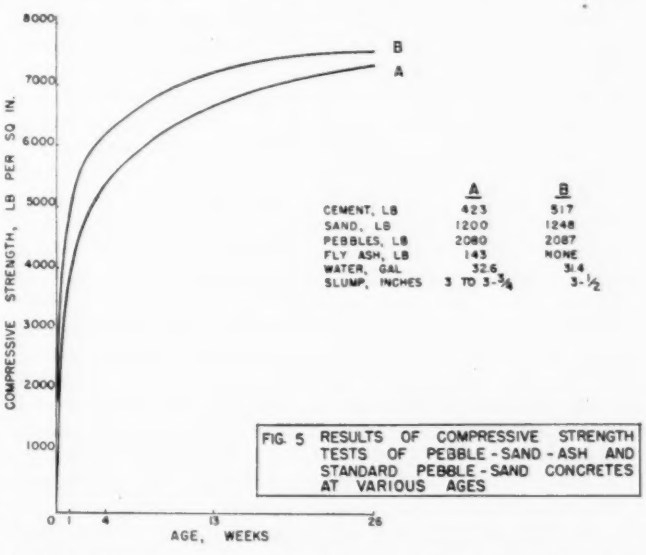

Fig. 5 Results of Compressive Strength Tests of Pebble-Sand-Ash and Standard Pebble-Sand Concretes at Various Ages

lower cement content, the pebble-sand-ash concrete had a lower early strength. However, after 6 months aging, both types of concrete reached approximately the same compressive strength value of 7400 psi, which is excellent concrete. Although in this case it took approximately 6 months for the two concretes to arrive at the same compressive-strength value, other tests have

shown that this point may be reached in a minimum of 28 days and a maximum of 1 year.

In an article[3] by F. R. McMillan and T. C Powers, a method is given for determining the relative values of admixtures and Portland cement in producing workability in concrete. Fly ash was one of the materials tested and in this case was approximately 11 per cent more effective than Portland cement in improving workability. No information was given as to the properties of the fly ash, but it is believed that its efficacy would be considerably influenced by the surface area, specific gravity, and possibly the carbon content. That the addition of finely divided materials is an accepted method for improving workability is evidenced by a statement taken verbatim from the article mentioned: "For example, if it is desired to bring about an improvement in workability, that may be done by enriching the mix, by correction of aggregate graduation, or by the use of almost any one of a host of available finely powdered materials."

Obviously, any material which not only is more efficient than Portland cement in producing workability but also contributes other valuable properties to the concrete should be given serious consideration, especially since the material is available at a fraction of the cost of Portland cement.

The presence of jagged and irregular particles in crushed-stone and to a greater extent in crushed-slag coarse aggregate leads to harshness and poor workability in concretes. The advantages, both as to workability and compressive strength, of using fly ash in slag concrete are shown in Fig. 4.

Recent permeability tests, conducted in the course of this investigational work on fly ash in concrete, were inconclusive in that it was not possible at pressures up to 90 psi to permeate sufficient water for accurate measurement. C. F. Ramseyer, formerly of the Chicago District Electric Generating Corporation, was more successful in his experimental work. In an article[4] reporting his results, curves are presented which show the relative permeabilities of different concrete mixes. The total water-loss permeation through a 28-day-old test specimen made from 6-bag per cu yd concrete was 340 cc at the end of a 7-day test period. The loss during the same period of time on a similar specimen, made from concrete containing 5 bags of Portland cement and 1 bag of fly ash per cu yd was 50 cc, a ratio of nearly 7 to 1. Low permeability is especially desirable in concretes exposed to frost action and ground waters.

From time to time there has been considerable discussion, both written and verbal, concerning the resistance of concretes containing fly ash to the deteriorating effects of alternate freezing and thawing. Some of the investigational work has been carried out on small specimens and it was necessary to screen out of the test-concrete mix part of the coarse aggregate. In order to approach field conditions as closely as possible, freezing-and-thawing tests were run on test specimens consisting of 8-in. concrete cubes from which no aggregate had been screened. The appearance of two tested cubes of pebble-sand-ash concrete is shown in Fig. 6. The results of this test and others indicate no reason to believe that concretes containing fly ash are particularly sensitive to freezing and thawing.

In certain locations, such as caissons or footings, substructures, and underground-cable duct, the resistance of concrete to the ground waters is very important. A great deal of investigational work has been carried on especially in Europe on the effect of

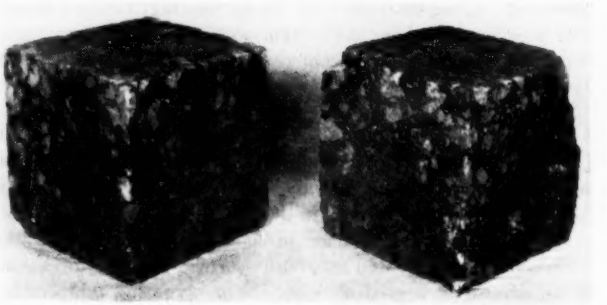

FIG. 6 8-INCH CONCRETE CUBES AFTER SUBJECTION TO 225 CYCLES OF FREEZING AND THAWING
(4½ bags cement, 150 lb fly ash, 36 gal water per cu yd concrete.)

ground waters on concrete. In a book[5] by F. M. Lea and C. H. Desch, a summary is given of the work of a number of investigators who have conducted experimental work on the effect pozzolanas have in increasing the resistance of concrete to the action of ground waters. In general, the results are favorable. In order to determine the effect of sulphur water on the concrete caissons of a powerhouse, an experiment was started by the company with which the author is associated, approximately 15 years ago in which various concretes were exposed to the particular sulphur water in question. An analysis of this water indicates that, in addition to hydrogen sulphide, it contains sulphates commonly found in ground and sea water and is practically neutral, that is, neither acidic nor basic. Some of the concrete cylinders exposed to this sulphur water contain fly ash. The last progress report[6] on this test contains the following conclusions:

1 The concrete should have a high cement content.

2 The concrete should have a minimum slump consistent with good placeability for a dense concrete.

3 The addition of fly ash up to 35 per cent by weight of the cement content is desirable.

This discussion regarding concrete has dealt with improving the quality of the product. In approaching a prospective user of fly ash, a sales argument that shows him how he can reduce his costs has much more appeal than one concerning improvement of his product. This is natural in that he is now selling his product and, therefore, believes it must be good enough for the job. The chance of making any substantial saving in the cost of concrete other than by a reduction in cement content is remote. Cement is a comparatively cheap material. Therefore, it is essential that there be a sufficient differential between the cost of cement and of fly ash to make it worth while to handle an extra material. Part of the delivered cost of fly ash is in the handling; this matter is discussed later on.

All the foregoing discussion has dealt with a standard concrete modified by the addition of fly ash. A new lightweight concrete is now available that uses fly ash in large quantities. It is known as cinder-ash concrete[7] and can be used wherever lightweight concrete is acceptable. All the floors and the roof in a six-story office building of a volume of 2,000,000 cu ft are constructed of this material. Before proceeding with the use of cinder-ash concrete in this structure, an extensive investigation was made of properties of the concrete. The results of this investigation are given in Table 7.

No. 100	100.00

The extensive use of this type of concrete would create a large market for fly ash because of the high ash content. The ash supplied for the cinder-ash concrete used in the building mentioned had about 25 per cent moisture by weight of dry ash. This in itself may seem a bit unusual and contrary to accepted practice. Early in this paper, it was stated that fly ash was a pozzolana and, according to the definition, a pozzolana was not cementitious in itself. Therefore there seems to be no reason that moist ash could not be used in all types of concrete. An investigation of this deduction disclosed that as good concrete can be produced with moist fly ash as with dry. However, it should be pointed out that the problems encountered in handling moist fly ash are quite formidable and any shipping advantages obtained from using the moist ash may be offset by local handling difficulties.

Bitumastic Road Fillers. Trinidad asphalt was at one time about the only bitumastic material available for road construction. Now, however, by-product materials from the oil refineries and the coke ovens provide a large amount of binder material. Trinidad asphalt is in fact a mixture of asphalt and mineral filler. From the chemical composition and the appearance of the particles, this filler evidently is pumice which is of volcanic origin. In the course of our investigational work in connection with the use of fly ash as a mineral filler in asphalt topping, an incomplete chemical analysis was made of the mineral filler in Trinidad asphalt. A comparison of certain chemical ingredients of fly-ash and Trinidad-asphalt-mineral filler is given in Table 8.

TABLE 8 PRINCIPAL INGREDIENTS OF ASPHALT FILLERS

Material	Composition, per cent by weight—SiO_2	Al_2O_3	Fe_2O_3	Total
Fly ash, as collected	45.9	26.9	9.1	81.9
Fly ash, burned free of carbon	51.4	30.1	10.2	91.7
Trinidad-asphalt filler	67.6	18.9	6.4	92.9

The use of fly ash as a mineral filler in bitumastic road construction is now definitely established in the Detroit area. This use was arrived at, however, only after an extensive period of experimentation and by overcoming a considerable amount of sales resistance. The fly ash is being used as a mineral filler in both asphalt and oil-aggregate or black-top types of roads.

The original installation of asphalt topping or wearing surface was installed on a heavily traveled thoroughfare in 1931, and it is still in use. Since 1939, approximately 1,325,000 sq yd of fly-ash-asphalt topping has been installed. Design data typical of this material are as follows:

Ingredient	Per cent by weight
Sand	76.7
Fly ash	13.0
Asphalt	10.3
Total	100.0

This mixture, when tested in a Hubbard-Field stability tester, gives a stability value of 1925 lb.

Oil-aggregate or black-top roads differ from asphalt topping in that the binding agent in the former is a slow-curing asphaltic oil, while in the latter it is asphalt. There is also a considerable difference in particle size and gradation of the aggregate, the oil aggregate having much larger particles and less mineral filler. Oil absorption by the filler is an important item in the cost and should be determined. The amount of absorption would undoubtedly be different for various ashes, depending probably upon the surface area and carbon content.

Rubber. In both of the large outlets for fly ash previously discussed, the delivery demands fluctuate widely and seasonally, there being practically no demand in the winter months. An attempt to improve this yearly load factor led to a rather extensive investigation of the possibility of substituting fly ash in some form for the clays and whiting now used as inert fillers in certain rubber products. It was realized that the "as-collected" fly ash would not meet the fineness requirements for rubber filler, but the air-classification process previously described did permit the recovery of approximately 50 per cent of the ash in a satisfactory particle size for use as a rubber filler. The estimated cost of classification was sufficiently low to make the process a commercial possibility. As previously mentioned, a considerable amount of ash was air-classified and a portion of this was burned free of carbon. Quantities of these materials were supplied for test purposes to a rubber company whose products were mechanical goods, such as floor mats, pedal covers, running-board mats, etc. The resulting rubber product was reported as having a tensile strength 10 per cent lower than that of the present material and of a darker color.

For the type of product being made, the limited color range did not seem particularly important to the author but it was just another hurdle to be overcome in breaking down the sales resistance. Considering the fact that, on the first trial, rubber was produced whose only limitations were color and a reduction of 10 per cent in the tensile strength, it does not seem that the door is completely closed yet in this field. Any company that is interested in the fly-ash-disposal problem should investigate the possibility of substituting processed fly ash for the present inert filler in low-cost mechanical rubber goods, because it affords a profitable outlet with a good yearly load factor and may also provide the rubber company with a satisfactory filler at a price advantage.

Handling Facilities

Because fly ash is usually sold in competition with low-cost materials, the desirable way of handling the ash is in bulk shipments. In some instances the ash must be handled in bulk because of the handling equipment available, while in others bulk use is necessary from an economic standpoint.

Fly ash has a very unfavorable reputation with respect to handling properties. In part, this reputation is deserved owing to the combination of small particle size and low specific gravity. When air becomes entrained, a light, fluffy, bulky product results, which flows very readily and leaks through very small openings. On the other hand when no air is entrained or when the material is allowed to settle for a long period of time, the ash is likely to pack hard in the bin and bridge over.

A large part of this poor reputation may be attributable to the attempts that have been made to handle fly ash with equipment

that was never intended to handle such fine material. Nevertheless, it is often the case that the equipment is already installed and, if fly ash is to be used, it must be handled with available machinery.

In using fly ash as a mineral filler in asphalt topping it was necessary to devise some means for handling the ash, as otherwise it would not be used even though the topping was technically satisfactory. A portable Fuller-Kinyon pump had been used for unloading bulk limestone dust from boxcars. This equipment, as built, could not be used to handle bulk fly ash. The problem was solved by delivering the ash in bulk-cement trucks, providing an adapter, and modifying the pump. This combination is shown in Fig. 7. However, it was found that trucks, which

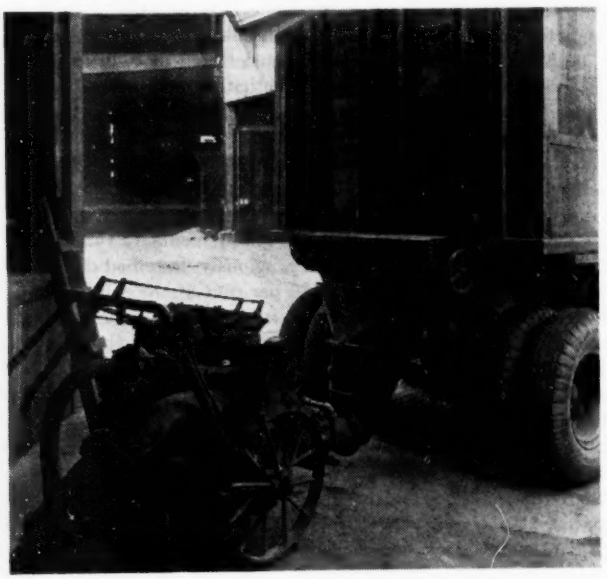

FIG. 7 UNLOADING DEVICE FOR BULK FLY ASH

were satisfactory for bulk cement, were not satisfactory for fly ash. The stop-gate construction at the rear had to be improved and holes in the body, that were not troublesome when the trucks were used for cement, had to be sealed.

At another asphalt plant, the ash is delivered in bulk cement cars and unloaded by means of a stationary Fuller-Kinyon pump located in a pit beneath the tracks. It is also possible to deliver ash by truck to this same plant, as shown in Fig. 8. If a portable Fuller-Kinyon pump is available, it can be converted to handle ash from the bulk-cement cars.

At the power plants, both the trucks and the cars are loaded from overhead bins through a rubber hose that is dropped into open hatches in the top of the conveyance. Between the bin and the hose line there should be installed a star-feeder to facilitate control of the rate of flow through the hose. A small vacuum breaker at the top of the hose line produces a much more uniform flow of ash than is obtainable if the hose line is sealed tightly. Because of the low specific gravity of fly ash and its tendency to aerate readily, the capacity by weight of bulk-cement conveyances is reduced when carrying the ash. This tends to increase the hauling charges. Laboratory investigations showed that by vibrating the receptacle with a commercial electric vibrator the unit weight of ash could be increased from 39.9 to 54.7 lb per cu ft, or 37.1 per cent, which would approach the bulk weight of uncompacted cement.

At a transit-mixed concrete plant and at an oil-aggregate batching plant, the ash is being handled successfully in bucket conveyers. The rate of discharge is somewhat slower than when handling cement or limestone dust. Precautions must be taken to keep the ash from bridging over in the feeding hopper to the conveyer, and better results are obtained if the speed of the bucket conveyer is kept below that recommended for use when handling cement.

At this point it is well to consider storage facilities. Previously it has been mentioned that the ash demand is seasonal for concrete and roads. Since both of these uses are dependent to some extent upon the weather conditions, there is a considerable fluctuation in day-to-day requirements. Also, if a contractor for a large project were considering the use of fly ash, it would be necessary to assure him that the ash could be delivered at the rate necessary to meet his requirements. These daily requirements might be considerably above the average daily ash output of the power plants. This means that adequate storage facilities must be provided, either by the producer or the consumer of the ash.

Of course, fly ash can always be furnished in paper bags similar to those used for Portland cement, but of a greater volume if it is desired to have the same weight of fly ash as cement. As a general rule bagged ash is supplied only to the small consumer. If a fly-ash producer should be so fortunate as to develop a large

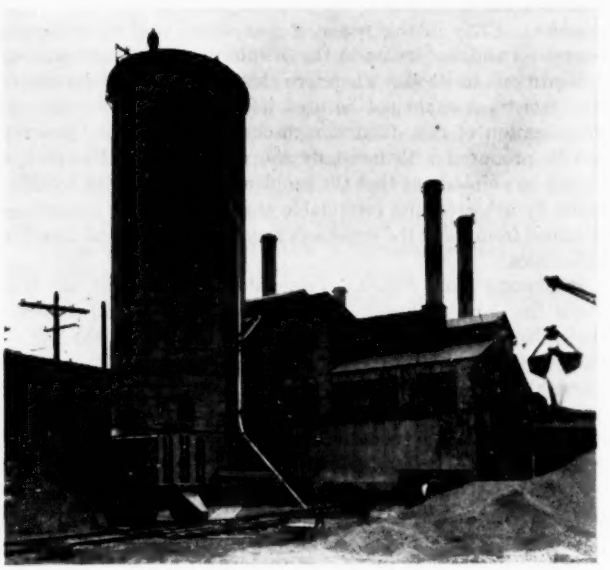

FIG. 8 CONVEYING, UNLOADING, AND STORAGE FACILITIES FOR BULK FLY ASH AT AN ASPHALT PLANT
(Unloading bulk fly ash from a truck with the same unloading unit as used with a bulk cement car.)

number of small customers, it might be well to consider a delivery unit that would be self-contained, that is, the customer would provide the bin, piping, and possibly compressed air, and the remaining equipment necessary to discharge the ash into the bin would be a part of the truck or semitrailer. Such an arrangement would eliminate the expensive bagging operation, cut the cost to the consumer, and decrease the handling cost.

In interviewing a prospective customer, it is essential that one be able to discuss intelligently means of handling the fly ash. This is important because in a great many cases the bad reputation of ash is already known to the customer, and, unless proper facilities are provided for handling the material, the results will be unsatisfactory.

Other Possible Uses

Being of such fine particle size, fly ash has not been considered a satisfactory ground-fill material. Nevertheless, the experience of the author's company with several fills along the water front indicates that, if properly handled, filled-in land of this sort can be made capable of sustaining coal piles 35 ft high. In one case, the fill, which in places contained 15 ft of fly ash, part of which was submerged in water, has sunk about 1 ft after several years of storage of coal.

An attempt was made to produce a satisfactory fill material by combining fly ash with an impure limestone that is available in large quantities as a by-product from the soda-ash and acetylene-gas industries. The production of a suitable fill material was unsuccessful because of the difficulties encountered in mixing the two ingredients mechanically. However, a material was produced that was quite comparable, in resistance to disintegration and compressive strength, to well-designed soil-cement stabilization mixtures.

In Table 4, dealing with possible uses of fly ash, reference is made to the use of fly ash as a filler in agricultural fertilizer, and the reason for its being unsuccessful. Fly ash, however, does produce certain beneficial effects in heavy clay soils. That is, it is a soil-amendment agent. Such an agent may not have any fertilizing value but does benefit the soil by improving its mechanical properties. When thoroughly mixed with heavy clays, fly ash, being a highly vitrified material, tends to decrease the tendency to bake hard, crack, and ball up, and to increase the capacity to hold moisture. Heavy clays may require an addition of 50 per cent by weight of fly ash in order accomplish to the desired results. It is realized that this market offers very little opportunity for revenue, but it might eliminate haulage charges for dumping. Since the fall and winter months are the ideal time to place the ash on farmland, such an outlet would fit in nicely with the bitumastic road and concrete requirements.

Conclusions

As a result of this extended investigation, conducted both in the laboratory and in the field, it appears possible to arrive at certain general conclusions regarding the fly-ash market.

1 There are only a few industries that can use the quantity of ash produced by a large steam power plant.

2 The ceramic industry, which is a large consumer of clays, is not likely to become a user of fly ash because of the cheapness with which clays are delivered to the ceramic plants and because the ash does not generally have the proper properties to improve the quality of the product.

3 Certain types of fly ash are satisfactory as mineral fillers in bitumastic road construction.

4 Certain types of fly ash improve the quality of standard concrete, make possible a new lightweight concrete, and also open the way to a possible reduction in the cost of concrete.

5 The seasonal load factor of the mineral-filler and concrete markets makes it desirable to develop a year-round outlet of large tonnage such as in the fields of rubber or plastic fillers.

6 Regardless of the merits of fly ash as a material, it cannot be sold commercially unless the customer's handling problem is satisfactorily solved.

7 There will be no fly-ash-disposal problem if the sales resistance of the concrete industry and the bitumastic road industry can be overcome.

Radio-Frequency Technology in Wood Application

By G. F. RUSSELL[1] AND J. W. MANN,[2] TACOMA, WASH.

As a basis for understanding the principles involved in applying radio-frequency heating to the resin-bonding of wood, the author explains certain fundamentals of radio theory which are involved. A particular quality of the radio-frequency field is its selectivity which results from the tendency of the field to follow the most conductive path between electrode extremities. Originally operations of bonding materials by this means placed alternate layers of wood and glue in the field so that the glue lines were established parallel with the electrodes causing the field to be perpendicular to the glue line. More recently it has been established that the normal resin-glue line is more conductive than the wood with which it is associated, and the technique of "parallel bonding" in which the field is parallel with the glue line has been developed. Details of the process, application of radio-frequency heating to specific cases, most efficient electrode arrangements, and results attained are treated comprehensively.

Technical Background

CERTAIN fundamentals of radio theory are essential to a proper understanding of radio-frequency heating effects. An electromagnetic field of force evidences itself through rapid alternations of charge on electrodes which constitute elements of the output circuit of a radio-frequency generator. When one electrode is charged highly negative, the opposite electrode is relatively highly positive. The next half-cycle results in a reversal of this relationship with the negatively charged electrode becoming the positive, and the positive becoming the negative. The electrodes with their connecting inductance constitute a simple oscillatory circuit. The space between the electrodes constitutes the part of the circuit wherein the dielectric is placed for heating.

When air is the dielectric between the electrodes, no loss takes place in the area. When other dielectrics are placed between the electrodes, however, a loss will result. When an energy-absorbing dielectric is introduced into a radio field of force, a phase shift takes place according to the standard laws

$$E\,I\cos\theta$$

which measures the total of real power. If wood of a certain density is introduced, a certain resistance will result. If wood of another density is introduced another phase shift will result. The energy absorption of the dielectric employed in the field has a major bearing upon the resultant phase shift.

Between the electrodes acting as boundaries of the capacitance portion of the circuit, there exists a half-standing wave of electromagnetic energy. This half-standing wave is a balance and a supplement to the half-standing wave resident in the inductance portion of the same circuit. When no resistance exists between the electrodes, there is a 90-deg out-of-phase relationship between voltage and current in the capacitive area established by the electrode boundaries, while the out-of-phase relationship in the inductance portion is in proportion to its ohmic resistance.

Radio-frequency waves are analogous to sound and similar to light waves. Each has the peculiar quality either of standing or traveling. The fundamental difference involved here is between the standing and the traveling wave. It is this difference which led to the discovery of and proof that there exists a half-standing wave in the capacitance portion of an oscillating circuit, and a half-standing wave in the inductance portion.

In electrical engineering language where there is no energy absorption in a circuit operating on 60 cycles, a 90-deg out-of-phase relationship exists between current and voltage. When resistance is introduced into this 60-cycle circuit, a phase shift results, and power loss may be calculated effectively by the vector method which shows total average power expended. This vector engineering is satisfactory when a traveling wave is considered to be active in the circuit study. It fails to show the placement of power loss when a circuit involving a standing wave is considered, because it only shows a total of the whole effect. The fundamental difference between a traveling wave as studied by vector diagrams and the standing wave which must be studied by chart diagrams is that the traveling wave averages its effect over a long distance, while the standing wave does not average its effect but in another manner maintains fixed and identifiable positions of energy conversion. The difference between the traveling-wave concept and that of the standing wave is observed to be the difference between averages of the whole effect and instantaneous values as fixed positions of power loss.

To return now to the half-standing wave between the electrodes of an oscillating circuit, it can be noted that the values are not averages, as would be the case of a vector analysis, but result in fixed but varying effects throughout the area wherein resistance is effective on the field of force. When a problem of heat placement is considered, the vector method of analysis might lead to the belief that heat distribution, as a result of natural forces, would be uniform. In this new approach, namely, the analysis of heat distribution by standing-wave instantaneous values, placement of the heat effect in its nonuniform distribution is almost exactly determinable.

Most investigators dealing with this problem of dielectric heating have discovered that greater heat exists in the center of a package of dielectric than on the outer edges of such a package. On the basis of analyzing the effect through vectors and averages, it naturally might be assumed that the less heating effect on the outer edges of the package is caused by radiation through the electrodes and through the outer atmosphere where there is a gradient of heat between the block and outside area. When the analysis of heat distribution is made by standing-wave method, the fallacy of even heat distribution in the radio-frequency field of force becomes apparent. Several simple steps show nonuniformity of heating effect in the radio-frequency field, the

Contributed by the Wood Industries Division and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

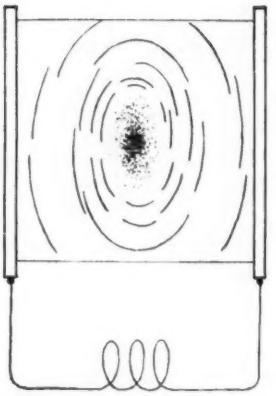

FIG. 1

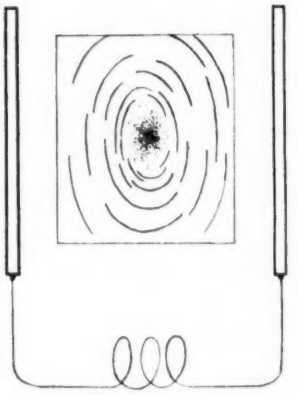

FIG. 2

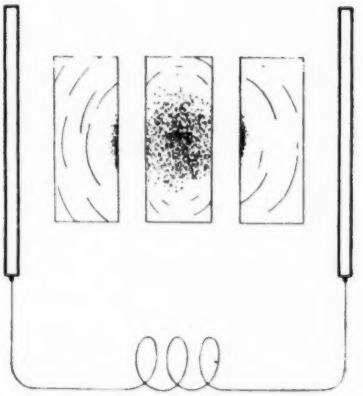

FIG. 3

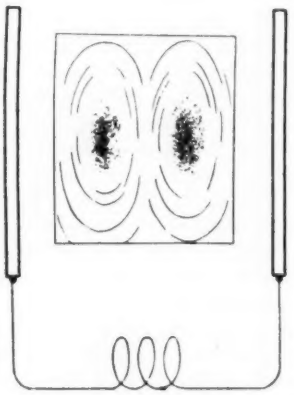

FIG. 4

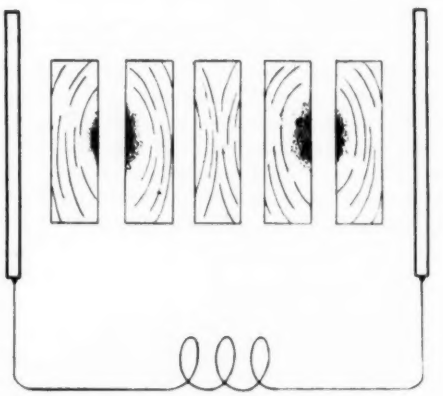

FIG. 5

first being to burn a single block in the center with electrodes contacting the outer face of the block as in Fig. 1. A second step is to separate the electrodes from the side of the block and burn it in a similar manner, as in Fig. 2. If radiation from the outer edges were the proper answer to the uneven burned effect of the dielectric, this could readily be proved by placing three blocks of dielectric in the field of force and having each separated from the other by an equal air space. This effect results in the center of the three pieces of dielectric being charred to an extreme, and the inside faces of the outer two grading down, leaving the outside faces of the outer two blocks unaffected by charring, as in Fig. 3. If the radio-frequency field of force were uniform, the three blocks would each be burned, respectively, at their centers.

It might be argued, at this point, that radiation still has its effect even on the three separated blocks and this, in part should not be denied, and so our studies should be carried a step further and show the effect of smaller phase shifts than occur in the examples of Figs. 1, 2, and 3. Producing this result shows a double burned area, with one burned spot on the left of the center and one on the right of the center, with the center and the two outsides remaining unaffected by charring, as in Fig. 4. The burned areas are the direct results of a shift in phase of less than that which causes the center burn in the other blocks. The conclusion of the series of experiments brings into the field five separated blocks with burned areas in the blocks next to the center one and also next to the outside ones, as in Fig. 5, reproducing the pattern shown in the single block, Fig. 4. All of the burns shown in the five illustrations are the result of double burned areas; but in the first three the two spots are merged into what appears as a single spot, the phase shift being greater and in phase relationship between the electrical components being closer than in the last two.

When a phase angle approaches 90 deg, but some energy absorption is effective, the two burned areas will be found at one quarter and three quarters of its thickness. When the phase angle approaches 0 deg and maximum energy absorption is effective, the two burned areas merge to form a single peaked area at the center of the thickness. In this latter case, heat distribution approaches the square of the instantaneous values of a half-standing wave of current. Returning therefore to the original formula for power, it can be said that $E\ I \cos \theta$, which shows total power does not show the distribution of a radio-frequency field of force, and that the relationship of power distribution to dielectric materials varies in uniformity with the adsorptive qualities of the load, and the effectiveness of the dielectric to produce a resistive effect.

The foregoing discussion is offered as in opposition to the uniformity theory, not to conclude that all that has gone before is wrong, but to see another side of the matter which results from a study of the physics of wave structure and electron motion, with the admonition to think twice before too much is assumed, based upon the vector engineering of 60-cycle alternating current.

The fact that the heating effect of the radio field can be predetermined; that its heat effect can be controlled; that its effect through the thickness of the material, while not uniform, is instantaneous and simultaneous makes it a new and useful tool for industry in many wood, plastic, and other applications. However, the primary concern in this discussion is with adaptations

to wood treatment and glue-setting technique in wood which stem from some of its unique, nonuniform, and selective qualities.

Gluing Technique

A particular quality of the radio-frequency field is its selectivity. This results from the tendency of the field to follow the most conductive path between electrode extremities.

Original operations of bonding materials with radio frequency placed alternate layers of wood and glue in the field so that the glue lines were established parallel with the electrodes. This means simply that the established lines of force between the electrodes would be perpendicular to the respective glue lines. There being no one path between the electrodes, under this situation, which would be any more conductive than any one other path, it was perfectly natural to bring the entire package of wood and glue up to the critical setting temperature of the glue for purposes of bonding the mass. It has been incorrectly assumed that it made little difference whether the glue lines were perpendicular to or parallel to the lines of force.

Parallel Bonding. Now it has been determined, however, that the normal resin-glue line is much more conductive than the wood with which it is associated, so we can adapt this knowledge of conductivity and selectivity to gluing technique and place the glue lines in the field so that they substantially parallel the main lines of force rather than exist perpendicular to them. This technique of gluing is called "parallel bonding" and differs materially from the older technique of "perpendicular bonding" in that it allows the concentration of the entire effect of the field on the glue joint, avoiding the necessity of wasting much heat in bringing the wood up to the same critical temperature as is required to set the resin glue. In some cases it had been found that in thick laminations only a small portion of the heat from the radio field is required to set a given package by the parallel-bonding method as was required to set an equal passage by the perpendicular process.

It should be pointed out however that, as the critical setting temperature of the resin is increased to a point approaching 212 F, the effect of parallel bonding diminishes, and that if the critical setting temperature of the resin is substantially above the boiling point as is the case of high-temperature phenol resins, little if any advantage remains through the use of parallel-bonding methods, as compared with perpendicular methods. This is due in part to the fact that much energy will be expended from the hot glue lines by conduction to the wood itself before the temperature reaches 212 F, and also in part to the fact that the moisture in the wood will be acted upon equally with or to the exclusion of the conductivity of the glue lines above 212 F. The selective effect of the radio field therefore has led to interesting and advantageous methods of gluing wood and the treatment of other materials.

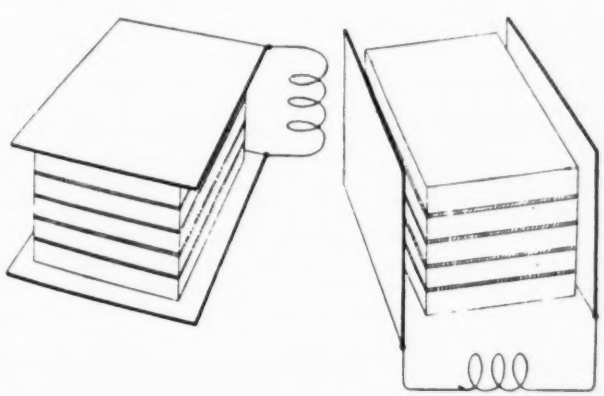

Fig. 6

Resins. This selectivity may best be utilized by parallel bonding techniques, using ureas, melamines, and the very new types of phenol resins, which are in time, cold-setting, or at least set below the boiling point. Heat will accelerate practically any resin adhesive, so if a cold-setting resin is used heat will accelerate its chemical reaction and complete polymerization in rapid order. Rather than spend time describing glues, our primary interest is in applications of varying techniques and electrode arrangements. It is one job to create a radio-frequency oscillator, but it is still another to apply it properly to a gluing operation. Fig. 6 illustrates the two general types of electrode arrangement used in most operations; the sandwich or perpendicular method and the parallel bonding method. The differences between these types has been described but some general principles can be illustrated from them.

Applying the Radio-Frequency Oscillator

In both methods, pressure is applied to the top and bottom of the package, the electrodes in the perpendicular method being between the package and the pressure sources. Surplus glue may squeeze out, fall downward toward the bottom plate electrode, and if the spread is not very carefully controlled to prevent this squeeze-out, the glue excess will start a high-frequency arc and carbonize a path between the electrodes which not only is dangerous as it reflects back into the oscillator or amplifier, but it may easily ruin the entire batch of material. In parallel bonding, since the electrodes do not have to contact the work, squeeze-out as a danger is entirely avoided.

In determining which method to use for a specific job, frequency of the package, which is dependent upon its size, shape, moisture content, and glue is sometimes a determining factor. With a fixed-frequency oscillator, of course, less flexibility in package dimension and electrode placement is permissible than with a variable-frequency oscillator. The latter types are variable, even so, only over the range of their variable capacitances. The lamination of ten plies of veneer $^1/_8$ in. thick with $^1/_8$-in. cauls above and below in a size 7 in. × 14 in., for example, can be treated at different frequencies, but its fundamental, using the sandwich method with plattens above and below, is in the neighborhood of 25 meters or 12 megacycles. With parallel-bonding electrodes on either side of the same-size package, its frequency fundamental is 10 meters or 30 megacycles. In a scarfed joint the same size and thickness, the fundamental frequency is slightly higher, due to a lesser content of resin glue. Frequency of oscillation, or wave length, undoubtedly has its effect upon speed of setting and effective heat penetration and conversion, but the study by Von Hipple and Deitz was inconclusive in this regard. It has been said that the higher frequencies are more effective in heat generation than are the lower ones, which in general may be accepted as founded on some logic, but it is believed that power input and conversion efficiency of the oscillator have a greater effect upon heating than does the variation of frequency within limits, for example, between 10 and 50 megacycles. At the lower frequencies, which is to say, under 6 megacycles, some noticeable reduction in heat-conversion efficiencies should become apparent.

Almost any wood-bonding load can be matched, one way or another within the range of between 10 and 50 megacycles. Simpler apparatus at these wave lengths is just another reason to go higher and higher in oscillating frequency. But limitations of power, because of the capacitances of the vacuum tubes, prevent large packages being operated upon at very high frequencies. Some day these limitations will be breached, and progress in that direction is currently very rapid.

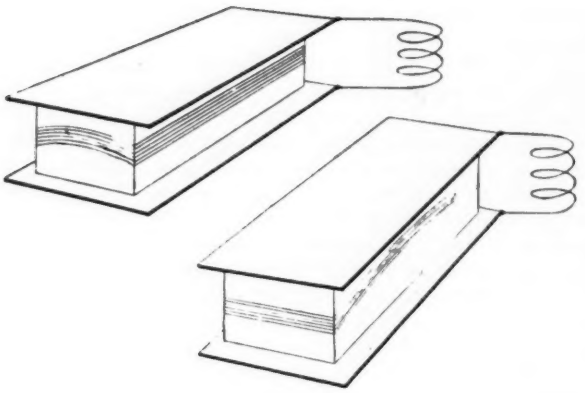

FIG. 7

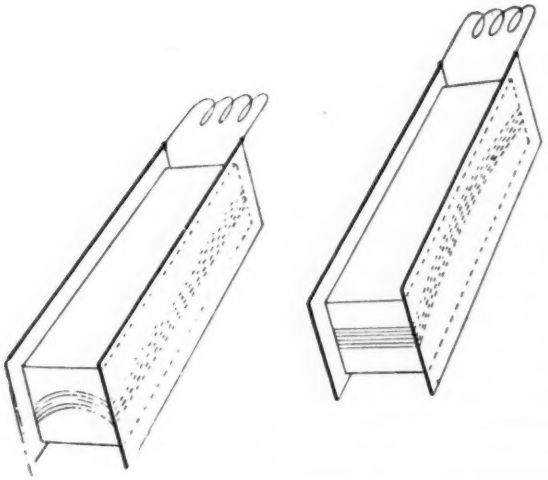

FIG. 8

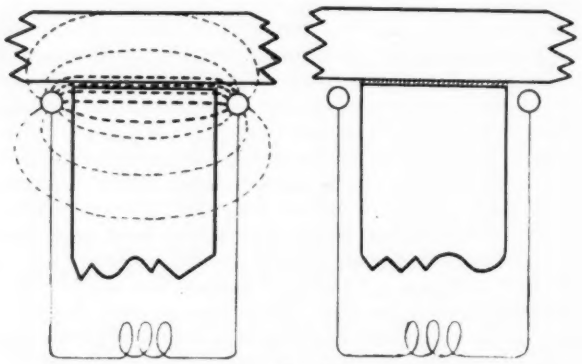

FIG. 9

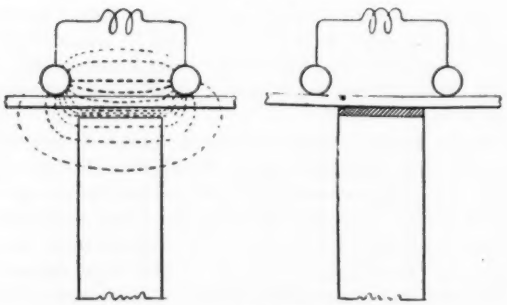

FIG. 10

Fig. 7 shows a perpendicular bonding setup which employs the advantages of and also approaches the effectiveness of parallel bonding. Here curved shapes may be bonded between male and female forms. Fig. 8 shows these two same curved shapes set up on a pure parallel-bonding method. The time of bonding using the same input power will be about one fifth as long with the parallel bonding means as with the perpendicular means, with a glue which sets below 212 F.

Fig. 9 shows an accessible butt joint with electrode arrangement and field distribution. This is a simple means of bonding joints quickly. Fig. 10 shows a similar application, but in the case of a thin skin abutting an inaccessible rib or other member. The field distribution shows how the energy seeks the conductive

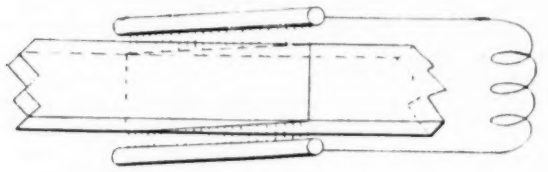

FIG. 11

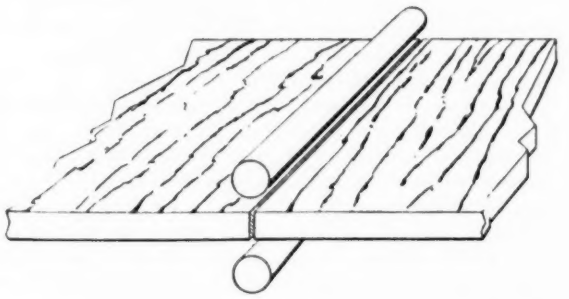

FIG. 12

glue line through the skin surface and accelerates its setting even through relatively thick sections. This application is one means of spot-welding wood or sewing thermoplastics. No matter what the accessibility of the joint, so long as no metal parts parallel the field of force and detract from the conductivity of the glue line, some method can usually be worked out to accomplish the job, and some system of electrode arrangement devised to supply properly radio-frequency energy to the joint.

MOST EFFICIENT ELECTRODE ARRANGEMENTS

A straight scarf, such as is employed in aircraft work shown in Fig. 11, when pressed from top and bottom, presents no problem when the scarf is under 6, 8, or even 12 in. in width. Rods or tubes placed along either side of the scarf, their centers aligned with the glue line and supported by standoff insulators, suffice for electrodes, either center or end fed. The field lines of force literally spit through the glue line in this setup but care should be taken either to space the electrodes away from direct contact with the glue lines, or to place a thin wood or other dielectric caul between them. An air gap when not too wide, say, $^1/_2$ or $^3/_4$ in. on either side of the scarf, will cause no material slowing of the reaction of the glue, as compared to using a thin caul and no air gap. A bar or tube rather than the conventional flat plate, as shown in Fig. 6, may be employed in order to concentrate emission from the surface closest to the glue line. Stray and therefore wasted field lines of force are minimized with rods, but are greatly increased when an electrode area of great width is presented to a single glue-line application.

The principle of presenting the minimum of electrode-surface

area to the glue line is well illustrated in Fig. 12, which shows a tube-electrode application to edge-glued lumber or veneer, employing the parallel bonding method. This means is employed on a continuous machine being developed to take the place of the tape splicer and also the hot-plate tapeless splicer

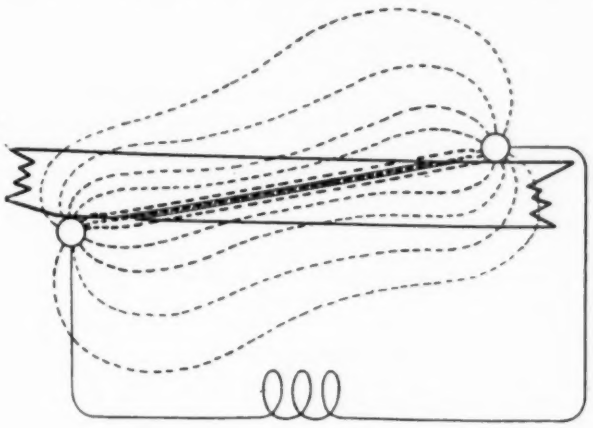

FIG. 13

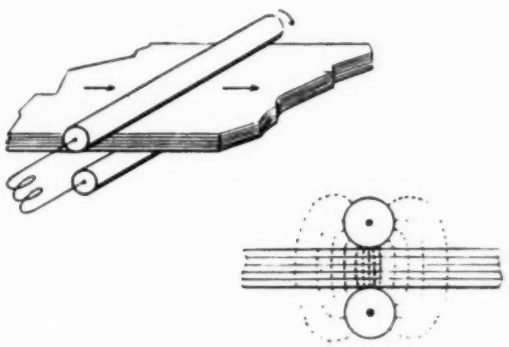

FIG. 14

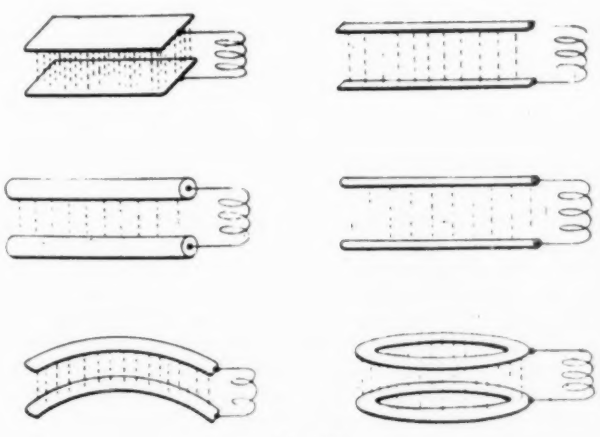

FIG. 15

used for core work in plywood, veneer, and furniture manufacture. It is anticipated that we will shortly see in operation such a machine running at a speed of between 50 and 100 fpm.

Fig. 13 illustrates parallel bonding applied to a scarf joint which is very wide, for example, in the 4- or 8-ft side of a sheet of plywood. These joints, 10 or 12 in. through and 4 ft long, are such as those used on the bottom of PT boats. It would be impractical to apply an electrode arrangement such as shown in Fig. 11, because its frequency would be much too high to come within the range of any currently used radio-frequency machines. It might even reach 300 or 400 megacycles or even into the microwave strata. Long tubes can be used running the entire length of the scarf and still take advantage of the parallel bonding method. These electrodes, supported by standoff or other insulators, run the entire length of the scarfed joint. Using tubes 3 in. diam and 50 in. long, as shown in Fig. 13, a frequency of 15 megacycles, and a wave length of 20 meters, creates a nice operating load. When these electrodes are extended to longer lengths and the width of the scarf widened also, the frequency is maintained at 15 megacycles.

For certain operations such as bonding plywood on a continuous basis roller electrodes are employed successfully. With one roller above and another below the package, the established field lines operate perpendicular to the glue lines. Such an operation, as shown in Fig. 14, not only applies to plywood bonding, but to the drying of wood, the treating of cellulose-plastic compounds, the dehydration of food products, and many other uses.

By reference to the several illustrations, possible electrode arrangements are shown for several different uses. These are but a few, and to show others would be to repeat largely the lessons evolved from the various types of placement. The shape of electrodes may vary even more widely than their relative placement. Fig. 15 has six separate shapes, plates, strips, rollers, bars, curves and circles, all of which with equal efficiency may be adapted to their special uses.

It might be asked how the two-spot heating effect, or even that of the single spot affects gluing procedures. On loads of relatively light power absorption or power factor, as some call it, the two-area heating will be encountered in parallel bonding. In perpendicular bonding, no such light load is apt to be encountered. The two hottest areas, in a light resistive load, will spread their temperature rise rapidly to adjacent glue-line areas, and in a flash which is so fast as almost to prevent stop-watch timing, distribute enough heat to polymerize the resin in the entire glue line.

One very interesting case occurred in bonding a small scarf joint $1^1/_2$ in. wide and 4 in. long in $^1/_4$-in. spruce aircraft stock, using tubular electrodes, and the method shown in Fig. 11. A 2-sec exposure to the field of a generator having an output rating of 2200 Btu per hr cured the two outer edges and into the scarf some distance, but when broken immediately after release from the press an uncured center showed up about $^1/_2$ in. through the glue line. This indicates quite clearly the two-spot heating effect. When exposed 5 sec, the entire scarf-joint glue line was cured throughout. Normally one might not encounter usual evidences of the two-spot heating effect, but it is there nevertheless and should be considered in gluing light resistive loads.

An Introduction to Aircraft Hydraulic Systems

By HOWARD FIELD, JR.,[1] INGLEWOOD, CALIF.

This paper traces the evolution of hydraulic systems for airplanes, from the hand-actuated piston pump and "motor" piston, through the stage of motor-driven gear pumps, down to the present-day systems which derive their power directly from the airplane engine. Three general methods of pump control have been developed which permit rotation of the pump but prevent build-up in the hydraulic system, since the pump operates continuously. These methods include "the constant-pressure," the "manual by-pass," and the "automatic by-pass," all of which are in wide use. Special applications of hydraulic control are described in the "power-amplifier" or "load-feel" system, the "follow-up" system, "follow-up plus load-feel" system, and the "full-automatic" system.

THERE are many means of transmitting power from its source to the place where it is to be used, among which are electrical, steam, mechanical, hydraulic, etc. Each has advantages and disadvantages which become of greater or lesser importance depending upon the particular problem at hand.

Having no regard for relative importance, and in fact, the relative importance is not constant, the advantages of hydraulic systems in aircraft are as follows:

1 Light weight per horsepower required.

2 Low inertia of moving parts, making quick starts and stops possible without undue stresses being set up.

3 Controllability to any degree of accuracy and sensitivity required.

4 Great flexibility of installation not only because tubes can be run anywhere but also because the same system can develop great forces or light rapid motions.

5 Ability to withstand large amounts of abuse without complete breakdown.

6 Reliability greater than many other competing forms of power transmission.

Since the hydraulic system is a method of transmitting power, it is obvious that there must be a means of applying the power at one end of the chain, in other words, a pump. This pump may be either hand- or power-operated, the simplest form being a cylinder containing a piston which may be manually moved. Next, a line or tube to convey the power to the output end of the chain, and a motor to reconvert the hydraulic power to mechanical motion and force are required. This "motor" may likewise be a simple cylinder and piston. If this "motor" piston be arranged to be returned by a spring, and a reservoir to take care of leakage or volume changes be added, the result is the well-known automobile hydraulic brake. Many small airplanes use this identical system for brake actuation, as shown in Fig. 1. It will be noted that none of the diagrams in this paper makes any pretense of showing the actual physical embodiment of the circuits or devices. They are intended to be only the simplest possible representation of principles. In many cases, undesirable devices have been represented rather than more desirable but more complicated ones, which would be more confusing. In general, no packings have been shown, although they are obviously necessary in the actual devices.

By substituting an ordinary double-acting pump for the simple master cylinder, a double-acting cylinder for the brake cylinder, and adding another line and directional-control valve, the resulting system (diagrammatically shown in Fig. 2) is complete. This was the first system used in aircraft for actuating mechanisms other than brakes. There are many control-valve designs, but all accomplish the same end. These valves are usually known as "selector valves," or "4-way valves."

The next step was to add another unit to be operated from the same pump and reservoir. This can be done by having the second unit in series or in parallel with the first. Since the series arrangement requires the use of tail rods or different sizes of cylinders to provide identical motions it is not used for the following reasons:

1 Tail rods require extra packings.

2 Different sizes complicate manufacture, and they might be improperly installed.

3 There is no way to bleed the trapped portion of the circuit between the two cylinders.

4 Thermal changes in volume or slight leakages would throw the cylinders out of synchronism.

5 The pressure is divided between the two cylinders; hence it is necessary to make them large and consequently heavy.

There are ways to overcome faults 3 and 4, but series cylinders

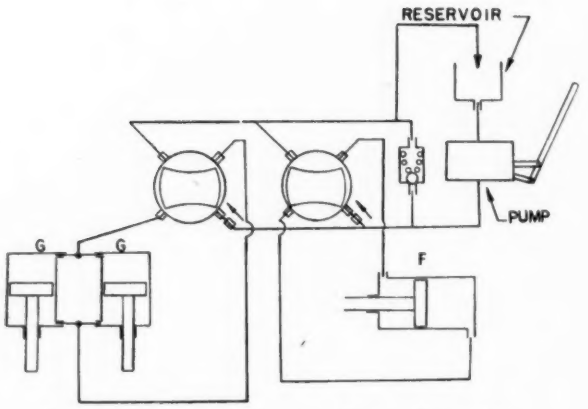

FIG. 3 SYSTEM WITH PRESSURE-RELIEF VALVE ADDED

are never used unless there are overwhelming reasons for so doing. All five of these difficulties are avoided by connecting the cylinders in parallel, although this introduces a new problem. The cylinder which, for any reason, moves easiest moves first. It is seldom that this causes actual difficulties and, where it does, corrective steps can be taken. For example, it may add aesthetic value to have both wheels of an airplane retract in unison, but it is not usually essential that they do so.

The addition of a relief valve to prevent excessive pressures from being built up in the pressure lines results in a circuit like Fig. 3, and consideration must be given to what would happen if the pilot should open both selector valves at the same time. In any system, there is a tendency for all potentials to seek a common level, and a hydraulic system is no exception. Assume that an airplane is coming in for a landing and the pilot pumps his flaps down; this may require 600 psi in the flap-actuating cylinder (cylinder *F* in Fig. 3). The pilot moves his landing-gear selector valve to "gear down." The gear falls part way by gravity, which requires no pressure, so the fluid runs out of the flap cylinder and into the landing-gear cylinders (cylinders *G* in Fig. 3). Since there is nothing holding the flap down, it moves to a trailing position, which reduces the lift and may result in a crash. Of course, if he had lowered his gear first, this would not have happened, but the simple addition of check valves at the fluid-pressure ports of the selector valves will prevent unwanted interflow between selector valves, although this introduces another difficulty.

Hydraulic fluid expands about $4^1/_2$ per cent per 100 deg F (much more than the metallic parts expand), and the check valves block off any chance of relieving excess pressures due to thermal expansion in the cylinders and lines through the relief valve. This can be overcome either by making the check valves "leaky" so they will permit the very slowly expanding fluid to pass, or by putting additional relief valves at each selector-valve pressure port. Circumstances dictate which method shall be used. The first would let the flaps creep up slowly (disadvantageous but not usually critical), while the second entails manufacture of more relief valves. Strangely enough, even though very simple, good relief valves are among the most difficult hydraulic parts to make.

General Power System

As airplanes grew in size, it became evident that some sort of power would have to be applied to hydraulic systems, since a pilot cannot be expected to produce more than about $^1/_5$ hp, and that only for a limited period of time. It was also true that as airplanes grew larger, the pilot had more to do and no longer had time to spend in purely manual labor. When airplane systems required 1 or 2 hp, it seemed a logical development to apply an electric motor to drive the hydraulic pump, which was generally of a positive-displacement type, such as a gear pump. This entailed the addition of a relief valve to provide a path for unused fluid to return to the reservoir.

Further experience showed that the pilot neglected entirely to turn off the motor when the operation was completed, and the system continued to run, heating up the oil. It then became necessary to connect a pressure-operated device to the switch so that, when a predetermined pressure was reached, the switch would operate automatically. Of course, the relief valve was set higher than the amount of pressure which was expected to be used. Fig. 4 shows the resulting power circuit. This automatic pressure "kick-out" device relieved the pilot but it had faults of its own. For example, the pressure had to be set very much higher than required for an operation or the switch would kick out when accelerations acted on the landing gear. Thus the system had to be designed for much higher pressures which shortened the pump life and made everything heavier.

No good solution was ever found for this condition because other factors increased the power requirements so fast that it became impracticable to draw the power from the airplane electrical

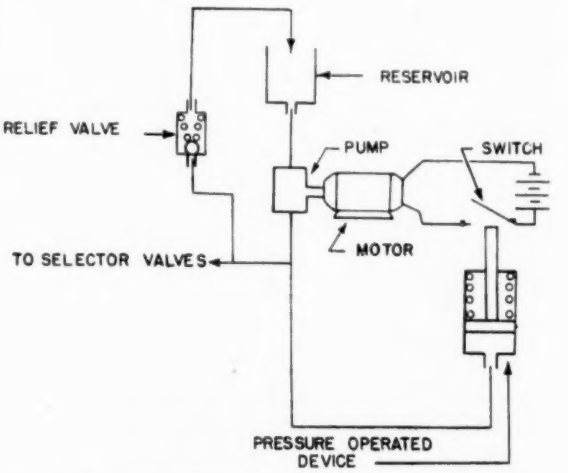

FIG. 4 HYDRAULIC CIRCUIT WITH ELECTRIC POWER ADDED

system. The obvious answer was to connect the pump to the engine, and thus to use the engine power directly, instead of indirectly through the storage battery and motor. With the pump driven by the engine, there was no such thing as turning it on when required unless some sort of clutch device were interposed between the engine and the pump. The idea of using the clutch was abandoned, as investigation showed that this would be cumbersome and heavy and would probably lead to service difficulties. Thus it was necessary for the pump to operate continuously whenever the engines were running, which meant that fluid was always being pumped.

By-Pass Methods of Relieving Hydraulic Systems

One method of relieving the hydraulic system and the pump when it was not required was to by-pass the fluid which was being pumped all the time the engine was in operation. This general scheme is the one used in almost every hydraulic system at the present time. This method of by-passing the pump may be subdivided into three general classes:

1 The class, known as the "constant-pressure" system, may in turn be subdivided into two classes:

(*a*) This class utilizes a relief valve to limit the pressure. In

this system, the fluid when otherwise not being used, constantly runs through this relief valve, which is undesirable, since the power put into the fluid by the engine-driven pump is wasted or turned into heat. Although this type of "constant-pressure" system is sometimes applied, it is limited to approximately $^1/_3$ hp because of the large heat-rejection problem.

(*b*) A variation of the "constant-pressure" system which is used to some extent, particularly in Europe, is one in which a variable-delivery pump is connected to the engine. This pump is so constructed that, as the pressure which it produces is increased, the amount of oil or fluid which it pumps is decreased. Thus when the pressure rises to some predetermined point, which is somewhat above that required for operation, the volume of fluid delivered falls to zero and no further pressure increase occurs. The pressure in the system remains at "cut-out" values, but since there is no volume being moved, the power absorption and consequent heat rejection is zero, except for the power required to overcome pump friction.

2 A method of relieving the hydraulic system, known as the "manual by-pass" system, is usually semiautomatic in that the pilot turns on the pressure, but it is relieved automatically. This method may again be subdivided as follows:

(*a*) An application, which uses a special by-pass valve for operation at some predetermined pressure, is utilized in the power system shown schematically in Fig. 5. The by-pass valve is constructed so that the pilot pushes the plunger "in" (to the left in Fig. 5), where it is latched. There it remains until the pressure in the release mechanism (shown as a cylinder and piston, restrained by a strong spring, in Fig. 5) builds up to a point where the latch is released, and the plunger is returned to an "open" position by the light spring behind it. The by-pass valve performs much the same function as the switch in an electrically operated system, in that the pilot closes it and it opens automatically. Unfortunately, it is subject to the same disadvantages as the electrically driven pump system because the pressure must be set at a higher point than is desirable, in order that the valve may not be operated by a surge in the hydraulic lines and thus stop operations which are not complete.

(*b*) Another scheme uses a special by-pass valve which opens a certain length of time after it is closed. This by-pass valve is shown in Fig. 6. This would connect to the general hydraulic system in the same manner as the by-pass valve in Fig. 5. In Fig. 6, a plunger is adapted to close the pressure line when it is pushed into its seat by the pilot. Then the pressure from the line exerts a force to push the piston to the right and withdraw the plunger, but an equal and opposite force is exerted by the fluid which runs through the check valve and acts against the right-hand side of the piston. Thus the hydraulic forces are in balance but the spring shown tends to move the piston to the right. In order to accomplish this, it is necessary that the fluid to the right of the piston escape to the return line. This is controlled by a properly chosen restrictor valve in the line connecting both ends of the valve. A number of trainer type airplanes use this scheme of operation.

(*c*) Yet another application of the "manual by-pass" system makes use of a special type of selector valve known as an "open-center" type. When in the neutral position, the fluid from the engine pump circulates through the valve and back to the reservoir. When any of the valves is displaced to operate some unit, this by-pass is shut off and the fluid is then directed to the proper operational device. The early versions of this open-center type depended upon the pilot returning the valve to neutral position when the desired operation was completed, and again the pilot forgot to do so, which left the oil at full pressure and being relieved through a pressure-relief valve. To avoid this difficulty, pressure-operated devices were arranged to return the valve to

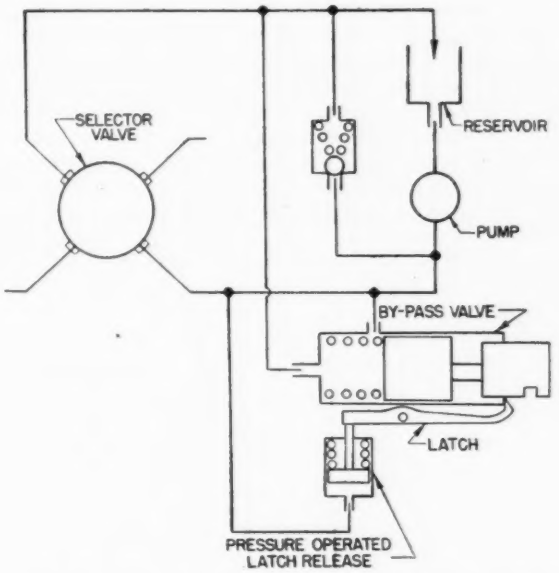

Fig. 5 Manual By-Pass System of Pump Relief With By-Pass Valve Operating at Predetermined Pressure

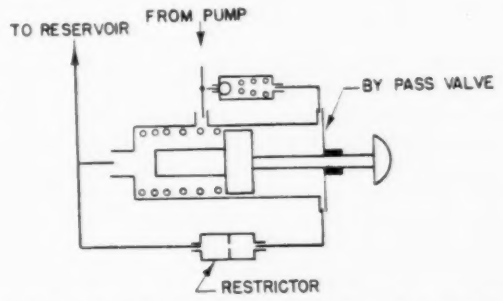

Fig. 6 By-Pass Valve Operating on Time-Lag Principle

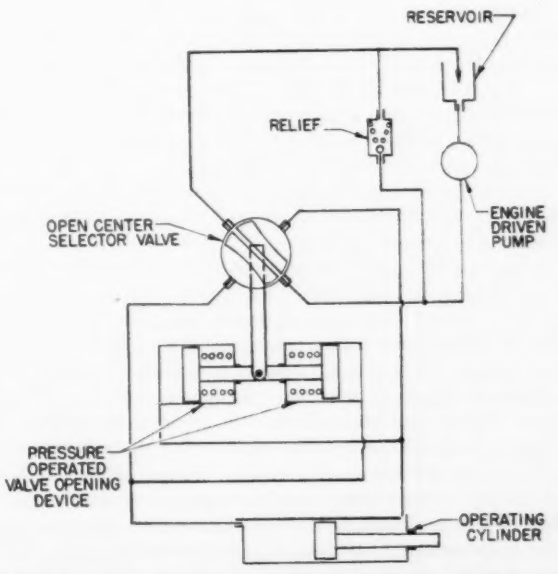

Fig. 7 Manual By-Pass System of Pump Relief Employing "Open-Center" Type of Selector Valve

neutral automatically when the end of an operation was reached. Schematically, this system is shown in Fig. 7. Here again, the pressure must be set higher than is desirable in order to keep the valve from being moved to neutral by pressure surges in the system. Although somewhat undesirable, this system is in use in some airplanes at the present time.

3 Another general method of relieving the pump is known as the "automatic by-pass" or "unloader" system. This method is now used on practically all airplanes built in the United States. The heart of the system is an "unloader" valve which is shown diagrammatically in Fig. 8. This valve is placed in a circuit with

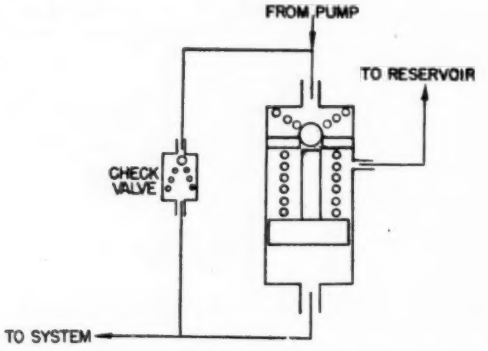

FIG. 8 DIAGRAMMATIC REPRESENTATION OF PUMP RELIEF BY MEANS OF "AUTOMATIC BY-PASS" OR "UNLOADER" SYSTEM

the fluid from the pump entering the valve as shown, and also flowing through the check valve and to the general hydraulic system. A small ball, seated in the partition across the valve body, forces the fluid to flow through the check valve and to the general system, since the ball prevents the oil from going through the valve seat and out through the side port and back to the reservoir. The pressure in the system is carried to the bottom of the piston which is shown as having an extension reaching the ball valve. The pressure acting below the piston tends to lift the ball from its seat. This is resisted by two forces, (1) the heavy spring whi h tends to push the piston downward and (2) the pressure acting on top of the ball tending to hold it to its seat. As the pressure increases, a point is reached where the pressure below the piston overcomes the spring and lifts the ball from its seat, thus losing the pressure which tended to hold it down, consequently the piston moves up rapidly opening the valve wide. Now, the fluid from the pump has free passage to the reservoir and, consequently the pressure drops. Obviously, the check valve, shown at the left, is required; if it were not for the check valve, the pressure would also drop in the rest of the system which would permit the piston again to return to its original position and thus close the ball valve, resulting in a system that was constantly opening and closing.

In this system an additional supply of fluid must be provided to react against the bottom of the piston in order.to keep it moving in an upward direction. Without this extra fluid supplied below the piston, the piston would move up only to a point at which the ball would rise off its seat a sufficient amount for the pressure loss through it to reduce the pressure below the piston to a degree that would cause the valve to stay in that position. To overcome this, an elastic device, which is known as an accumulator, is used in the line to the system. Originally, accumulators were simply cylinder-piston combinations which were loaded by means of heavy springs, but, since operating pressures increased to the neighborhood of 1000 psi, this type of accumulator became impracticable because of the excessive spring weight. Later, accumulators were designed which used compressed air in place of the spring. This proved much lighter than the old spring-loaded type and has been in continuous use since then.

The air-loaded accumulator consists of a chamber, usually spherical in shape, which is divided at its diameter by a diaphragm of flexible material. The chamber on one side of the diaphragm is pumped up to some initial-charge pressure, such as 400 psi, through an air valve, the diaphragm serving to separate the air from the oil which is admitted to the other side of the accumulator. Obviously, as the pressure in the fluid is increased, the air is reduced in volume so that it functions in the same manner as did the spring in the earlier design; but the air is practically weightless.

There have been numerous difficulties with this type of accumulator, most of which have been due to the requirements of the diaphragm material. It not only must be immune to attack by the fluid but also must have flexibility at very low temperatures. Improved synthetic-rubber materials have been developed which now make this type of accumulator entirely practicable.

A third type of accumulator, coming into wider use, is something of a combination of the two former types in that it consists of a cylinder having a piston to separate the oil and the air, but utilizes air above the piston instead of a spring. Early attempts to construct this type of accumulator were generally unsuccessful because of the difficulty of making packings which seal properly when the pressure on both sides are equal. Some of the newer type packings solve this problem satisfactorily.

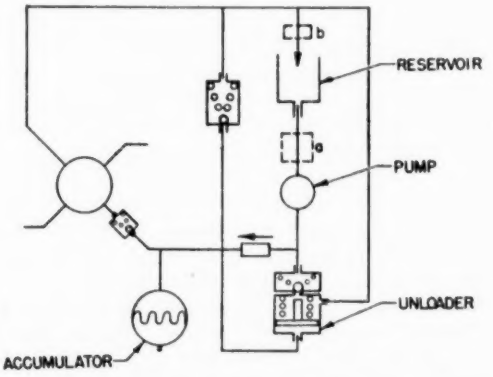

FIG. 9 DIAGRAM SHOWING UNLOADER VALVE AND ACCUMULATOR CONNECTED INTO POWER CIRCUIT

The unloader valve and the accumulator are connected into the power circuit as shown in Fig. 9. Here the pump draws the supply of oil from the reservoir and then discharges it to the upper portion of the unloader valve and also to the general system. The accumulator is shown connected to the general system at the left. It is obvious that if the selector valve, or valves, be closed, the oil delivered by the pump will first be used to charge the accumulator; and when that is accomplished, the pressure will rise to a point at which the unloader will open, thus permitting the pump to circulate the oil freely through the unloader valve and back to the reservoir. When a selector valve is opened, the pressure tends to fall, and the oil is drawn from the accumulator which starts the operation desired. As the pressure reaches the level at which the unloader valve again closes, the pump will discharge to the system and to the accumulator instead of back to the reservoir. Of course, when the pressure is again increased, the pump is again unloaded.

In Fig. 9 the dotted rectangles are shown as possible locations of filters. While location (*a*) is more desirable, since fluid is filtered before it goes to the pump, this location is seldom used because of the increased losses in the intake pressure at the

pump. If the filter be installed in location (*b*), this difficulty is avoided.

Special Power System

Among the advantages of the hydraulic system, as applied to aircraft, has been "greater flexibility of installation." Examination of one or two simple devices might illustrate this point. Suppose that the general hydraulic system was designed to operate at a pressure of 1000 psi, and then an additional device such as, for example, an automatic pilot which operates at a pressure of approximately 200 psi were added. By connecting a pressure supply for this device properly, it can be operated from the general system without endangering the system at all. Fig. 10 shows a method of connecting the reduced-pressure system into the general hydraulic system. Here, the unloader valve and check valve to the full-pressure system are exactly as shown previously. The check valves between the engine-driven pumps and the general system prevent by-passing of fluid through either pump in case of shaft failure. Between one pump and its check valve, what is known as a selective relief valve is inserted, and immediately above that a tap-off of fluid to the reduced-pressure system. Of course, a shutoff valve to prevent flow in this reduced-pressure system when it is not being used and an ordinary relief valve, connected to this reduced-pressure system to eliminate overpressures, are necessary.

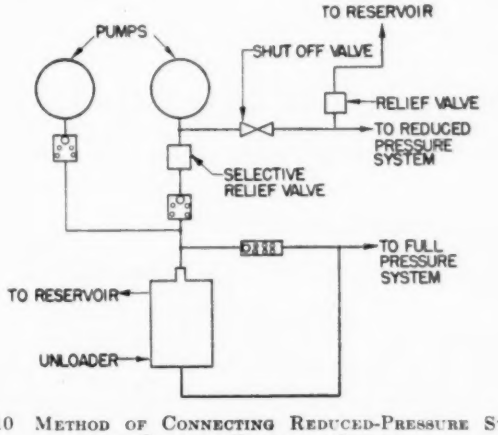

Fig. 10 Method of Connecting Reduced-Pressure System Into General Hydraulic System

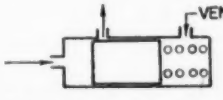

Fig. 11 Selective Relief Valve Diagram

The selective relief valve is somewhat similar to the ordinary relief valve and is shown diagrammatically in Fig. 11. Here, the fluid enters the valve from the left where it acts upon a piston. When the entering pressure is low, this piston covers up the outlet port and, consequently, there is no flow through the valve. However, as the pressure increases, the piston moves to the right a sufficient distance to make the loss through the valve equal to whatever pressure the spring was set to produce, as shown in the right-hand end of the valve.

The real difference between the ordinary relief valve and the selective relief valve is that the piston in the selective relief valve is packed and the rear of the piston is open to the atmosphere. Then the valve is unaffected by back pressures in the outgoing line, because these back pressures cannot act against the back of the piston. Hence it tends to hold the entering pressure to a definite figure or a definite amount above atmospheric rather than above return-line pressure; any higher pressure merely holds it wide open.

As this valve is installed in a system corresponding to Fig. 10, the oil from the right-hand pump enters the end port of the selective relief valve and discharges through the side port, through the check valve, the unloader, and the general hydraulic system. If the shutoff valve be opened to use the reduced-pressure system, this selective relief functions to maintain the predetermined pressure in the lines going to the reduced-pressure system, but it does not prevent the pump being used in the general or full-pressure system whenever the reduced-pressure system is turned off. It is, of course, true that all the time that the pump operates, it is operating against the pressure established by the selective relief valve. However, this is usually of so low a value that the pump can operate against it indefinitely. This results in a flexible arrangement in which both pumps can be used to operate the general system. Whenever the reduced-pressure system is being used, one pump is always available to the full-pressure system, and the other pump operates the reduced-pressure system.

This selective-relief-valve installation is shown merely as an example of what may be done with the hydraulic system in an airplane. It would be difficult even to begin to enumerate all the special conditions which are being provided for hydraulically in various airplanes at the present time. All sorts of sequence-operating devices are being hydraulically controlled, and many complicated actions have been made possible by proper valving. In many cases, it has been impossible to accomplish the desired result by any means other than hydraulic.

Special Control Systems

Some of the rather special systems which are used primarily because of the great degree of controllability or sensitivity are of interest. Among these are units in which the pilot must not only be able to direct the fluid or the power to the desired operational unit, but he must also be able to feel the load of the operational unit and to know its position at all times. Actually, four definite types of systems are used because of this great degree of controllability:

1 In the "power-amplifier" or "load-feel" system, the pilot supplies part of the energy for the operation, and the hydraulic system supplies the remainder. This system can be arranged so that the pilot supplies most of the power or, on the other hand, he may not supply more than 0.1 per cent of the power, but the part that he does supply is always in definite relation to the total amount required.

2 A second type of control is known as a "follow-up" system, which may be subdivided into mechanical and hydraulic types of positional transmission, both of which will be shown later. These are devices in which the pilot selects the position to which he wants some operational unit to move and, upon completion of this movement, the system automatically stops. Such a system is frequently used to operate landing flaps. In this case, the pilot merely moves his flap-control handle to whatever position he desires, say, for example, 30-deg flaps. The flaps move to that position and stop of their own accord. It is the fact that it is not necessary for the pilot to know what load is required to move the flap to the selected position, which differentiates the "follow-up" system from the "power-amplifier" system.

3 A type of control system which combines the two previous ones is usually known as a "follow-up plus load-feel" system. This is the type of system used for surface-control boosters. In these, the pilot must know not only in what position his control surfaces are, but he must also supply some of the power required to move the controls to this position. While it would be possible to handle control surfaces by means of a power follow-up system,

moving the controls very lightly from one position to another, he would have no conception of how hard it is to get them there. Unless the pilot has some idea of the amount of energy required, he is apt to force the ship into a more violent maneuver than it was designed to withstand, so the use of the "follow-up plus load-feel" system is indicated.

4 The fourth control type might be classified as the "full-automatic" system. Many different services are performed by the hydraulic system without any attention whatever from the pilot. A good example of these is the automatic temperature control for engines.

Application of the "Load-Feel" System

One of the most common examples of the "load-feel" system is the power brake valve. This form of valve control is shown diagrammatically in Fig. 12. The pilot does not want to know the

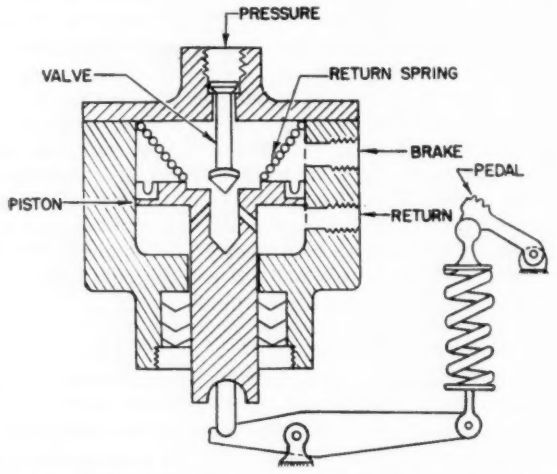

Fig. 12 Application of "Load Feel" System to Power Brake Valve

exact positions of the brake shoes or disks, the only thing which interests him is the pressure that is being applied to them. On smaller airplanes, the pilot was able to supply sufficient energy to operate the brakes without assistance from the main power supply. However, for airplanes having gross weights of about 10,000 lb or more, few pilots are physically capable of applying the brakes without assistance.

In the brake valve, shown in Fig. 12, the inlet for the pressure from the hydraulic system is at the top. Since the valve is shown in the closed, or brake-off position, this pressure is prevented from going to the brake by the cone-shaped valve closing the port. On the other hand, the brake line is open to the return port. This insures that the brakes will not be applied until the valve is moved. When the pilot applies the brake, he pushes down on the pedal as shown. This motion is carried through the brake-valve lever at the bottom of the figure and results in the upward movement of the piston in the valve. The first effect of this movement is to close off the return port by seating of the lower cone of the return valve, thus preventing any pressure admitted to the brake line from escaping through the return line. A very slight further movement of the piston in an upward direction will then open the pressure valve admitting pressure to the brake. As this pressure builds up, it will act downward against the piston in exact proportion to the pressure in the brake. This downward force on the piston is transmitted through the brake-valve lever and up to the pedal so the pilot feels the reaction on his foot. Obviously, if he pushes only lightly on the pedal, the pressure builds up in the brake valve to such an intensity that the piston reacts strongly enough to move his foot back a few thousandths of an inch, no more pressure passes into the brakes, and the result is a very light application of the brakes. As the pilot pushes harder on the pedal, the pressure in the brake valve builds up higher and greater brake action is achieved.

Notice that the actual movement of the brake pedal is very small, as a matter of fact, only a few thousandths of an inch. The valve acts perfectly. It does what is required but it feels unnatural to the pilot, since he has been accustomed to mechanically operated brake pedals in smaller airplanes, or to automobile brakes in which the pedals have a substantial movement. It does not feel natural to push on a pedal which is apparently as unyielding as a brick wall. To make this feel more natural to the pilot, a spring is introduced between the pedal and the piston. In Fig. 12, this is shown as though it were directly in connection with the pedal itself. This spring does not have any actual function in so far as the brake valve is concerned. It is merely introduced to make it feel more natural to the pilot. Here is an example of a power amplifier in which the pilot's first effort is amplified by the hydraulic system and then applied to the brake. There is apparently no particular limitation as to the amount of power which may be controlled by the brake valve, and it is to be expected that, as airplanes continue to get larger, the pilot will actually supply only about 1 or 2 per cent of the power required to apply the brakes.

Preselective Flap Control, Example of "Follow-Up" System

The mechanical version of the second class of control system, called the "follow-up" system, is illustrated in Fig. 13. This is a system which might be used as a preselective flap control. When

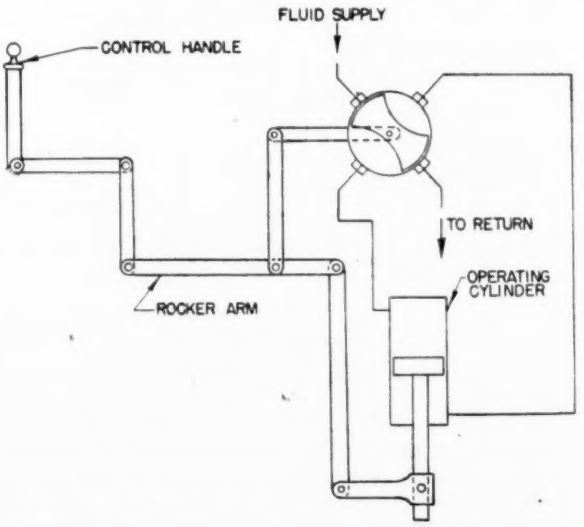

Fig. 13 Mechanical Follow-Up Type of Control System

the pilot moves his control handle to some position, the valve is opened and the resulting motion of the operational unit is transmitted mechanically to the valve through a rocker arm so that, when the desired position is reached, the valve has been brought back to neutral and the operation ceases. This mechanical position-transmitting type of "follow-up" system is seldom used, except where the power required for the operation is fairly large or where structural considerations make its application easy.

If the power requirement is low and installation difficulties prevent direct mechanical connections between the control handle

and the unit to be operated, a "follow-up" system having hydraulic positional transmitting connections may be used, Fig. 14. In this system, the operating unit, which is known as a "slave unit," is connected by lines to a follow-up cylinder and a valve whose body is fastened to the follow-up cylinder and moves with it. In the figure, the piston rod is shown as being anchored, and the valve lever is connected to a handle for pilot operation. If the handle be moved in the direction shown by the arrow, pressure will be admitted to the right-hand end of the follow-up cylinder. This pressure will push the cylinder itself toward the right, reducing the space in the left-hand end of the cylinder, thus forcing the fluid to flow through the pipe to the right-hand end of the slave unit. Since the slave unit is fixed, the piston will move to the left, and the oil returning from the left-hand end of the slave unit passes through the valve and is returned. It is evident that, as the follow-up cylinder moves to the right, it will move the valve body to the right, and, since the pilot's control handle is in a fixed position at that time, the valve will automatically

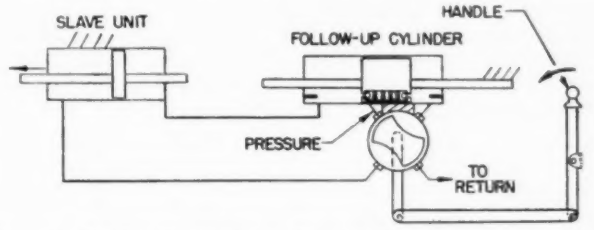

Fig. 14 Follow-Up Control System With Hydraulic Positional Transmitting Connection

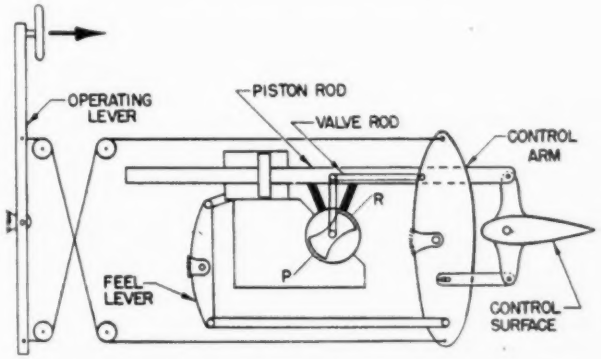

Fig. 15 "Follow-Up Plus Load-Feel" Type of Control Unit

close off when the position of the slave unit corresponds to that of the handle.

This type of circuit is, in effect, two cylinders in series and, in order to compensate for thermal expansion of the fluid or leakage, check valves are placed within the piston of the follow-up cylinder, and lifters are arranged at the ends of the cylinders so that whenever an extreme position either right or left is reached, one or the other of the check valves will be raised from its seat, permitting fluid to equalize between the follow-up cylinder and the slave unit and thus resynchronize.

"Follow-Up Plus Load-Feel" System of Control

The type of control known as the "follow-up plus load-feel" is used where the pilot must not only know the position of the controlled unit but also have some realization of the loads required to move it to that position. Fig. 15 shows such a system connected up as a surface-booster mechanism. The operating lever in the left-hand side is connected by cables to a control arm. The piston rod of the operating cylinder is connected to a horn attached to the control surface and, at the same distance from the center, a valve rod which operates the valve is connected about as shown. The valve body is fastened to the piston rod and moves with it. If the operating lever be moved in the direction of the arrow, that is, to the right, the control arm is pushed in the opposite direction. This moves the valve rod and opens the valve in a direction which will permit pressure to enter the right-hand end of the cylinder. This pressure entering will move the piston rod to the left thus moving the control surface in the desired direction. If the piston rod moves to the left, it carries the valve body with it and, since the valve rod is fixed in position, the valve will close when the piston has moved a sufficient distance to bring it into synchronism with the control arm. There is no need of having any connection between the control arm and the control surface, but a connection having lost motion is used because in the event of failure in the hydraulic system, the pilot would wish to have control of the airplane by manual means even though he might have to push very hard for the controls to accomplish the desired results.

Referring again to the operating cylinder, notice that it is not fixed to the structure but is connected through a lever and rod back to the control arm. The cylinder could have been fixed but, if it had been, an irreversible system would have resulted and the pilot would not have any "feel" of the loads required. By connecting the cylinder back through this lever and rod, the position of the pivot about which this lever moves can be so varied that the force transmitted to the control arm is in any desirable proportion to the effort which is exerted by the cylinder. If the pivot be put nearer the cylinder, the pilot will feel only a small portion of the effort.

It is, of course, obvious that the type of valve, shown in this diagram (Fig. 15) and also in the previous one, is not at all suitable for this use, since it is not sensitive in action and must be rotated through large angles. However, it was used merely for illustration since the principle is the same, and the rotary valve is much easier to understand in a diagram than the somewhat complicated but more sensitive valve which is actually used in practice.

Fully Automatic Type of Hydraulic Control

The final type of system is the fully automatic one in which the pilot has nothing to do with the operation. Such controls are used frequently as temperature controls, manifold-boost controls, or propeller controls. A fully automatic temperature control is illustrated in Fig. 16, which shows an operating cylinder, the piston rod of which is connected to a bell crank so that as the piston moves to the left, the scoop is opened wider. At the right-hand side is shown a rotary valve with its operating lever connected to a sylphon bellows which expands when heated. This bellows would be placed in the coolant circuit and, as the engine increases in temperature, the coolant temperature would increase and the sylphon bellows would expand. This would rotate the valve in a clockwise direction, admitting pressure to the right-hand end of the operating cylinder, thus moving the piston to the left and

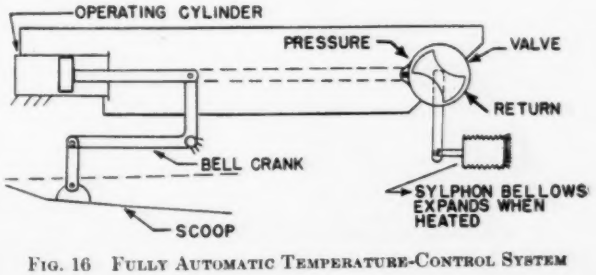

Fig. 16 Fully Automatic Temperature-Control System

opening the cooling scoop further. It is probable that the scoop would operate a great deal faster than the temperatures of the engine, and, consequently, the bellows would change so the scoop would be opened completely before the bellows had a chance to contract and close the valve. The scoop, being too far open, would overcool the engine and the sylphon bellows would contract, thus opening the valve in the opposite direction and closing the scoop. This would go on indefinitely, resulting in the scoop alternately opening and closing fully all the time.

Of course, restrictors might be placed in the lines so that the scoop could only move slowly. It is not advisable to control the hunting tendency in this manner since it limits the rapidity with which the scoop can be moved, and many times it is necessary to open a scoop quickly.

Another way of controlling this hunting would be to connect the valve body with the piston rod by a connection which is shown in dotted lines. Then, if the bellows heats up, the valve opens admitting pressure to the right-hand end of the cylinder and the piston moves to the left thus opening the scoop, but at the same time the valve body moves to the left which tends to close the valve. Now, if the engine should get warmer, the bellows would expand further, again opening the valve, and the scoop would open still further. Hence it is evident that the temperature of the sylphon bellows will have to be somewhat higher when the scoop is fully open than it would be when the scoop is nearly closed. In other words, a definite fixed temperature cannot be held regardless of the opening of the scoop. The relation between this range of temperature and the valve operation gives the system what is known as "drooping" characteristics.

Nearly all fully automatic controls require that there be some droop in the characteristics, in order to avoid hunting. The amount of droop depends upon the particular application and circumstances. It is expected that many more fully automatic controls will be used in airplanes in the future as designers become familiar with the simplicity of these automatic devices and learn that the most important feature about them is to select properly the amount of droop in their characteristics.

The discussion of various types and details of aircraft hydraulic systems might be continued indefinitely, although the basic ideas have been shown.

The detail design of hydraulic units and systems is based upon just three factors: (1) an understanding of the principles which have been illustrated, (2) a knowledge of fluid mechanics, and (3) experience. Most of the difficulties in connection with present-day hydraulic systems are due to the inexperience of the designers of the particular system or, in some cases, lack of test information, both of which are inherent in such a new and rapidly growing field of endeavor.

Controversy Over the Choice of a Medium for Aircraft Power Transmission

By RICHARD L. HAYMAN,[1] BURBANK, CALIF.

The growth in size and the increase in speed of modern aircraft has created the need for powered operation of many controls, accessories, etc., to supplement the work performed by the crew. The services performed by engine power and remotely transmitted to various parts of the airplane are too numerous to mention here but are tabulated in part in the paper. The choice of a medium for the transmission of this engine power to remote points has provoked one of the most intense controversies of aircraft engineering. In spite of the bitterness of the controversy that has at times prevailed, it has probably proved to be a dominant factor in the improvement of the two major surviving media, namely, hydraulics and electricity. This paper sets forth the cause of the controversy and presents a fair evaluation of each system of power transmission.

Introduction and General Explanation

MOST powered operations on aircraft can and have been performed by either the hydraulic or the electrical method, although perhaps not as conveniently one way as another. The choice actually resolves itself down to an evaluation of the comparative advantages and disadvantages of these two media for the particular job at hand. Certain companies subscribe almost completely to all-hydraulic operations; others cling to all-electric operations, while the majority hover between the two. This would verify the fact that opinions differ widely as to the proper evaluation of the services. To understand this radical difference in opinion of sound engineering minds one must study the complexity of the problem. This paper will attempt to present some aspects of the controversy in its present stage of development.

The problem is rightfully divided into two parts: (1) the transmission of power from one point to another, and (2) the conversion of this power into useful work. While no attempt will be made to treat these parts separately, the division should nevertheless be borne in mind.

Three Basic Forms of Power Transmission

The three basic forms of power transmission (other than purely mechanical) in common use in modern aircraft are hydraulic, electric, and pneumatic (including vacuum). Of these three basic services, electricity alone is an absolute necessity. Lighting and communications are two chores that make the use of electrical power mandatory. Since it is desirable to keep the number of different types of power media to a minimum, this fact is a strong argument for the use of all-electric power.

The use of vacuum and compressed air is relatively minor at this time in this country and will be neglected in this paper. Certain instruments have utilized vacuum for their operation for some time. The vacuum pumps necessary for this work have served double duty by providing the low-pressure air used by the inflatable wing-deicer boot. The use of electrically operated gyros and heat deicers may make obsolete these services. The use of hydraulics is universal, however, in spite of the fact that most of the services performed by it could be done electrically. To understand this we must enumerate the requirements of a power medium.

A brief explanation of the three basic services follows:

Aircraft hydraulics utilizes a low-viscosity mineral oil, and operates (in this country) at pressures ranging up to 3000 psi. Aircraft electricity consists of 12 and 24-v d-c systems, 110-v a-c systems, and an experimental 208-v, 3-phase, 400-cycle a-c system. Pneumatic power ranges from vacuum air systems to high-pressure air systems.

Choosing a Medium for Power Transmission

The Requirements. If the requirements for a power-transmission medium were to be listed in the order of their importance, they might read as follows:

1 Reliability (including lack of vulnerability).
2 Functional suitability.
3 Low weight (including efficiency).
4 Simplicity (from both development and maintenance standpoint).
5 Low cost (in terms of time and material now; in terms of money after the war).
6 Compactness.

There are probably others that could be added under separate headings, but we will try to include all requirements under one of those listed. The order of importance of the requirements may vary with the size, type, and function of the airplane and is therefore subject to change. All of the requirements listed necessarily overlap to a certain extent, so that it is impossible to discuss one without referring to others. Thus reliability and simplicity will go hand in hand. Simplicity and functional suitability will combine, and simplicity and cost will be contested as being synonymous. Low weight and compactness will fall into a similar category.

Reliability. The relative reliability of electrical and hydraulic systems has been strenuously contested verbally, but very little

TABLE 1 UNITS FREQUENTLY OPERATED BY CYLINDERS OR MOTORS IN LIEU OF MANUAL OPERATION[a]

Power Plant	Flight Controls
Starter	Surface-control power boost
Cowl flaps	Dive flaps or brakes
Oil-cooler flaps	Tabs
Prestone radiator flaps	Wing flaps
Carburetor hot-air valve	Automatic pilot
Carburetor air-filter control	Slots
Two-speed supercharger contr	**General**
Propeller-feathering pump	Landing gear and landing-gear door
Propeller deicing pump	Floats
Fuel booster or assist pump	Folding wings
Armament	Brakes
Gun chargers	Steering
Ammunition boosters	Fans (heating and ventilating)
Elevation boosters	Cabin supercharger
Gun turrets	Winches (for loading, etc.)
Bomb doors	Dump valves and chutes
	Landing lights
	Deicer pumps and controls

[a] The list is not necessarily complete.

[1] Hydraulics Engineer, Lockheed Aircraft Corporation.

Contributed by the Hydraulic and Aviation Divisions and presented at the Semi-Annual Meeting, Los Angeles, Calif., June 14–17, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

conclusive proof has been brought forward to substantiate a claim for either medium. Actually it is extremely difficult to make a good comparison and arrive at any definite conclusion. In every case unreliability of one or the other is a function of poor design, installation, or maintenance. Since, however, we will always be limited by human ability to perform these functions, we can do no more than take actual cases as a parameter to compare the two services.

In an endeavor to make an evaluation of any usefulness, it was felt that actual service records should be explored. Service reports on types and makes from many different companies, covering a period of several years, were studied toward this end. In every case of failure of electrical or hydraulic equipment or systems, the seriousness of the failure naturally depended on the nature and the importance of the units being powered. Both systems have necessarily gone through a period of strenuous development. Aircraft hydraulics is newer than aircraft electricity and, although lacking the standardization that electrical-parts manufacturers have achieved, concedes no ground to electrical systems in reliability.

We find in practically every case that trouble was due to lack of experience, either on the part of the equipment manufacturer, the aircraft manufacturer, or the ultimate operator of the aircraft. Since the use of these auxiliary powers to such a great extent in aircraft is really quite new, lack of experience is natural. Both systems went through similar epidemics of trouble. In the hydraulics field at certain times, there were numerous failures of regulators, accumulators, ball-check valves, and packing. Sheared pump shafts provided another flurry of trouble and less predominant were hose failures and control-valve failures. In the electrical field, the same period was marked by frequent generator, voltage-regulator, inverter, limit-switch, and starter failures, and burned-out or broken wires or plugs. Less frequent were motor failures, fused battery solenoids, and burned-out relays. Cold-weather operation caused trouble to both systems, although perhaps more to hydraulics, while high-altitude trouble was more serious to the electrical systems. No one of the troubles developed in either system has been insurmountable. All have been susceptible of solution, the net result being a marked improvement in the equipment of all manufacturers.

For purposes of comparison, three different airplanes, representing three different manufacturers, were singled out. Service troubles were totaled for both electrical and hydraulic systems for these airplanes over a given period of time. It will be evident that these reports occurred during epidemics of trouble. They do not, however, represent all of the failures that occurred, as a large percentage are never formally reported. The reports cover a considerable number of airplanes and represent a long period of time.

The figures, as noted, list the number of unsatisfactory reports received on airplane No. 1 for a given period, but do not necessarily mean the total number of failures, as several unsatisfactory reports include more than one failure. In this airplane, the electrical-system source was capable of a maximum of approximately 3.25 hp delivery, while the hydraulics source delivered a peak of approximately 5.5 hp at any one time.

Hydraulic Failures

1 Packing failures: 27 unsatisfactory reports, comprising 28 or more[2] occurrences; of these, three reported belly landings due to the failure.

2 Hose failures: 4 unsatisfactory reports; one reported belly landing due to the failure.

3 Broken lines or fittings: 4 unsatisfactory reports; three due to interference.

4 Pump failures: 4 unsatisfactory reports; comprising four or more[2] occurrences.

5 Cylinder failures: 11 unsatisfactory reports of which 9 were structural failures.

Electrical Failures

1 Burned or fused wires or groups of wires or plugs: 24 unsatisfactory reports, comprising 32 or more[2] occurrences; of these, 9 reported complete electrical-system failure, of which 6 reported forced landings due to runaway propellers.

2 Voltage regulators: 3 unsatisfactory reports; one reported 30 per cent of all voltage regulators tested were out of adjustment.

3 Inverter failures: 4 unsatisfactory reports, comprising 21 or more[2] occurrences; 18 were reported due to high altitude.

4 Generator failure: 8 unsatisfactory reports, comprising 22 failures; average life reported to be 15 hr.

5 Starter failure: 4 unsatisfactory reports.

6 Relay failure: 5 unsatisfactory reports comprising 7 occurrences.

7 Fused battery solenoids: 4 unsatisfactory reports, comprising 4 or more[2] occurrences.

There were other miscellaneous trouble reports in both systems, but since they were not repetitive, no inclusion was made in the foregoing list.

Both electric and hydraulic motors were in use on this airplane, and only one unsatisfactory report on an electric motor was received.

Another airplane of a different type, made by a different manufacturer, indicated a total of 108 unsatisfactory reports for hydraulics, and 110 unsatisfactory reports for electrical equipment for the same period of time. Only basic electrical-system failures were included here; no heating, lighting, communications, or instrument failures were listed. Airplane No. 3 of a different type by a different manufacturer shows 63 reports of trouble with hydraulic pumps against 38 reports of trouble with generators, voltage regulators, and relays. Total maximum horsepower available from the hydraulic pumps was approximately 45, as compared to approximately 13 delivered by the electrical generators.

If these troubles were summarized, they would probably prove to be nearly equal. If, however, a comparison is made on the basis of number of troubles experienced per horsepower transmitted, the favor rests rather heavily with hydraulics. It may be disputable as to whether or not the power comparison is a fair yardstick, but for want of a better one it will have to suffice.

In passing, a plea should be made for more immediate action on service complaints. They are all eventually acted upon, but the length of time that often elapses before any action is taken is appalling. This has undoubtedly done more toward prejudicing certain persons against one or the other system than any other avoidable cause.

Vulnerability. The subject of relative vulnerability of hydraulic systems and electrical systems is a delicate one indeed. In order to be clear on all fronts, we will define vulnerability as lack of ability to survive gunfire.

The first, and natural, and perhaps correct assumption is that electrical systems are less vulnerable. Foremost and insurmountable is the fact that there is no fluid to be lost in electrical systems, and any number of minor lines may be severed without damage to the rest of the system. Although fusing of wires or plugs from short-circuits is not infrequent, it is seldom that a serious fire results from this cause. In a hydraulic system, however, we are carrying an inflammable fluid around in pipes to

[2] One or more unsatisfactory reports noted "many failures," but did not specify how many.

most parts of the airplane. Thus, while the hydraulic system itself may be incapable of starting a fire through its own operation, the fluid it utilizes may be ignited from the incendiary projectile that breaks the line or unit containing the fluid. The same projectile that would break a hydraulic line, but fail to ignite the fluid, might conceivably break electrical connections in the immediate vicinity, creating a short that would ignite the fluid. While this may or may not be a far-fetched conclusion, the blame for the fire would rest with the hydraulic fluid, since the electrical wires were there of necessity.

In contrast to these arguments it can and has been theoretically shown that hydraulic systems can be made less vulnerable than comparable electromechanical systems by virtue of the smaller exposed vulnerable area. Where gravity cannot be utilized emergency measures can usually be applied more readily to a cylinder than to an electric motor-gearbox combination. Relative to emergency means of operation, the advantage enjoyed by a gravity extendable hydraulic landing gear over the electromechanical gear disappears with the use of the ball-bearing screw jack. A functional advantage may still rest with the cylinder for the gravity extension by use of the dashpot. The same thing may be accomplished on the electric drive by means of a centrifugal-governor-operated brake, but not so simply as the dashpot on the cylinder.

Enough more could be said on this subject of vulnerability to make a separate paper. It is certain, however, that those best qualified to present the facts are too busy fighting to keep the airplanes in the air to take time out to write about it. Unfortunately, the information that does filter back is often as conflicting as the arguments which arise over the basic subject under discussion.

Functional Suitability. By functional suitability, we mean a solution to a mechanical problem that gives us the exact operation we are seeking in the simplest, most direct manner possible. It is here that hydraulics enjoys one of its greatest advantages. As stated earlier, the problem of translating transmitted power into useful work is practically a separate and distinct problem from the transmission of power itself. It is in this translation of power into useful work that the hydraulic cylinder plays a principal role.

As has been said so many times before, the straight-line motion of the cylinder has no satisfactory electrical counterpart. There is more, however, to the advantage of the cylinder than just straight-line motion. The starting, stopping, and rate of travel of the cylinder are very simply controlled. The cylinder is its own basic travel-limit device for both extremes of its stroke. By means of the dashpot, the rate of travel of the cylinder during part of the stroke may be effectively governed. No special means have to be provided to start and stop the cylinder anywhere in its travel, as we are dealing with lightweight parts, traveling at low speed, immersed in oil. The electric motor-screw jack combination does not offer a favorable comparison with this operation. Limit switches must be provided to govern the length of stroke, and magnetic clutches or brakes must be employed to start and stop the unit with any reasonable accuracy. For use in areas subject to extreme vibration, the cylinder is ideal and natural. As a vibration damper, the oil column serves a very useful purpose. Use of a screw jack, gearing, and flexible shafting in a function in which vibration defies stress analysis does not seem logical. Electromechanical units have been developed through years of experience, however, that will withstand this vibration. Similarly, electrical brakes and purely electrical power turrets have been developed that have been operated successfully. These electrical uses, however, are functionally about as natural as the use of phosphorescent hydraulic oil for lighting.

The transmission of power from one point to another cannot be done so simply or economically with hydraulics as with electricity. In this regard, the electrohydraulic gun turret offers a common-sense solution to a difficult mechanical problem. It enjoys the simplicity and lack of vulnerability of the electrical transmission system, but utilizes the compactness and natural sensitivity of control and response of the hydraulic system. It might be said that this is an ideal example of intelligent use of both media. This should not necessarily be inferred as being a recommendation for the use of an electric-motor-driven pump for each and every piston in the airplane; rather, it is a plea for open-minded intelligent use of both media, employing them to their best advantage wherever possible.

It was stated earlier that the cylinder had no electrical counterpart; this is not strictly true. The solenoid is essentially similar to the cylinder in its action. For aircraft use it is limited by size and weight to light duty. This can be put to excellent use in the hydraulic system itself. The directional-control valves for landing gear, flaps, power-plant-cooling flaps, etc. present a problem in remote control all their own. The problem can be solved by two basic methods: (1) either the control valves can be located in the cockpit and directly controlled, or (2) they can be located at the unit to be remotely controlled. To locate them at the unit to be controlled obviously provides the cleanest hydraulic system from the standpoint of plumbing complications. It is in this remote control that the solenoid finds an ideal use. The solenoid-operated valve presents another common-sense solution to a problem involving the use of both media.

It has been said that to combine both systems is to double the vulnerability and be subject to the malfunctioning of both. The following statements would prove this untrue:

1 Conceding that present electrical systems are less vulnerable to gunfire than present hydraulic systems and that the installation of double wiring is feasible for such valves, we are not doubling our vulnerability.

2 A magnificent reduction in piping and cables can be made by the use of solenoid-operated valves. Reducing the quantity of piping involved reduces the vulnerability in direct proportion. This can only too readily be demonstrated on many airplanes where the multiplicity of piping strains the imagination as to how a projectile could possibly miss all of it.

3 Whether the valve be directly controlled in the cockpit, remotely controlled by cable, or remotely controlled by electricity, a suitable emergency means of operation must be provided if the operation involved is of major magnitude. The use of solenoid valves for these operations does not change this.

4 The design of solenoid-operated valves has progressed to the point where they can no longer be regarded as being in the experimental development stage. It is only extensive use that will provide the opportunity to prove them to the point where their use is as natural as direct control.

Returning to the subject of functional suitability, we find that the smoothness of operation that can be obtained with calibrated valves, as used on power turrets, on surface-control power boost, or similarly as the metering pin on oleo struts cannot be so simply duplicated electrically. Similarly, the ability of hydraulics to transmit true "feel" through its transmission lines is an advantage readily utilized by the hydraulic brake. It might also be worth mentioning that the ability of a hydraulic cylinder or motor to absorb an overload indefinitely without damage cannot be so naturally accomplished electrically.

Electricity, on the other hand, presents many functional advantages which cannot be equaled hydraulically. For very low power requirements, hydraulic power transmission is not economical, and we naturally turn to electricity. Units utilizing high-speed rotary motion, such as centrifugal pumps, are ob-

viously better done electrically, and the synchronous electric motor will find many unparalleled uses. The ability to store energy for ground operation is readily accomplished by the battery for the direct-current electrical system. Size and weight limitations of the battery, however, make the compressed-air bottle or hydraulic accumulator more satisfactory for storing large amounts of energy for emergency operations requiring heavy work, so that no advantage can be conceded to the battery. The alternating-current electrical system, unless augmented by direct-current service, is no better than a hydraulic system for ground operation and lacks the ability of the compressed-air bottle for emergency duty.

Other advantageous properties that must be conceded to electrical-power transmissions are its cleanliness and its relative independence of normal operating temperatures. Gearbox and motor lubricants, mechanical clearances, etc., are affected by temperature, but they do not present the design problem that an expanding and contracting fluid offers.

Summarizing, it may be safe to assume that, for most purposes, hydraulics is more suitable as a solution to mechanical problems involving relatively large forces or power, while electricity is more suited to light-duty work.

Low Weight. It is believed that no voice will be raised too strongly in objection to the statement that, power for power, present-day direct-current electrical systems are heavier than equivalent hydraulic systems of the 1000 to 1500-psi range. This fact has been one of the main talking points other than functional suitability for the use of hydraulics to supplement electricity.

Power for power, hydraulic pumps are lighter by far than electrical generators, be they direct-current generators or alternating-current alternators. Likewise, the hydraulic motor is lighter for an equivalent power rating than even the presently proposed high-speed alternating-current electric motors, and by far lighter than direct-current motors. For example, a piston motor has been successfully run continuously at 4000 rpm at 1500 psi, delivering approximately 8.6 hp. This motor weighs 4.3 lb, thus giving a ratio of 0.5 pound per hp. For intermittent duty, the motor has been run at higher speeds and higher pressures. An intermittent-duty 8-hp d-c motor running at about 5500 rpm is quoted at approximately 17 lb, while a 12,000-rpm intermittent-duty 8-hp a-c motor weighs approximately 14 lb. For continuous duty at this power, no actual figures could be obtained, but an approximation of 30 to 40 lb seems to be in order. The analogy breaks down, however, for small power requirements, and the electric motor becomes lighter than the hydraulic motor. In transmission, electric wires are lighter than equivalent hydraulic lines and oil, for small power on 24-v direct current, and for all power on the higher-voltage alternating-current systems.

The weight and size of the cylinder are dependent upon the total work performed, and the efficiency of the stroke, not upon the rate of operation. Thus for a given operating pressure, it is the peak load on the stroke-load curve which determines the cylinder diameter. It is desirable, of course, to keep this peak load as small as possible. On a landing-gear cylinder, where the cylinder size and time of retraction may well dictate the size of hydraulic pump and lines required, this becomes of extreme importance. Thus in Fig. 1 we have a typical landing-gear-cylinder load curve.

Assuming that this cylinder is used in a system with a peak design pressure of 1500 psi, the cylinder diameter required would be 6 $^{7}/_{8}$ in. (neglecting rod area). The cylinder volume would then be 2.57 gal on the retraction side. If it is desired to retract this gear in 10 sec, approximately 15.4 gpm must be fed to each gear cylinder. Assuming for simplicity that the nose gear would have the same load curve as the two main gears, the total flow required from the power pumps would then be 3 × 15.4 or 46.2 gpm. By attaching the cylinder to the drag-link fulcrum horn by means of differential linkage, the peak load was reduced to 36,000 lb as shown in Fig. 2. The cylinder diameter required for this condition was then 5 $^{5}/_{8}$ in.; the volume was reduced to 1.72 gal. The rate of flow to each cylinder now became 10.3 gpm, and the total flow required from the power pumps was 30.9 gpm. The added weight of linkages was more than compensated for by the reduction in cylinder weight alone, while the weight saved in line-size reduction, oil, power pumps, and the attachment structure for the cylinder was pure gain.

Utilizing the higher pressures (1500 to 3000 psi) and taking as full advantage as possible of design features as just illustrated,

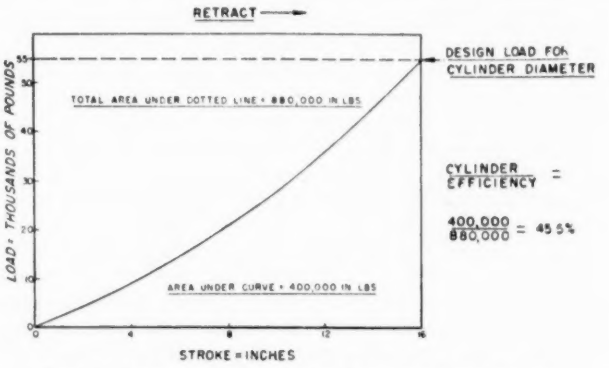

FIG. 1 TYPICAL LANDING-GEAR-CYLINDER LOAD CURVE

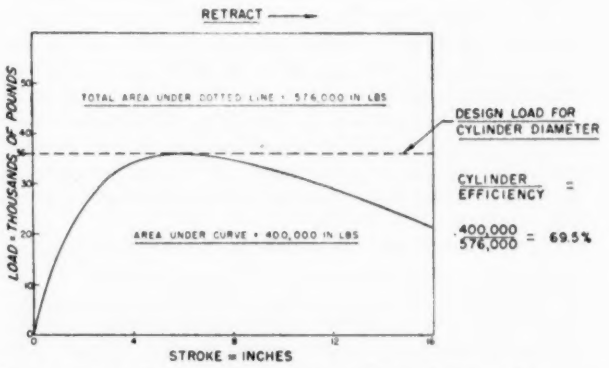

FIG. 2 CURVE SHOWING REDUCTION OF PEAK LOAD IN LANDING-GEAR CYLINDER

the weight superiority of hydraulic systems over 24-v d-c systems can be maintained in most cases over a-c systems. This is true, however, only as long as we are dealing with relatively high power requirements. As allowable gear- and flap-retraction times are increased and the power requirement drops, a turning point is reached where the electrical system enjoys a weight advantage over the hydraulic system. Where this point lies must be determined for each different airplane, unless a cursory inspection of conditions makes it self-evident.

In this regard, the a-c alternator has a property that must not be overlooked, i.e., the ability to absorb approximately 50 per cent overload for 5 min without damage. Thus it is conceivable that, on a large cargo and/or passenger airplane, the alternator size, as dictated by lighting, heating, communications, equipment, air conditioning, and other ordinary duty, will be sufficient to handle landing gear and flap loads without any increase in size, merely by being overloaded for a short period of time. If there is no duty which requires hydraulic service, the

total weight of the complete hydraulic-power system must be added to the comparable weight analysis of cylinders versus motors and gearboxes, etc. This free power may well place the weight advantage in electrical operation many times. The comparative weight between high-pressure hydraulic systems and a-c electrical systems then resolves itself down to particular cases.

Simplicity. It would seem logical that hydraulics, since it is really the mechanics of fluids, would be far simpler than electricity. Practically, it may be said that this is reasonably true. The hydraulic cylinder by no means presents the design problem that the gearbox does. With the use of "O" ring packing and the establishment of standard clearances, cylinder design has become extremely simple. Similarly, the development and testing of the cylinder is much simpler than that of a high-reduction gearbox. Providing both cylinder and gearbox satisfactorily pass a life test, there should be no service required other than a periodic drain and flush for the gearbox lubricant and a periodic check of the cylinder packing.

As a balancing factor against the mechanical development time required by the gearbox is the standardization of electrical parts. In practically every case 100 per cent of the purely electrical equipment is purchased from electrical-equipment manufacturers, and the development cost of such equipment is amortized over many different companies. The aircraft electrical engineer's job, then, is one of installation, rather than of design and development.

Aircraft hydraulics, however, is relatively new. We have not settled as yet the majority of problems that will have to be resolved before we can begin to use standard items "out of stock." It may be a long time before we are ready to agree on a type of system, an operating pressure, and even upon such basic parts as a suitable leakproof coupling. Consequently, the aircraft hydraulic engineer's problem is one of design and development as well as installation. It is realized, of course, that electrical systems will undergo a period of development with the advent of a-c systems, but such development work will be a function of the electrical-equipment manufacturers rather than the ultimate users, even though they be the guinea pigs for its testing.

In the field of hydraulics, there is no parallel gigantic research organization to which we can present our problems and know they will be worked out from beginning to end. There is no one organization set up to engineer, develop, and manufacture a complete hydraulic system from reservoir, to pump, to valve, to cylinder. Each aircraft company is dependent upon its own engineers plus those of a multitude of vendors. Undoubtedly, there is room in the hydraulics field for such a complete organization. Perhaps we shall someday see one.

Simplicity of maintenance, like reliability, is very close to being a stand off between the two systems. A mechanic with only a smattering of electrical knowledge will favor the hydraulic system because it is basically easier to visualize what goes on in a pump or cylinder or valve, than in a generator, electric motor, or relay. Similarly, the trouble is ordinarily easier to trace in a hydraulic system, although on occasions this can be a drawback.

In military theaters, the necessity of stocking hydraulic oil is undoubtedly a nuisance. If, however, this hydraulic oil is the only satisfactory low-temperature lubricant for gearboxes, etc., its use might be justified. It would seem easier, also, to replace a shot-up wire or bundle of wires than a similar group of prefabricated tubing. If we consider, though, that the tubes and hydraulic cylinders are replacing gearboxes, torque tubes, flexible shafts, and cables, we are not so prone to concede the advantage. As it is necessary to have trained mechanics and trained electricians wherever the aircraft goes, any claim to advantage in one or the other system would seem purely academic.

Low Cost. Low cost is closely allied with simplicity, and the same remarks apply to it as to simplicity. The cylinder is basically cheaper than the motor-gearbox combination, but the standardization of electrical parts is much superior to hydraulics standardization, thus resulting in somewhat of a balance. If the electrical engineer is forced to use special generators, special voltage regulators, special motors, etc., his cost would probably be greater than a similar hydraulic arrangement.

It is too often believed that cost should not be considered in time of war. Cost, we must remember, however, is a measure of time and material, and time and material is a measure of quantity of production. Thus to achieve the correct balance, we must weigh cost carefully with function to make sure that the time and material expended justify the purpose. Too often recently we have seen numerical superiority prove more important than quality. To strike a happy medium, then, is the purpose of every conscientious engineer and manufacturer.

Compactness. A strong case can be made for the hydraulic cylinder when space is at a premium. In a small fast pursuit plane, where every nook and cranny contains some piece of equipment, the ability of a cylinder to change its "gear ratio" by changing its diameter and stroke, and yet do the same amount of work, is extremely useful. It is usually in such planes that rapid rates of gear retraction are demanded, thus making the job a natural for hydraulics. Small motor - gear screw combinations can be made, but they cannot compete with the cylinder on a power basis simply because the cylinder is independent of rate of operation while the motor is not. Plumbing, however, outdistances wiring by a great deal in space consumed. Thus from a compactness point of view, the choice depends upon where the compactness is wanted if it is going to be a contributing factor to the decision.

Aside from the solenoid, electrical power is limited to high-speed rotary motion. To convert this into low-speed rotary motion or linear motion requires gearing of some sort or other. Such gearing, however, as developed by electrical-equipment manufacturers is not necessarily extremely heavy or inefficient. The use of precision-built planetary gearing in steps provides very high reductions with amazing efficiency for relatively low weight. A new design of ball-bearing screw jack has opened up new fields for electric motors by its very high efficiency. Thus with spur gearing and the ball-bearing screw jack, one may conceivably go through a very high gear reduction, translate into linear motion, and emerge with a relatively high mechanical efficiency. Such gearboxes may also contain torque limiters, magnetic brakes, speed limiters of the centrifugal type, and all the necessary bearings and still be compact and relatively light in weight.

Evaluation of the Two Media

As previously stated, the evaluation of the comparison between the two media is probably the most opinionated part of the whole controversy. To those who say that everything must be sacrificed to vulnerability during the present emergency, the obvious answer seems to rest with all-electrical service. The weight, simplicity, and functional advantage usually resting with hydraulics, however, would seem to justify its use, even though necessary to employ some armor and self-sealing tanks. That this view is held by certain German designers is evident from some of their more recent designs.

Any tendency to adopt all-electrical service could be construed as being partially a fault of the hydraulics engineers in that we have not worked together perhaps as closely as we might have. That this was originally due to competition is undoubtedly true. Nevertheless, our aircraft electrical men were compelled to work together by being so dependent upon outside

sources, and in so doing have gained very definite advantages.

Through simplification of existing systems and careful design of future systems, hydraulics can be made, it is believed, no more vulnerable than a comparable electrical system. For civil aircraft where vulnerability to gunfire is of no concern, hydraulics should again be the favorite it has been in the past. Surface-control power boost will play no small part in more firmly establishing hydraulics as a power-transmission medium. With the advent of larger and faster aircraft, the power requirements will grow accordingly and with this we shall probably see general use of a-c electrical systems and 1500- to 3000-psi hydraulic systems.

In the field of naval vessels, the same trend to all-electric operation and control was made. The pendulum is now swinging back again, and the newest electrohydraulically controlled ships have proved themselves so well in actual combat that a definite movement to extensive electrohydraulic control is foreseen.

A decision to restrict all new military aircraft to all-electric control on the basis of past performance would therefore seem unwarranted and short sighted at this time. There are very definite advantages to be gained through the use of hydraulics in military aircraft as well as in civil aircraft. It is recommended, then, that the best uses of both systems continue to be utilized, even though it may mean mergers of the services in some cases to achieve ideal conditions.

Discussion

H. F. Rempt.[3] The author's presentation is so fair that it is quite difficult for the writer to pick out exactly where the aircraft electrical system is really stepped on. However, since the problem is a controversial one, the following comments are given on parts of the paper, in the order that they were presented:

The two main parts of the problem were expressed as "transmission of power" and "conversion of power." It is believed that a third part should be included, namely, "remote control of power." In the present airplanes, it is hard to find one application of power that is not remotely controlled.

[3] Electrical Engineer, Lockheed Aircraft Corp., Burbank, Calif.

The author states, "of the three basic services, electricity alone is an absolute necessity." If this fact is conceded, then it is necessary for every hydraulic application not only to compare favorably with the same electrical application, but also to justify its share of the installation of the entire hydraulic system.

Under "failures," the number of unsatisfactory reports for hydraulic and electrical operation was approximately the same. However, the statement was made, "the favor rests rather heavily with hydraulics if the comparison is made on the basis of number of troubles experienced per horsepower transmitted." Rather than use horsepower as a comparison, it is believed the number of systems or units should be used.

The assumption that electrical systems are less vulnerable than hydraulic systems is true, particularly if the comparison is made by similar systems.

The writer differs with the statement under "Suitability," that electrical power turrets are not functionally natural. Since the guns elevate in an arc and the turrets revolve, it is believed an electric turret is a natural application for rotating power.

The mention of some type of operation "providing the cleanest hydraulic system" does not agree with the writer's experience when standing in wheel wells. The writer does not believe there can be a clean hydraulic system.

The comparison of compressed-air bottles and accumulators to the battery is in error, since the battery is in the airplane anyway and the bottles and accumulators then become added weight.

The writer cannot subscribe to the statement, "the aircraft electrical engineer's job is one of installation rather than design and development." Most of the new developments in aircraft electricity come about by a design and development program undertaken by an electrical manufacturer in conjunction with preliminary design information from the aircraft electrical engineer. The main difference between electrical and hydraulic equipment is that the electrical equipment is not usually made in an aircraft plant because of the special machinery and technique that is required.

For simplicity, the engineer's ideal of a "little black box that snaps in place" is practically answered by present-day electrical equipment. The airplane will be simple to service if the parts are simple to install. By means of bench-testing of complete electrical systems, the installation problem is also simplified. There is no comparable method of bench-testing complete hydraulic systems.

The writer considers the use of electrohydraulic control a step in the right direction. It will be only a matter of 5 or 6 years before the complexity of control requirements will make the all-electric airplane a reality.

The Evolution of the Hydraulic Pump as Applied to Aircraft

By DALE HERMAN,[1] BEVERLY HILLS, CALIF.

Having passed through a period of manual control of auxiliary power functions on earlier aircraft, and later the hand-pump and low-pressure vane- and gear-pump stages, continued demands for higher pressure eventually led to the present-day types of piston pumps which supply necessary power to hydraulic systems of control. The author outlines the basic requirements for well-designed oil-hydraulic equipment including pumps, and then in detail describes the gear pump and the axial-piston pump in both the constant- and variable-delivery designs. Considerations in selecting pumping equipment and the design of the hydraulic circuit are stated.

EXCEPT for earlier simple types of aircraft and small craft of current design, power to perform many auxiliary operations formerly handled by direct manual control has long been a necessity. Power was first introduced in the form of hand pumps, actuated by the pilot, to operate retractable landing gear and brakes.

Being capable of high pressures at reduced volumes, these pumps are still widely used for emergency service. With the advent of larger and faster aircraft, power-operated pumps became necessary, and the earlier hydraulic systems were equipped with low-pressure vane and gear pumps. Continued progress made it expedient to provide more power for the hydraulic system, necessitating higher pressures, and consequent improved designs of gear pumps, and later the introduction of piston pumps to cope with the loads. Today the engine- or electric-motor-driven pump is the heart of the aircraft hydraulic system, and the trend is definitely toward higher pressures on military, transport, and cargo planes.

Basic Pump Requirements

Well-designed oil-hydraulic equipment, including pumps, as used for aircraft, should be neither heavy nor bulky and should transmit power efficiently. Consequently, pump bearing loads lean toward the permissible maximum in order to reduce bulk, and operating clearances are held to a minimum to reduce leakage losses, commonly termed "slip" in pumps, and higher speeds are used to reduce weight per horsepower.

The weight feature of the pump and of other hydraulic equipment is carefully evaluated by every aircraft engineer when undertaking a new design. The efficiencies of the accessory items, such as the hydraulic pumps, which are being added to the engine loads, are not always given as close attention. The hydraulic horsepower generated by a pump is expressed by the following commonly accepted formula:

$$\text{Hydraulic horsepower} = \text{displacement (gpm)} \times \text{pressure (psi)} \times 0.00058$$

The engineer should study the characteristics of the pump selected, from the standpoint of power input under system operating conditions, as well as from the hydraulic output, as represented by this formula, to determine efficiency, and to evaluate the useful work transmitted.

The component parts of hydraulic pumps, designed for high-pressure service, must be manufactured with precision, and ample provision must be made to lubricate properly all working parts, which are in turn suitably housed to protect them from dust, moisture, etc. present in the atmosphere. However, the efficiency and life of the pump, like that of any other piece of precision machinery, incorporating bearings and close running fits, will depend largely upon the care with which it is installed and the attention it receives while in service.

Oil under pressure tends to leak through small running clearances, however minute. All such leakage represents a loss in the applied energy without accomplishing useful work. Such loss in energy is transformed into heat, raising the oil temperature, and if considerable leakage is present, auxiliary cooling may become necessary. Consequently, clearances between moving parts, subject to pressure, must be held to a minimum to insure high operating efficiency. These must be more closely controlled in high-pressure pumps.

If foreign matter of an abrasive nature is allowed within the hydraulic system due to inadvertent carelessness while installing or maintaining the equipment, it will impair the life of all operating parts in the pump, valves, and motors comprising the system. It is noted, therefore, with considerable satisfaction, that the aircraft manufacturers who are pioneering higher operating pressures in hydraulic systems have not overlooked the matter of improved oil filters. This subject is covered in detail in a paper by W. W. Thayer.[2]

In his connection with a manufacturer of vane, gear, and piston pumps for industrial and marine service, the author has acquired considerable experience with the gear and piston designs, which are employed exclusively on aircraft systems, and thus is qualified to discuss the merits of each design, and the class of service for which each is best adapted.

Gear Pump

A large percentage of aircraft systems to date has employed the gear-type hydraulic pump, as pressures below 1000 psi have predominated. The gear pump which is relatively simple in construction, consisting of two accurately machined and fitted gears in mesh, occupied a prominent place in the field until pressure and volume characteristics reached a point at which the requirements exceeded the efficiency limitations of this construction. Gears and the bores in which they operate can admittedly be machined to the same degree of accuracy as pistons. However, due to the larger critical dimensions of the gears, as compared with pistons, to obtain required displacements, these parts have greater linear expansion with temperature change, and must therefore be fitted initially to insure adequate running clearances at the two temperature extremes to which they are subjected in service. Fits on both the width of the gears and the diameter have a bearing on the internal slip or leakage of

[1] West Coast Engineer for Vickers, Inc., Detroit, Mich.

Contributed by the Aviation and Hydraulic Divisions and presented at the Semi-Annual Meeting, Los Angeles, Calif., June 14–17, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[2] "The Modern Hydraulic Reservoir," by W. W. Thayer, appearing on p. 589, of this issue of the Transactions.

the pump and therefore on its volumetric and over-all efficiencies.

In developing a line of hydraulic equipment for machinery manufacturers, and subsequently for aircraft, first consideration was given to the design of a suitable pump with constant-displacement characteristics. The gear pump, which was most commonly used, was first considered but discarded because this pump is hydraulically unbalanced over the projected area of each gear, as illustrated in Fig. 1. While running, the extent of this unbalance undoubtedly will exceed that shown on the diagram,

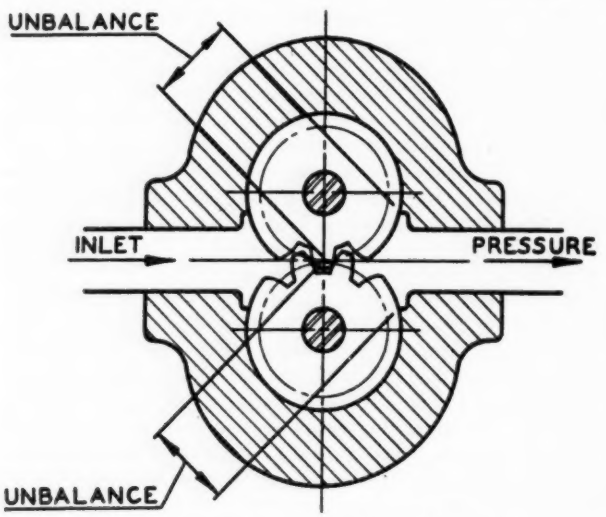

FIG. 1 UNBALANCED GEAR-PUMP DESIGN

because the pressure will tend to distribute itself around the periphery of each gear, being maximum at the discharge port and decreasing toward the suction port. Since the bearing diameters must necessarily be smaller than the periphery of the gears, it is necessary to increase the length of the bearings in proportion to the width of the face of the gears, in a conventional design, to keep the projected areas and the resulting bearing loads within safe operating limits. This also tends to limit the maximum pressure and displacement characteristics of such a pump.

It therefore became apparent that the necessary running clearances between the outside diameters of the gears and the pump body, as well as that of the bearings to their bores, had to be accurately maintained or the radial loading, combined with the differential expansion of the respective parts due to temperature changes, would cause the periphery of the gears to come into metal-to-metal contact with the housing. This would cause scoring and loss of efficiency. Bearing wear, resulting from this unbalanced hydraulic loading, which is accelerated by the presence of foreign materials in the oil, will therefore result in rapid deterioration of the pump.

The design was then modified to balance the gears hydraulically by arranging porting that would apply pressure on the periphery of each gear diametrically opposite to the discharge port and of like area. Gear motors, balanced in this manner, have been used on aircraft, as well as on marine and industrial applications, but their efficiency due to slip does not compare with the piston motor; and the same condition holds true when they are used as pumps.

On most gear pumps the running clearance over the side faces of the gears is fixed to conform with thermal-expansion and lubrication requirements. One manufacturer has introduced an innovation in the normal recognized construction of gear pumps, to control the running clearances over the width of the gear. In certain capacities, this design has been recommended and approved for 1500-psi service.

Gear pumps are made commercially having constant-delivery characteristics, the delivery per revolution being fixed except for slip which increases with pressure. Hence it is necessary to use such pumps with an accumulator system where variable volumes are required for operating different devices, for best efficiency.

As an alternative, on extremely low-pressure systems, where pumps of small displacement are used, such as on gyropilot systems, the delivery of the pump beyond system requirements is by-passed through a relief valve at a constant pressure, thus converting the unused energy into heat. To avoid the necessity for such a second low-pressure pumping system, the use of a pressure-reducing valve is recommended. This takes oil from the high-pressure system on the plane and reduces it to the low pressure required for the automatic pilot or similar auxiliary controls.

AXIAL-PISTON PUMP

The axial-piston pump is essentially a multipiston engine, the stroke of the pistons being determined by the angle of the rotating group, including cylinder block, pistons etc., to the drive shaft. These units were first developed in larger sizes for industrial-machinery applications, and a wealth of experience was available as a result, when the design of lightweight aircraft models was undertaken. Pumps of this same design have been in use in marine, ordnance, and machinery service for power transmission for 8 years. Sizes are available from the smallest constant-delivery aircraft unit that weighs $3^1/_4$ lb and develops 4 hp at 4200 rpm and 1000 psi, to marine gears requiring variable-displacement pumps, operating at 850 rpm and developing up to 300 hp.

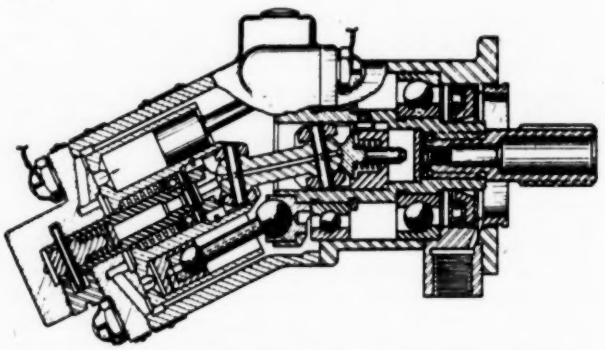

FIG. 2 CONSTANT-DELIVERY TYPE OF AXIAL-PISTON PUMP

The design is well adapted to aircraft service because the bearings can be small in diameter, permitting high-speed operation; and rotating parts are compactly spaced in a manner to minimize weight. The units operate equally well as motors or as pumps, and at the same time offer the advantages of interchangeability of the rotating group of parts as a service consideration. Of equal importance, they may be constructed for variable-delivery output.

These pumps are now available in aircraft types with constant- or variable-delivery characteristics. Basically they have seven or nine pistons that are joined to the drive shaft by connecting rods, the latter having ball-and-socket bearings on both ends. No piston rings are used, but the pistons are fitted to the bores of a bronze cylinder block to a clearance of a few ten-thousandths of an inch, depending upon their diameter. The cylinder block is in turn mounted on a stub shaft and is driven by a universal shaft, having a universal joint at either end to insure that the

speed of the cylinder block corresponds to that of the drive shaft. This universal drive merely acts as a timing member, and overcomes bearing friction within the cylinder block. It does not transmit power, as all working loads are transmitted from the drive shaft directly through the rods to the pistons.

In the constant-delivery type of pump shown in Fig. 2, the angular position of the cylinder block is fixed as determined by the housing. These angles vary from 10 to 25 deg, depending upon the delivery required, as this angle determines the stroke of the pistons and thereby the displacement.

The drive shaft is, of course, mounted on ball bearings, with the angular-contact type taking the thrust produced by the pressure on the pistons, and the radial bearing carrying the radial load imposed by the angular position of the pistons. On pumps designed for pressures over 1000 psi, two radial and one angular-contact thrust bearings are incorporated.

The valve porting in the cylinder block and valve plates of these pumps is clearly illustrated in Fig. 3 and is designed to balance hydraulically most of the hydraulic thrust equivalent to the effective piston area subjected to pressure. Therefore, the Kingsbury type bearing, on the periphery of the hardened and lapped steel valve plate, carries relatively low loads.

These constant-delivery pumps are available in various capacities up to a displacement of 0.507 cu in. per revolution, and for three pressure ranges, as follows:

1000 psi continuous duty	1250 psi intermittent duty
1500 psi continuous duty	2000 psi intermittent duty
2000 psi continuous duty	3000 psi intermittent duty

Although the principal working parts of these pumps are interchangeable, the shafts, bearings, housings, and valve plates must necessarily be proportioned for the pressure service. In other words, it was not necessary when designing for higher pressures to decrease clearances or to add any parts or stages to the lower-pressure design. The addition of stages would naturally reduce the over-all efficiency by the introduction of additional parts, creating friction and other internal-leakage points.

The largest constant-delivery piston pump available, rated for 1500-psi service, which delivers 6.4 gpm at 3000 rpm cruising and at rated pressure, weighs 5 lb. The weight per gpm at rated pressure is 0.8 lb. This is a more favorable weight-performance ratio than for any other aircraft pump design of comparable capacity known to the author. The input is 6 hp under these conditions.

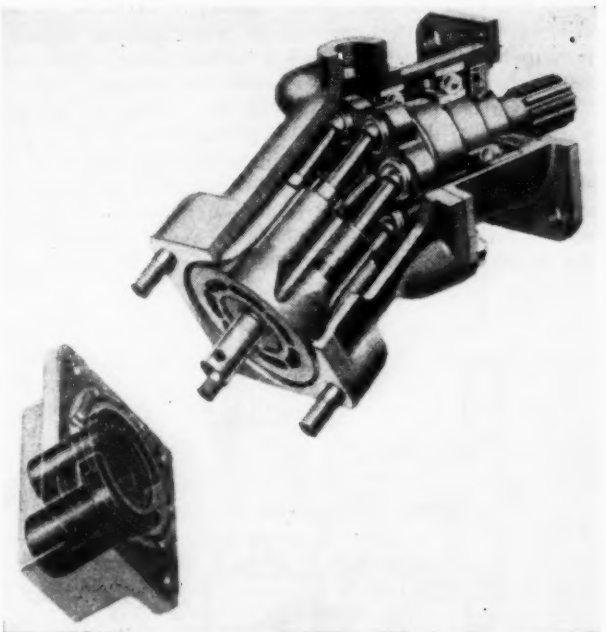

FIG. 3 VALVE PORTING IN CYLINDER BLOCK AND VALVE PLATES OF CONSTANT-DELIVERY AXIAL-PISTON PUMP

Another design of this pump, rated for 2000 psi, is being used by one manufacturer intermittently on an accumulator circuit operating at 3000 psi. At the latter pressure the delivery is 6.3 gpm at 3000 rpm cruising, and the pump weighs 6 lb. The weight per gpm under these operating conditions is 0.95 lb.

The reduced running clearances on the piston-type pump, as

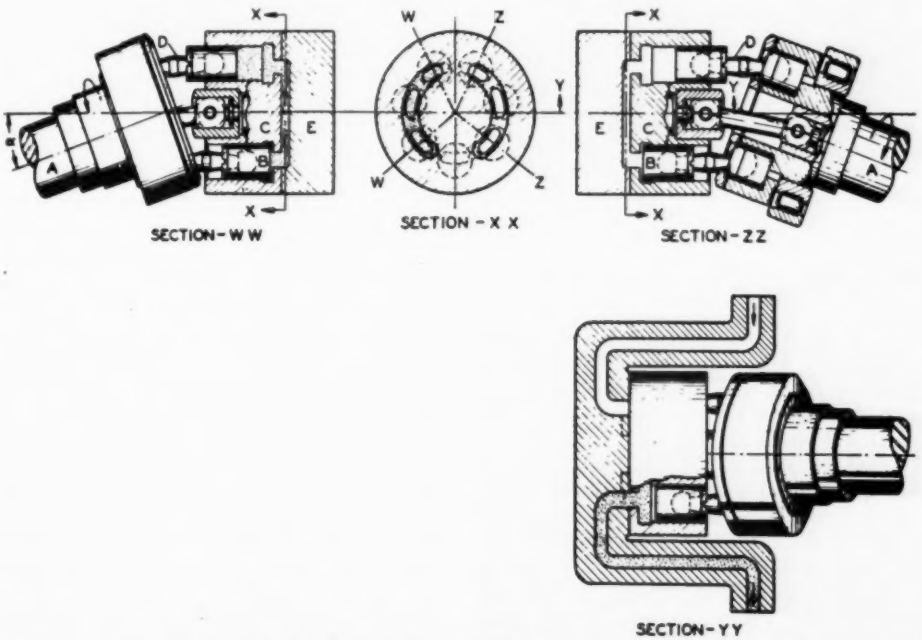

FIG. 4 OPERATION OF VARIABLE-DELIVERY TYPE OF AXIAL-PISTON PUMP

compared with the gear pump, materially improves its self-priming characteristics, particularly when starting against a pressure head, and when there is air in the system. This condition might be encountered in an accumulator circuit.

The variable-delivery version of the axial-piston pump is essentially like the fixed-stroke type, except that the angular position of the cylinder block can be changed relative to the shaft, while in operation. The degree of angle determines the amount that the pistons may reciprocate in their bores, creating suction during one half of the revolution and discharging during the other half, thus varying the delivery. By moving the

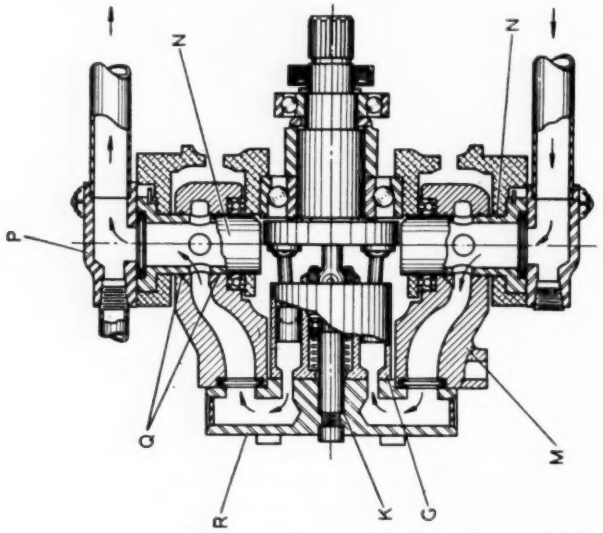

FIG. 5 CONSTRUCTION FOR SWINGING CYLINDER BLOCK TO OBTAIN VARYING VOLUME

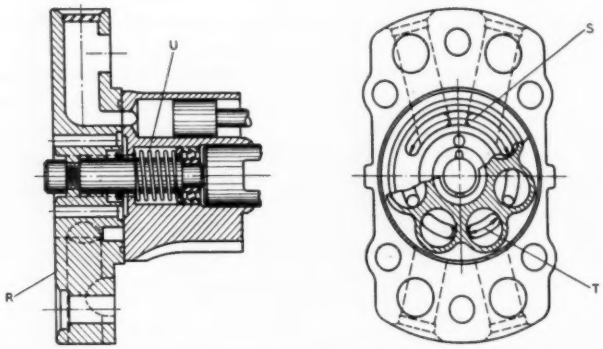

FIG. 6 DETAILS OF PORTING IN CYLINDER BLOCK AND VALVE PLATES OF VARIABLE-DELIVERY AXIAL-PISTON PUMP

cylinder block across the center, the direction of flow through the pump may be reversed. This latter feature is used to advantage on certain rotary drives such as are employed on gun turrets, where both directions of rotation are required. The operation of this pump is illustrated in Fig. 4.

The construction used for swinging the cylinder block to obtain varying volume is shown in Fig. 5. A yoke containing the stub shaft on which the cylinder block is mounted is supported on two stationary pintles, and ball bearings are inserted in the arms of the yoke to reduce friction to a minimum. The porting of the oil to and from the cylinder block through the yoke and pintles is indicated by arrows. Flanges mounted on the pump housing, which is not shown on this schematic drawing, sealed by neoprene Vickerseals, retain the pintles and contain the connections. Circular seals are inserted into the yoke arms, and pressure is applied to their outside diameters to insure a minimum of leakage between the swinging yoke and the pintle.

Fig. 6 shows further details of the porting in the cylinder block and valve plate.

Several methods of controlling the flow from these variable-delivery pumps are used in production. The first consists of a mechanical linkage, by which the operator can vary the delivery of the pump by moving a lever or cam. A hydraulic servo or power booster is sometimes introduced between the linkage and the pump yoke, to minimize the manual effort. The latter control is also used in conjunction with syncromotors for remote electrical control and is employed on armament equipment.

The method commonly employed on engine-driven pumps is the self-actuated pressure compensator. This in its simplest form is a spring-loaded piston connected to the yoke, which normally holds it in the maximum displacement position, whereby, with pressure connected from the discharge of the pump acting on the piston, it overcomes the spring load and strokes the pump to the neutral position. Such a control causes the delivery to vary approximately inversely with the pressure. The conventional control of this type requires a heavy spring for high pressure and smooth operation and becomes quite bulky. Besides, on most installations the change from full pump volume to zero stroke must be accomplished with a minimum pressure differential, say, from 1500 to 1700 psi. This makes a practically constant pressure available to the system regardless of pump delivery. To accomplish this a compact pilot pressure-controlled device, providing convenient pressure adjustment has been designed, which insures accurate smooth regulation within the desired range. The differential rate generally employed is from 100 to 200 psi. This control is designed so that two or more pumps can be operated in parallel on the system, and each will supply its portion of the variable demand. With this type of control, and all valves in the system closed, resulting in no demand, the pump will maintain a constant preadjusted pressure, pumping only sufficient volume to compensate for slip within the pump itself, and in valves which are exposed to pressure.

Pumps of this general type for 1500-psi 15-hp service were first furnished to an aircraft manufacturer in 1939, and are now available for applications requiring maximum pressures from 800 to 2000 psi. Pumps furnished for 1700 psi have a maximum displacement of 1.518 cu in. per revolution, providing 25 gpm at 3750 rpm, during take-off, and 19 gpm at 3000 rpm, when cruising. The maximum input approximates 28 hp, and this unit weighs 25 lb.

SELECTION OF PUMPING EQUIPMENT

When selecting a hydraulic pump for a new design, the engineer must first consider the total hydraulic horsepower to be transmitted in terms of the formula previously mentioned. The two factors entering into this equation are the maximum pressure for which the system is to be designed, and the maximum displacement required for the limiting operation, which on many installations is that required to operate the landing gear. The pressure selected is generally determined by the size of the ship, taking into consideration weight and availability of the pump and all other accessories used in the system, such as unloading valves, relief valves, accumulators, hydraulic fittings, tubing, etc. The average pressure in use today would fall somewhere between 1000 and 1500 psi in production aircraft, but the tendency on new designs is to consider higher pressures. One manufacturer has designed a satisfactory system, functioning to a maximum pressure of 3000 psi. The power-driven pump must operate intermittently at this pressure, as a conventional unloading-valve and accumulator system is employed, requiring

that the pump obtain this maximum pressure only while charging the accumulator.

Rather than attempt to take sides in a controversial matter, the author prefers to point out the features which favor the use of higher-pressure systems and those substantiating a more conservative viewpoint, which would approach the matter of higher pressures more gradually. The arguments advanced for higher pressures are that they will permit the use of smaller sizes of tubing and fittings, as well as valves, cylinders, pumps, and hydraulic motors, resulting in considerable weight saving. Such savings will obviously add to pay-load capacity and also allow steel fittings at many points, thereby increasing ruggedness and decreasing bulk.

On the other hand, experience with systems of this type is at present somewhat limited and the necessary auxiliary equipment required for a complete system is not available to the same extent as for lower pressures. Closer manufacturing limits will be necessary in order to obtain the fits required in certain of these accessories, thereby in some cases increasing manufacturing costs. Control valves of the type that meter or throttle the oil flow for control purposes will present more of a problem because of the smaller sizes of the orifices necessary to obtain nicety of operation; and lint and other foreign substances in the system will become more critical in valves of this type. More consideration will have to be given to distortion of valves and other portions of the system resulting from pressure changes. The combination of vibration and high pressures will present difficulties in maintaining seals at fittings and flange joints of the respective units incorporated in the system.

The foregoing represents an unbiased viewpoint since the author's company manufactures certain equipment for systems falling within this range of pressure. It would, however, seem that any transition should be along conservative lines.

In the case of hydraulic circuits on machine tools on which we have had broad experience, the maximum pressure used approximates 1000 psi, as on this class of equipment nicety of control on fine feeds and reversal together with long life are the paramount considerations.

Another design problem which must be considered is whether or not a constant-volume pump, which is generally used in conjunction with an accumulator system, or a variable-volume pump should be used. In making this choice, the engineer should take into consideration the equipment which is hydraulically actuated by the circuit.

The majority of military and transport ships now in production employ the constant-delivery pump, with an accumulator suitable for supplying intermittent high demands and also providing a source of pressure for the brakes when the plane is on the ground and the engines are not running. Our observations are that such a system is most desirable on installations requiring intermittent hydraulic demands in flight. Most of the unloading-valve systems at this time function only during take-off and landing, and the remainder of the time the accumulator remains charged and the unloading valve cut out. During this time the pump will circulate freely to the reservoir during flight, unless there is an occasional demand, or some leakage from the accumulator portion of the system, in which case it may require intermittent recharging from the pump. The equipment operated from a system of this type generally includes: landing gear, flaps, oil coolers, wing floats, cowl flaps, power brakes, bomb doors, and wing-folding operations.

The use of a variable-volume pump would on such installations only eliminate the unloading valve and possibly the accumulator from the main system. Therefore, it would not offer any great weight saving or other economy.

The constant-delivery pump on such a system is subject only to intermittent service at system pressure, which is a desirable feature, as it tends toward long pump life.

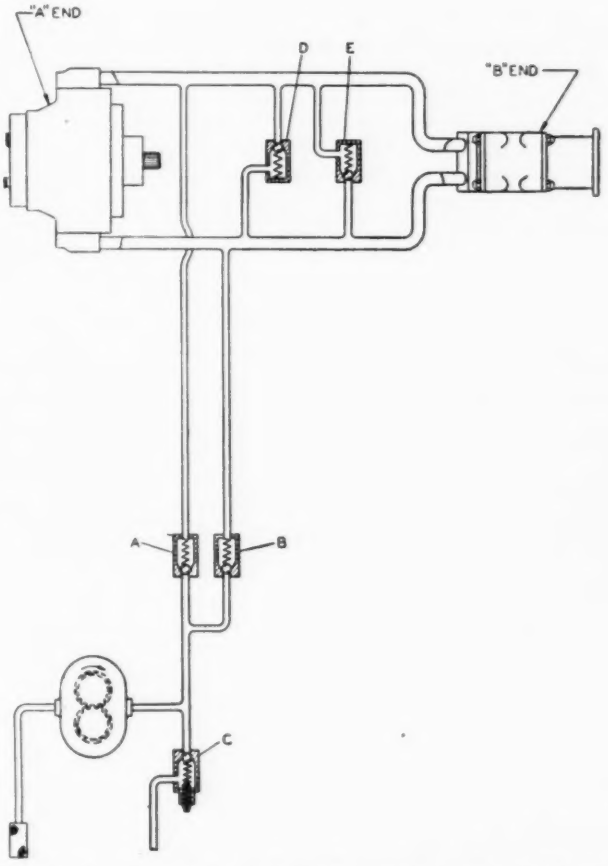

FIG. 7 VARIABLE PUMP AND FIXED-DISPLACEMENT PISTON MOTOR COMBINED IN LOCKED CIRCUIT FOR CONTROL OF ARMAMENT EQUIPMENT

The repeated stressing and relieving from pressure in the lines between the pump and unloading valve introduces some line shock and fatigue in this portion of the circuit. This becomes more pronounced at higher pressures. A properly designed unloading valve, however, minimizes this objectionable feature.

The variable-volume pump is gaining more acceptance on the larger-plane designs, where larger volumes of oil are required, and there is a continuous varying demand for hydraulic power during flight. Another feature of the variable-volume pump is that it will supply a system requiring a constant maximum volume in flight, irrespective of engine speed. The pump will operate at relatively short stroke during take-off, but at maximum stroke while the engine is idling, so that its delivery will remain constant throughout the normal operating speed range of the engine. Some of the controls which favor the use of the variable pump are (1) power boosters for control surfaces; (2) cabin supercharger drives, using hydraulic motors; (3) fan drives, employing hydraulic motors; (4) turret drives; (5) constant-speed accessory drives.

It is obvious on hydraulic circuits with the operations listed, that the steady usage would cause the unloading valve on a constant-delivery system to operate frequently in flight, and the pressure surges might introduce complications within the power-booster system, for example. The maintenance of steady pressure with a variable pump that would adjust itself to demands is conceivably better for such an installation.

The sensitivity of control, combined with reversible flow without a dead spot, made possible with the variable pump and fixed-displacement piston motor offers decided advantages for the operation of armament equipment. An infinite range of speed control, relatively unaffected by varying loads, due to the position of the guns in the slip stream, from the slow rates necessary for tracking the target to high slewing speeds, is possible with such a system. A typical locked circuit of this type is shown in Fig. 7. Control of this type is used on turrets in "Flying Fortresses," on various antiaircraft mounts, tank turrets, and in the largest gun turrets on ships. The low moment of inertia characteristics of the hydraulic motor and its corresponding high torque for a minimum of weight combine to make this type drive ideal for this service.

As a summary, it would be apparent that each design or type of construction has merit in one or more applications, and full consideration must be given to the circuit before selection is made.

The Modern Hydraulic Reservoir: How It Provides Micron-Range Filtration and Pump Supercharging

By W. W. THAYER,[1] LOS ANGELES, CALIF.

At the present time, the term "high pressure," with reference to aircraft hydraulic systems, means 3000 psi. Successful design of such systems, now in quantity production by the author's company, depends upon careful consideration of details, rather than upon the adoption of any features that might be classed as unorthodox. For instance, detailed attention has been given to an improvement in service life of certain hydraulic units whose operation depends upon close-fitted sliding parts. This consideration, resolving into a study of methods for combating abrasion and cavitation, has led to the development of a filter for the removal of particles as small as 10 microns, and a simple arrangement for reducing pump cavitation by building up a supercharging pressure in the hydraulic-system reservoir.

WHEN contemplating the design of large airplanes, almost without exception, the aircraft designer is thinking in terms of high pressures for the hydraulic system that will operate landing gears, bomb doors, wing flaps, and other services. It has become traditional in the aircraft industry to refrain from defining the word "large," as applied to airplanes. However, "high" as applied to hydraulic pressures, means, at least for the moment, 3000 psi. This is twice as high as the next highest pressure in common use.

The author's company has been the first to go into quantity production of airplanes with 3000-psi hydraulic systems. Obviously, the higher pressures yield major savings in weight and space. Experience has been that design practices for the higher pressures are consistent with the same fundamental principles that have been well established at low pressure. It has not been necessary to resort to any engineering trickery to make high-pressure systems work, but painstaking attention to design detail has been essential.

Improving Service Life of Hydraulic Units

As an example of design detail, this paper will describe the work that has been done toward improving the service life of hydraulic units, which, because of some specialized function, depend for leakage control upon close-fitting sliding contact between metallic parts, rather than the well-known V-ring or O-ring packings. Common examples of such units are pressure regulators, surface control booster valves, wing-flap synchronizers, constant-flow valves, and piston pumps.

Such hydraulic units are subject to wear because abrasive particles find their way into the hydraulic fluid, despite all practical precautions. Contamination may result from the natural wear of metal parts, from the flaking-off of protective plate, from dust sucked in as the reservoir breathes, from machining chips or free abrasives remaining in parts after washing, from particles broken loose by screwing in fittings, flaring lines, and tightening connections, from attaching the system to portable test stands that may have accumulated dirt, from dirt that enters past piston-rod packings or when filling the reservoir with oil, from blowing out tubing with an air hose, etc.

In addition to the effects of abrasive wear, deterioration of pumps may be accelerated by prolonged operation under conditions of cavitation. Sizable pits frequently occur where least desired, even in steel parts that have been hardened and ground. Furthermore, torque pulsations in a pump, running under cavitating conditions, may lead to the serious consequence of drive-shaft fatigue failure.

A typical aircraft hydraulic-pump installation is illustrated in Fig. 1. (A fixed-displacement pump is shown, rather than a variable-displacement type, due to the rather limited application of the latter in aircraft up to the present time.) The pump runs whenever the engines are running. As long as there is sufficient pressure in the "accumulator" to hold the "pressure regulator" in the by-pass position, the discharge from the pump is returned directly to the reservoir, at essentially zero pressure. Whenever the accumulator pressure falls, as it does whenever a hydraulic-operating cylinder begins to move, the pressure regulator acts to divert the pump discharge into the power system.

In the unloaded condition, the torque pulsations in a cavitating pump are probably less severe than if it were loaded, but the forces tending to cause pitting are undiminished.

Various changes were necessary to free the ordinary hydraulic system from the effects of abrasion and cavitation. It was the development of these protective measures which brought the commonplace hydraulic reservoir out of obscurity and into the center of interest.

There are few units in the hydraulic system which give the service mechanic, the design engineer, or the test pilot the same feeling of self-confidence as that engendered by the hydraulic-system reservoir. Everyone, with the possible exception of the weight engineer, casts a friendly eye on its bland, rotund exterior. They know that it is nothing but a hollow sheet-metal shell, conceived according to easily applied formulas set forth in Army-Navy specifications; so much foam space, so much basic volume, so much hand-pump reserve, etc. The reservoir has consistently been the one item in the hydraulic system which could be identified, and thoroughly understood, without the aid of a schematic diagram.

During the last year, even reservoirs have "gone modern;" incorporating a built-in filter working in the micron range, and air injectors for automatic self-pressurizing. The modern reservoir has acquired, as service mechanics found if they unscrewed the filler cap without heeding placarded instructions, a literal, as well as a figurative, "air of mystery."

By the time the first of these super reservoirs was actually installed in an airplane, the filter, originally designed solely for dirt removal, had become so important that the pumps could

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

scarcely operate without it, and the automatic self-pressurizing device was serving an auxiliary function that alone would have justified its inclusion in the hydraulic system.

Analysis of Filter-Performance Requirements

About 3 years ago, a search was begun to find a filter suitable to protect hydraulic units for 3000-psi systems. In most cases, these units already employed the hardest practical materials, to minimize the effect of abrasive particles. After more than a dozen filter vendors had been contacted, it was obvious that no one had made a thorough analysis of the requirements of such a filter. The problem resolved itself into the following four highly controversial questions:

1 Where should the filter be located in the circuit?
2 What size are the finest particles it must remove?
3 What flow resistance or how large a filter could be tolerated?
4 How long a life could be reasonably demanded, or what service or maintenance responsibilities must be accepted?

There were several possible answers to the question as to where the filter should be installed, as follows:

1 A single filter, through which all the oil must pass before reaching the pumps, would provide the best protection for the entire hydraulic system, provided that it removed small enough particles. The original prospects of obtaining a suitable filter for this location seemed remote indeed, since the location combined the maximum flow rate found anywhere in the system with the minimum amount of pressure available to force oil through the filter. Actual flow rates reached as high as 30 gpm, in the particular airplane for which a filter was immediately required, while even the most optimistic estimates allowed no more than 2 psi to force this amount of oil through the filter, at 70 F, if the hydraulic pump had to provide the necessary suction. Actually, as will be shown later, when the need for pump supercharging is discussed, even this amount of pressure was not available. Since the maximum flow resistance of the filter was to be no more than 2 psi, and since flow resistance increases as the filters accumulate dirt, the resistance of a new clean filter was limited to something on the order of 1 psi. Furthermore, in order to conserve space and reduce weight to a minimum by the elimination of a separate housing, the size of such a filter was arbitrarily limited by the largest object that could be conveniently taken in and out of the hydraulic reservoir under consideration, this being a cylinder about 6 in. diam and 9 in. long.

2 The finest practical filter, with an acceptable flow resistance, could be located ahead of the pumps, and as fine a filter as necessary could be located ahead of each one of the critical units, where flows were relatively low. This arrangement sacrifices a certain amount of protection for the pumps, where it is vitally needed, requires more maintenance, and is contrary to the present emphasis on standardization, because of the wide range of flows and operating pressures which must be accommodated.

3 Another alternative consists of installing a by-pass-type filter at any convenient point in the system, such as the regulator return line. This system obviously offers less protection against abrasive particles than either of the other two systems.

Evaluation of Critical Particle Size

Before making a choice of one of these three installations, it was necessary to determine the smallest dirt particle that it would be advisable to remove. A large number of simple slide valves (as shown in Fig. 2), with 0.0003 to 0.0005 in. initial diametral clearance were built and wear-tested. The wear tests consisted essentially of cycling the valves, while oil containing a known percentage of a known size abrasive passed through them.

A simple hydraulic system was proposed for the cycling test. The slide valve was located between two reservoirs, and oil forced back and forth between them by applying air pressure alternately to one reservoir and then to the other. The need for a filter in an airplane hydraulic system, with hundreds of feet of tubing and dozens of valves and cylinders, was strikingly demonstrated by the troubles experienced when this simple arrangement was used in an initial run to establish a reference datum for operation under supposedly ideal conditions, with clean parts and new oil. It was found to be impossible to operate the valves even a few thousand cycles without scratching.

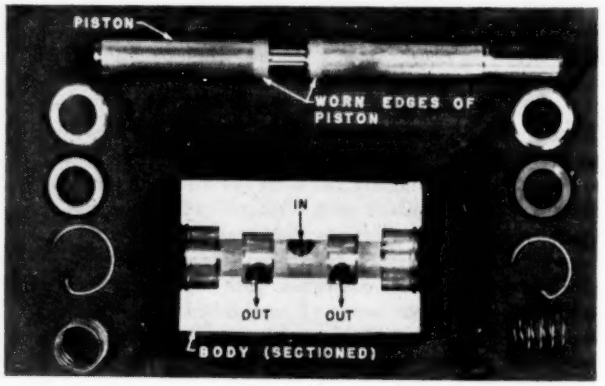

Fig. 2 Construction of Typical Valve Used to Evaluate Critical Particle Size

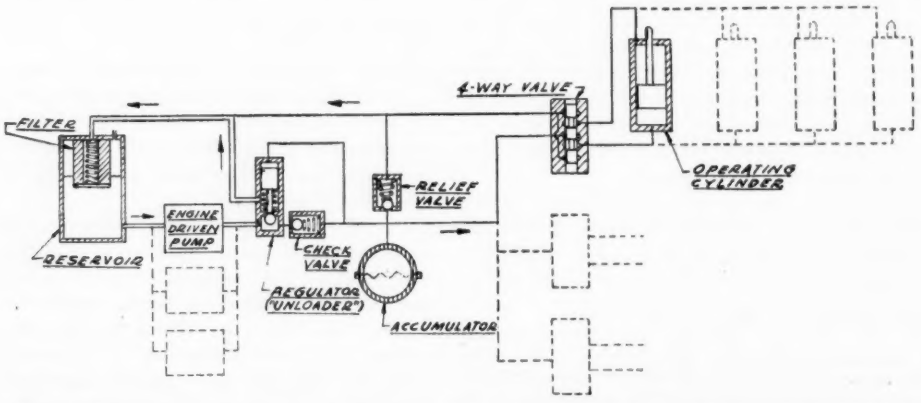

Fig. 1 Schematic Diagram Showing the Basic Parts of an Aircraft Hydraulic System

Finally, after a number of unsuccessful attempts to clean the system thoroughly, a slide valve was operated with only standpipes full of oil at each port. When this valve did not scratch, it was evident that scratching was not inherent in the valve itself, as it was almost beginning to seem, but must be due to dirt.

In slightly revised form, this simplified system was used to test the relative rates of wear of seven grades of abrasives, having nominal sizes ranging from 3 to 58 microns. A micron (μ) is 0.000001 meter, and 1 μ-in. is 0.000001 in., so that 1 μ is 39 μ-in. It is an interesting side light that the very character of the word "micron" may have been responsible, in no small measure, for the success of the entire development program. The filter manufacturers were quick to realize that something about the word attracted popular attention; its applicability to future advertising may well have mitigated the usual difficulty in obtaining research funds necessary for this type of work. Now, after three years, the word is widely used throughout the aircraft hydraulic industry, symbolizing a distinct change in the concept of satisfactory filter performance.

All the abrasives used in the test program caused some change in the valves, but there was a tremendous difference depending upon the particle size. From a study of the leakage measurements, wear measurements, and appearance of the pistons, some of which are shown in Fig. 3, it was decided that all 10-μ-size particles should be removed, and as many as possible of the 5-μ size. Indications were that particles as small as 1 μ would not be very serious.

In order to obtain some idea of the amount of dirt that a suitable filter must be capable of absorbing, the dirt content of several samples of hydraulic fluid that had been in service for 1000 hr was measured. From this it was estimated that the filter should be capable of absorbing 2 or 3 cu in. of dirt before requiring service or replacement, on the basis of service periods not more often than every 2000 hr flying time.

Thus the requirements for the type of installation in which all the oil is filtered each time it flows through the reservoir may be summarized by the following:

1 Remove all particles larger than 10 μ.

2 Pass 30 gpm at 70 F, with 2 psi pressure drop, after collecting 3 cu in. of dirt.

3 Occupy a space no larger than 6 in. diam × 9 in. length.

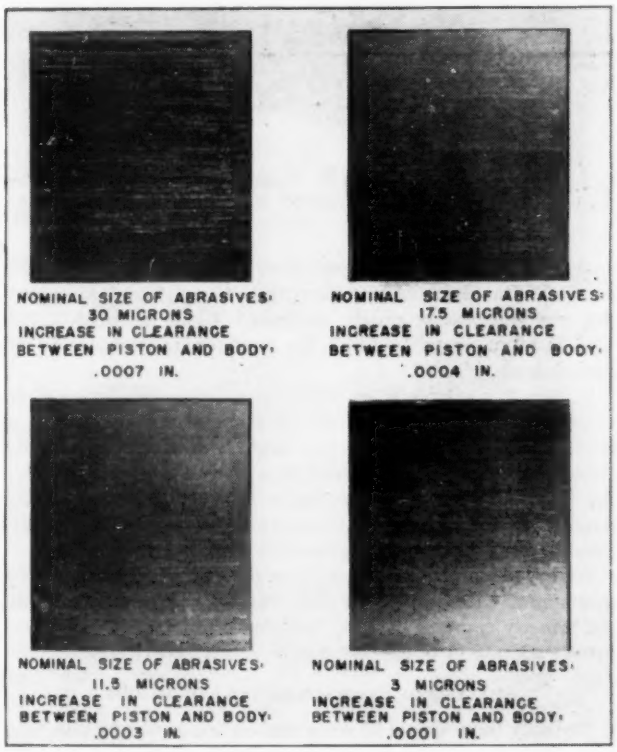
These requirements are so difficult to meet that for a long time it was necessary to maintain active interest in the other types of filter installations that have been mentioned, so remote did it seem that any satisfactory filter of the type 1 would be found. The first thing that was brought out by detail tests on various filter media, particularly felt and paper, was that a tremendous surface area would be required for such a filter, and that the thicker the filter medium, the greater would be the required area. This narrowed the field to the use of paper, or some other very thin filter medium, for in no other way could so much area be built into such a small space.

The problem of the filter manufacturer then became one of arranging the paper in the best possible manner. If too much paper is used, the internal passageways will become too small and tortuous, and may perhaps clog up, shutting off large areas of the filter. If too little paper is used, the flow rate per unit area will be high, and so will be the pressure drop. As the result of considerable development work, several successful designs are now available.

Approval of the retentivity of the filter papers used in these designs was granted after tests using the same graded abrasives that had been used for the wear tests.

Measurement of Filter Flow Resistance

The measurement of flow resistance through such a filter proved to be a more interesting matter than had been anticipated, for it was here that the filtering and pumping problems became interwoven. In the first place, the flow rate into the particular reservoir for which this filter was originally designed is quite high, amounting nearly to 5 changes per min. The reason for the high flow is that airplane operators feel it is well worth while to be able to retract the landing gear in a matter of seconds, and, in this case, 45 hp is available for the purpose. At 3000 psi, this requires a flow of about 25 gpm. (When this figure is compared to the 75 gpm that it would take to do the same work at 1000 psi, the reason for widespread interest in high-pressure hydraulic systems is obvious.)



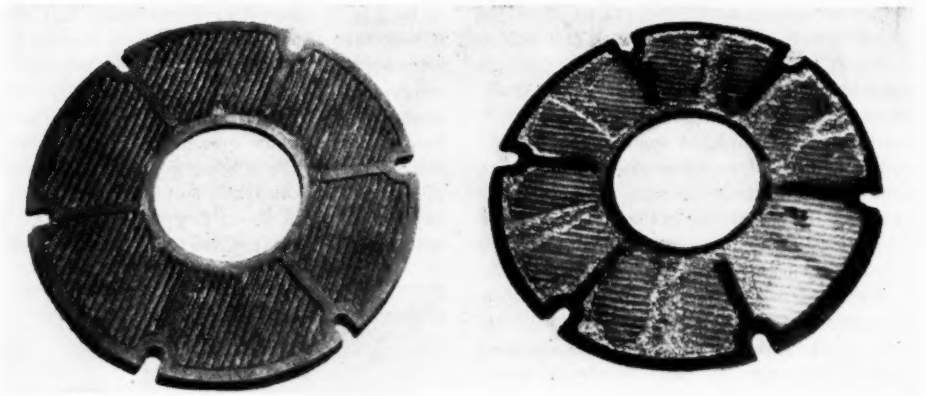


Fig. 3 Partial Summary of Wear-Test Results

It had been the original intention to discharge the return oil into the reservoir tangentially, and suck it out to the engine-driven pumps through the filter. When an attempt was made to measure the flow resistance of the filter using this arrangement, it was not only impossible to obtain accurate readings, but the energy in the return oil was sufficient to set the entire content of the reservoir in rapid rotation, promoting so much air entrainment and foaming that it was virtually impossible for the pumps to operate. A number of modifications were tried without success. Finally, the filter was utilized as a diffuser, through which the oil was discharged into the reservoir. In this case, instead of entering tangentially at 30 fps the oil entered radially with a velocity of less than $^1/_2$ fps. This arrangement effectively eliminated all troubles due to foaming.

In addition, this revised installation yielded a particularly accurate means for measuring flow resistance of the filter. A hole was simply tapped into the unfiltered oil region, inside the filter, and a standpipe extended up from it. Oil was circulated through the filter at the required rate, and the pressure drop was determined by measuring the height of the oil in the standpipe, above the oil level in the reservoir. By injecting measured

(*a*) (*b*)

FIG. 4 SAMPLE FILTER DISKS; FILTER ASSEMBLY CONSISTS OF MANY SUCH DISKS
(*a*, Shows amount of dirt collected during 1000 hr of service in an airplane. *b*, Shows amount of dirt collected during test without causing objectionable flow resistance.)

amounts of dirt into the oil just ahead of the filter, the dirt capacity of the elements was investigated, and found to exceed the requirements originally estimated. This completed the final tests necessary to fulfill the predetermined standards of performance.

In Fig. 4, a sample filter disk from a laboratory-tested filter is compared to a disk, obtained at a much later date, from a filter assembly with 1000 hr of aircraft service. The ample dirt-storage capacity of the design is obvious. Unfortunately, the illustration does not emphasize the fact that, despite its relatively clean appearance, the service-tested disk has actually caught a large number of dangerous dirt particles.

While the completion of these filter tests provided considerable reassurance with respect to slide valves, where abrasion was the primary cause of concern, additional problems were anticipated with respect to the piston pumps, due to cavitation.

ANALYSIS OF PUMP OPERATING CONDITIONS

Probably there should be some explanation as to why pumping problems still exist, after airplane hydraulic systems have been built for so many years. For example, operators are demanding satisfactory operation at higher altitudes, and more hydraulic operations are being required at altitude conditions. Whereas, the commonest employment of the hydraulic system has hitherto been landing gear and wing-flap operation near airport levels, now surface-control boosters, turrets, bomb doors, etc., find frequent use at service ceiling. Even if the hydraulic pumps are running unloaded, injurious cavitation may occur at high altitude, at low temperature, or at high pump speed. Furthermore, the trend to larger airplanes moves the pumps farther and farther away from the hydraulic reservoir, perhaps 30 to 50 ft. It is frequently impossible to locate the reservoir higher than the pumps, and the line connecting the reservoir and pump must be kept as small as possible to reduce weight and facilitate installation.

Operation of pumps under conditions of cavitation can be dangerous in at least four different ways. If carried to the extreme, the hydraulic system will be rendered useless because of lack of oil supply. Before this condition is reached, pump efficiency may fall so low that overheating and seizure may result. As an even earlier effect, the extreme vibration attendant upon partial cavitation may cause fatigue failure of the pump shaft. Still another effect is the formation of small pits frequently in parts which must remain smooth for sealing purposes.

Sufficient study has been made of the pressure losses between reservoir and pump to conclude that some form of supercharging is justified from the weight standpoint, and is the only answer for high-altitude operation.

The minimum allowable absolute pressure in the hydraulic-system reservoir is essentially the sum of the following major pressure losses:

1 Line loss, plus the difference in head between pumps and reservoir.
2 Valve-port loss, getting the oil into the pump cylinder.
3 "Unavailable pressure," due to vaporization of oil and to dissolved or entrained air.

If atmospheric pressure at the altitude of flight does not exceed the sum of these losses, cavitation will exist unless supercharging is provided.

It is not necessary to determine the magnitude of these losses with scientific accuracy in order to determine which factors are most important from the standpoint of making a general improvement in pump operating conditions.

SURVEY OF PRESSURE LOSSES ON INLET SIDE OF A PUMP

Line loss may be readily calculated from well-known and reliable formulas, which are further simplified because the calculations of interest usually fall in the laminar-flow range. Such calculations show that the use of larger lines to reduce pressure loss is extremely limited and costly. The use of the next size larger lines in one particular airplane would involve a 23-lb increase in weight, and save only slightly more than 1 psi line loss at 70 F, or, if viewed from the temperature standpoint, would permit operation with oil about 20 deg F lower in temperature. Temperature has such a tremendous effect on line loss that it is impossible to take care of very cold oil by increasing line sizes. Fortunately, the flows are usually low when the oil is cold, because under these conditions the main engines, which drive the pumps, are likewise cold and must be run slowly. As the engines warm up, the oil may be expected to warm up also, due to the friction of circulating it through the lines. Of course it is always possible to provide additional resistance in the circuit, if necessary to accelerate warm-up, at the expense of adding a thermally controlled relief valve.

Losses through the various expansions and contractions at the inlet to a pump cylinder may be approximated using formulas and coefficients available in any hydraulics textbook. It requires a bit of optimism to trust such calculations to any great

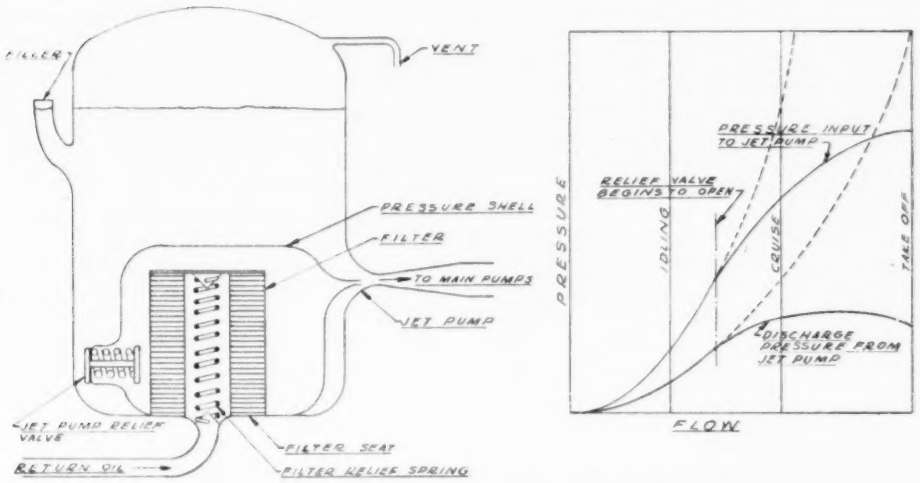

FIG. 5 JET-PUMP METHOD OF PUMP SUPERCHARGING; RESERVOIR UNPRESSURIZED

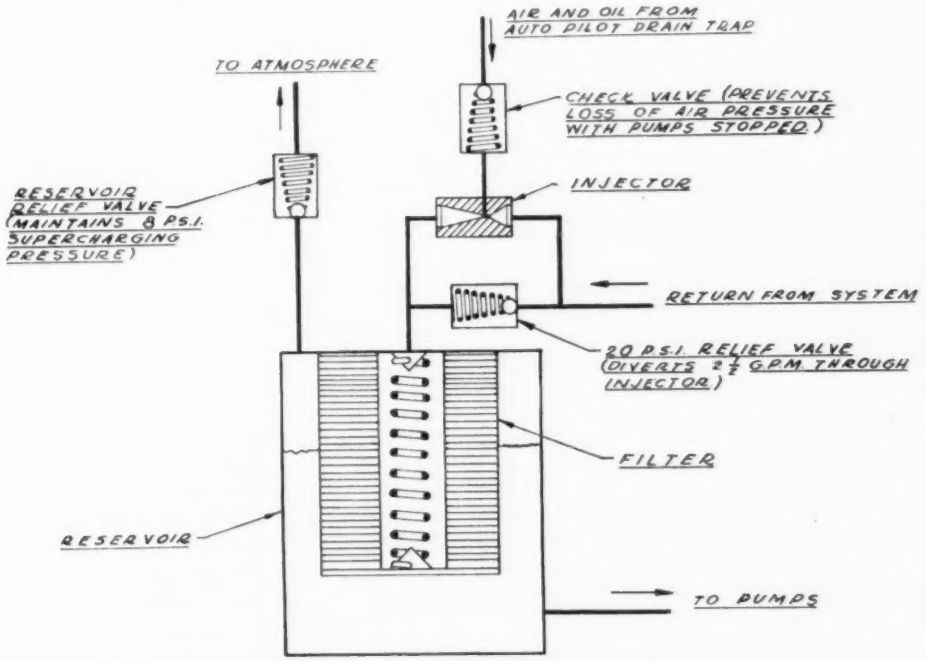

FIG. 6 AIR-INJECTION METHOD OF PUMP SUPERCHARGING; PRESSURIZED RESERVOIR

extent, because the resemblance between the passageways in the pump and those in the textbooks is rather remote. Furthermore, there is a surprising lack of agreement among texts as to the coefficient for sudden contractions under ideal conditions. The calculated losses for one particular pump amounted to 2.7 psi, which, when added to the other calculated operating losses, yielded a total that was quite closely confirmed by test. This restored a measure of confidence in these methods, which, if correct, bring out the point that even if the port losses could be cut in half the increase in safe operating altitude would be small.

The loss due to oil vaporization is in a similar category. It is probably impractical to effect any improvement, but, before making such a decision, it is necessary to have some idea as to what the magnitude of the loss might be. The fact that some oil actually turns into vapor in a pump chamber is substantiated by an observed decrease in volumetric efficiency, above a critical speed, for a positive-displacement pump, operating at constant discharge pressure. Since the pump chambers are not running full of oil, the remaining space must be occupied by vapor. This would seem to indicate that an extremely low absolute pressure is reached in the pump, since one vendor of hydraulic fluid quotes a vapor pressure as low as 5 mm of mercury at 175 F. However, this vapor-pressure figure may be very misleading, because oil, being a mixture of hydrocarbons, has no fixed boiling point.

Vapor pressure is frequently measured by allowing the liquid to vaporize until it fills a space several times as large as the liquid volume. In pumps, the vapor volume becomes important while yet a small fraction of the liquid volume. For this reason, the vapor pressure of interest to aircraft hydraulic engineers is not the vapor pressure that is likely to be quoted in good faith by a chemistry laboratory.

When this point was investigated further, measurements of the gas volumes developed from hydraulic fluid, maintained at

150 F, and a vacuum of 25 in. of mercury, until gassing stopped, yielded a value nearly equal to one half the liquid volume. In a hydraulic pump, the liquid has only an instant to flash into vapor, so that there is an additional factor, time, of unknown importance. Furthermore, no line has yet been drawn to define the critical ratio of gas to liquid volume. The one item which has been established is that the pressure rendered unavailable to the pumps, due to oil vaporization, is of the order of 5 in. of mercury, rather than 5 mm.

If this figure of 5 in. of mercury is accepted as the minimum absolute pressure normally attainable in the cylinder of a pump handling hydraulic fluid, then the importance of entrained or dissolved air becomes greatly minimized. For instance, the fluid would have to contain 14 per cent air, by volume, at sea-level pressure, in order to amount to half air and half liquid at 5 in. of mercury abs. However, if the pressure could fall to 5 mm of mercury abs, it would take less than 1 per cent of air at sea-level pressure to reach this same ratio.

When all of the foregoing losses are considered, it is apparent that the volumetric efficiency of the pumps on an airplane would begin to decline, well below the service ceiling demanded by current airplanes, even if the pumps were mounted in the hydraulic-system reservoir.

No one is prepared to say how low a volumetric efficiency is safe for continuous operation, but there is obviously no reason to take chances, if a supercharging pressure can be readily obtained.

Methods of Pump Supercharging

Various systems for boosting the inlet pressure at the engine-driven pump have been suggested, but most of the obvious ones can be discarded because they involve moving parts, or make the reliability of the hydraulic system depend upon the reliability of some other apparatus that is relatively complicated. The author's company has developed a satisfactory arrangement using a jet pump, Fig. 5, but this was not selected, because another method is available which pressurizes the reservoir with equipment that is already required to perform another service.

The system finally adopted, Fig. 6, employs a simple Venturi, which, acting as an air injector, builds up a pressure of about 8 psi in the sealed hydraulic-system reservoir. In addition, it serves to inject into the reservoir the hydraulic leakage from several unpacked lap-fitted slide valves that are component parts of the autopilot system. The latter function requires the Venturi to provide a subatmospheric pressure at the autopilot drain connection, at all times when the engines are running; that is, the Venturi must never stall, either because the reservoir pressure becomes too high for it to pump against, or because the fluid flow through it is reduced.

In order to insure that stalling can never take place, it is necessary to provide the Venturi with a flow that is never less than a predetermined minimum, and set the reservoir relief valve, which governs the pressure against which the Venturi is pumping, at some pressure less than that which the Venturi is capable of producing, when supplied with minimum oil flow. The flow provision is a simple matter. Whenever the engines are running, oil is circulated through the reservoir. It is only necessary to add a spring-loaded valve in the reservoir return line, and locate the Venturi in parallel with it. Since too much air added to the oil tends to defeat the basic purpose of the system, which is, of course, to force solid oil into the pumps, it is wise to design this spring-loaded valve so that its resistance is essentially independent of flow, and thus introduce no more air into the oil than is absolutely necessary.

The rate of introducing air was chosen so that the supercharging system would maintain sea-level pressure in the reservoir, if the airplane took off with an initially unpressurized reservoir and climbed directly to its service ceiling. Ordinarily, the reservoir will never be unpressurized, because a check valve in the air-inlet line prevents the escape of pressure back through the Venturi when the engines are stopped.

Every pound per square inch of pressure in the reservoir is purchased at the expense of about 3 times that much "back pressure" on the oil returning to the reservoir; that is, the nominal setting of the spring-loaded valve which controls flow rate through the venturi is roughly 3 times the minimum amount of supercharging pressure that is provided. This additional pressure is expended in overcoming the resistance of the check valve in the air-inlet line, in overcoming pipe friction, venturi inefficiency, and pressure loss through the filter, and in providing a margin for tolerance on the pressure settings of the reservoir relief valve and the valve controlling venturi flow rate.

Each major unit in the hydraulic system has had its share of notoriety in past years; the power brake valves, pressure regulators, accumulators, surface-control boosters, brake de-boosters, emergency air valves, 3000-psi pumps. It is truly a fitting reward for loyal service that the lowly and obscure hydraulic reservoir, now with built-in pump supercharging and micron-range filtration, at least achieves in some measure, the attention that has been accorded its associated units.

Aircraft-Engine Temperature Control

By WILLIAM A. RAY,[1] GLENDALE, CALIF.

Exposed to variations of as much as 200 deg F in ambient temperatures over short periods of time, the aircraft-engine temperature-control problem is a vital consideration of design and operation both of military and commercial aircraft. Weight, compression ratios, combustion rates, factors of safety, efficiency, ambient temperatures, and general operating conditions are all factors contributing to the necessity of controlling engine temperatures. The author undertakes an objective analysis of the problem and describes a system of hydraulic control which has been developed and which has proved satisfactory in service.

A PROPER appraisal of aircraft-engine temperature control should be based upon an objective view of the engine itself, its work load, and its surroundings, as compared with typical internal-combustion engines with which most engineers are familiar, either in stationary or automotive work.

The most obvious difference between internal-combustion engines and aircraft engines is that of weight; the former seldom being lighter than 5 or 6 lb per hp, whereas aircraft engines will average just over 1 lb per hp. Combustion rates and compression ratios are high on aircraft engines, whereas the factor of safety on mechanical stresses is generally low by comparison. On the heavier internal-combustion engines, high factors of safety on mechanical stresses are used to overcome those normal defects which occur in all mechanical structures but which cannot be economically sought out, at least up to the present time, on automotive or stationary engines. Aircraft engines necessarily light and safe from an economic standpoint justify extreme care in manufacture. There are no marginal factors of safety to cover these typical manufacturing defects. All aircraft engines must be normal or better.

On the operating side, aircraft engines also have their distinct differences. Over-all operating efficiency must be a maximum. Inefficiency cannot be tolerated since extra fuel would be required, thus seriously reducing pay load and cruising range, particularly on ocean flying where landing fields may not exist for 2000 or 3000 miles.

With the average internal-combustion engine employing customary cooling methods, it is usually impossible to operate at too hot or too cold a temperature from a safety standpoint. However, this can easily occur on an airplane, since any substantially fixed cooling arrangement, which may be used on most other engines, can never meet all conditions that occur on an airplane, with the result that an engine may get too hot, resulting in fire; or too cold, resulting in misfiring. The latter often occurs, particularly on military airplanes, when the need for maximum power exists, as, for example, when pulling out of a glide dive.

The aircraft engine is also subjected to wider ambient temperatures on the cooling medium than almost any other type of engine, it being quite possible to have changes in the temperature of the air medium through which the plane is flying approaching 200 deg. The effectiveness of this cooling medium is further complicated by the variation in speed of the airplane, most variations of necessity having no relation to the cooling needs of the engine.

Furthermore, from an operating standpoint, for the sizes of the engine involved or horsepower output, all airplane engines are warmed up faster than any other type, particularly on military planes which are subjected to widely variable and sudden load changes.

These questions of weight, compression ratios, combustion rates, factors of safety, efficiency, ambient temperatures, and general operating conditions have all contributed toward the necessity for control of engine temperatures. All these factors likewise accentuate the time function, requiring both responsive and watchful temperature control.

Analyzing the Engine-Cooling Problem

An objective analysis should include a scrutiny of the cooling job itself. There are normally three ways that heat may be dissipated from aircraft engines, two of which are always used depending upon the type of engine, that is, whether it is air-cooled or liquid-cooled. Both types dissipate a great deal of heat to the lubricating oil, in contrast with stationary-engine practice where little or no effort is made to dissipate heat through this medium. However, the design of aircraft engines for higher work rates makes it imperative to dissipate substantial amounts of heat through the lubricating oil. Thus the lubricating oil, distinctly a cooling agent and subjected to extremes of temperature may catch fire at one extreme, yet freeze to a solid at the other. This heat in the oil is usually dissipated through a radiator, the effectiveness of which is dependent upon the atmospheric conditions through which the airplane is flying. The air-cooled engine dissipates additional heat from cylinder walls or finned heads. Here again extreme temperatures may at one end result in loss of strength of the engine parts, and at the other end misfiring, because cylinder and head temperatures affect ignition. The liquid-cooled engine, originally using water as a coolant, now uses a chemical (ethylene glycol, commonly known as prestone) as a coolant, because of the more desirable properties of this chemical as compared with water. On a liquid-cooled engine this coolant collects that heat occurring at the cylinder walls and cylinder in the same manner as in the air-cooled engine. The coolant heat is then dissipated by a radiator in the air stream. Here again extremes of temperatures will result in engine failure or misfiring.

Hence it is important to control the air flow over these cooling elements, whether in the form of the lubricating-oil radiator, the prestone radiator, or the air-cooled engine cooling fins. This control is usually obtained by suitable flaps that permit or restrict the air flow. These flaps are desirably located around the engine, a point more often than not remote from the pilot's control, making it necessary to obtain some kind of a remote operation of the flap. Mechanical operation is not always satisfactory because of the work loads involved, and the difficulty of working the operating gear through the airplane structure. The result is that on most airplanes, a more flexible, outside, work-doing medium is used to power the flaps and secure remote control. Until quite recently, this remote control has been mainly manual. The pilot or flight engineer periodically checked engine temperatures and corrected the flap position as required.

[1] Chief Engineer, General Controls Company.

Contributed by the Aviation and Hydraulic Divisions and presented at the Semi-Annual Meeting, Los Angeles, Calif., June 14–17, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

Thus on the typical airplane, there has existed a means for operating the temperature flaps, so in order to secure automatic control, it has only been necessary to provide some automatic piloting method to control the operating medium. The sensitive thermal element of the automatic control is usually more accurate, minimizes the human element, and stays on the job at all times.

The ease with which automatic temperature control can be adapted to the usual flap-operating gear, also makes it possible, in most cases, readily to switch back to manual control for such occasions when only human perception can decide the best condition, such as for take-off, landing, or fast warm-up. However, if the ship has automatic controls sensing such functions, they can be made automatic as well. Thus if desired to minimize head resistance, as when taking off heavily loaded ships, flaps can be retracted more than usual; or when landing, when head resistance may be desirable, flaps can be opened more than usual.

Hydraulic Controls Developed

Development work, as done by the author's group, has hinged around hydraulic operation, as it was felt that this actuating medium was more reliable and more easily repaired, because of its mechanical simplicity and the ease with which faults in the system may be detected. Electric operation, lubricating oil under pressure, air under pressure or vacuum, and even direct thermal operation are possible alternatives. Direct operation, consisting of a thermal unit powerful enough to position flaps, is not practical for larger engine installations.

However, hydraulic operation as mentioned, is believed to be admirably adaptable to most temperature applications and readily lends itself to constant operation without destruction either to control valves or operating cylinders, has very few moving parts, and the weight is well in line. Hydraulic operation has further advantages in that in most cases of system failure, the flaps will fair or trail. Although maximum engine power is not always obtainable with faired flaps, and retirement from combat may be necessary, sufficient engine power is available for safe operation of the airplane. In fact, on most aircraft, the design is such that the flaps will fair or trail at cruising speed.

The selection of hydraulic oil as the working medium resulted in the initial development of a temperature control that is adaptable either to lubricating oil or engine coolant. This particular control is operated by a sensing element or thermal element of the liquid-expansion type. This element was selected because of its great work-doing possibilities, compared to other types of sensing elements, such as bimetal expanding or bending members, thermocouples, vapor-tension or gas expansion. A liquid element is particularly suited to aircraft work in that it is not responsive to altitude conditions; hence it holds its temperature calibration regardless of atmospheric pressure, provides a hard working force, and in general, does not require compensating means or glands. Development work has also overcome the slowness of response of this type of unit to a point at which it is comparable, for example, with bimetal immersed directly in the fluid.

This liquid-charged element operates a four-way selector valve which, in a sense, is an amplifier, since a small work load of the order of 0.01 to 0.02 in-lb will cause or prohibit the operation of 1 hp of net work at the flap, the smaller work being provided by the thermal element. The four-way selector-valve operation controls the flow of hydraulic oil usually at 1500 psi pressure to the hydraulic cylinder or strut, which in turn operates the air-controlling flap. This arrangement is additionally effective in that hydraulic oil or pressure is readily convertible to force in its most usable form in so far as flap operation is concerned, hence the efficiency of this working medium is very high.

The most desirable type of control is one that will modulate the flap, that is, not open or close only, but assume some position best suited to obtain the correct temperature control. Operating efficiency of the engine installation virtually requires modulating control, not only to maintain actual engine efficiency by holding correct temperatures, but maximum aerodynamic efficiency by lessening unnecessary flap opening. However, modulating controls have an inherent weakness, that is, a tendency toward instability, to "hunt," or to oscillate about the desired position. This is overcome in nearly all modulating mechanisms by what is known as the reset or follow-up mechanism. This mechanism readjusts the calibration point of the temperature control for the particular flap position. Thus when the engine is cold, and the flaps are closed, the temperature control will respond at a temperature 20 deg, 30 deg, or 40 deg F, as the case may be, lower than it would if the flaps were open.

Modulated Temperature Control

A typical modulating control does not have a fixed temperature-responsive point in the sense that we understand the typical thermostat to have. For example, a typical on-and-off thermostat would turn on at a certain temperature, say 210 F, and turn off at 220 F. The 10 deg F difference is known as differential, and the operated unit would open or close, only in response to such a control unit. The modulating control may start at 210 F and initiate opening of the flap, the resultant operation of which would shift the range of the control, resulting in a small movement suited to the cooling needs. The flap would not open fully, but would open, for example, at 20 per cent, and additionally, the control point or response point of the control would be shifted from 210 to 216 F. Another rise in temperature would cause a further opening of the flaps, an increment suited to the rise of temperature. The flaps would be fully open, for example, at 240 F, and the new response point of the control, because of the reset mechanism, would be at 240 F. The temperature dropping some amount below 240 F would result in a closing of the flap again an incremental amount as needed. Thus with a reset mechanism, an actual closing condition is obtained which may be higher in temperature response than another point at which the flaps would open. The reset mechanism is solely responsible for this condition, and ideally prevents "hunting," or oscillating about the control point, or unnecessary flap operation.

The range, in this case, from 210 to 240 F is known as the reset range, and is here 30 deg F. As compared to the on-and-off control, first mentioned, it appears to be wide, and would result in a wide controlling temperature. However, the on-and-off control is subject to swing in control. For example, a control which shuts off at 220 F, as just outlined, does not result in holding the control medium at 220 F. A swing occurs which will carry it greatly beyond this point, depending upon the characteristics of the medium and system on which the control is being used. A properly designed reset range, and it should always be wide enough to be so designed, will result in holding the control temperature entirely within that range, particularly if the control is rapidly responsive. Hence although the reset range of the modulating control is wider than the differential of typical on-and-off control, the actual control temperature is more often closer or narrower than that obtained with an on-and-off type. Therefore, a reset mechanism was included in the control, not only to prevent "hunting" but for closeness of control.

Pilot supervisory control can be exercised taking the flap control completely away from the automatic control. This can be done mechanically, electrically, or hydraulically as the work

involved is slight, and hence reasonable, regardless of the medium used. The medium to be used depends upon the remoteness of the location as well as upon the reliability of the types available. The use of certain mediums is precluded because of inaccessibility. The particular control in question may be overridden either mechanically, electrically, or hydraulically. Each will work equally well. The mechanical method of overriding has the obvious advantage of providing a direct operation in the event of either electric- or hydraulic-system failure, particularly in view of the fact that the hydraulic temperature control will fair the flaps upon proper operation of the selector valve. However, electrical or hydraulic operation is used where it may be physically impossible to reach the control mechanically. The overriding control thus provides four positions, i.e., automatic, open flap, closed flap, locked flap. Predetermined flap positions are possible or manual modulation may be used, according to needs.

An engine temperature control using a hydraulic work medium is successfully operable from either lubricating-oil or engine-coolant temperatures. In addition, operation is fast enough to cover all flight conditions, even those existing in pursuit ships. In fact, actual test curves on one of the fast pursuits shows that the control is never lost—never has to overshoot to catch up with its position. Also, overriding or pilot supervision is just as effective as if the temperature control never existed. The weight is low. Field experience and operating life have been satisfactory.

The development and subsequent operation of this contro have demonstrated the excellent possibilities of hydraulic operation of engine temperature control. Further advancement gives indication that air-cooled-engine cowl-flap control may be solved hydraulically. Advances in the art, accelerated by the substantial production now existing, will most certainly result in even greater reliability, lower weight, lower cost and accuracy for any aircraft temperature-control problem.

High- and Low-Pressure Airplane Hydraulics in Europe

By JEAN MERCIER,[1] NEW YORK, N. Y.

Development of hydraulic control systems for aircraft began to make progress in Europe about 1936, the trend being toward pressures of 5000 psi and higher. Details of the equipment comprising the hydraulic systems, applications made, and lines of development when the war interrupted the program are treated in this paper.

IT may be recalled that during the heroic phase of the airplane in the first world war, the kinetic energy of any abnormal landing shock was absorbed, as is said in French, by "breaking wood." The wood referred to was, of course, the wooden undercarriage, even when it ceased to be made of wood as originally.

So many of the Allied planes were thus immobilized that the author's father, Henri Mercier, who at the time was Director of the Mechanical Section of Inventions of the War Department in France, suggested what he and his colleagues termed "a pneumatic shock absorber with a very long stroke!" Compared with the shock absorber of today, the very long stroke, which was 30 in., will surely bring a smile. To avoid any drag which might disturb the flight, a telescopic retracting system was developed.

The Armistice of 1918 interrupted this research before any test flights were made. Incidentally, the fluid retraction of the landing gear was not hydraulic but pneumatic; a small Letombe compressor actuated by a propeller was the prime mover.

Twelve years passed before another French engineer, the late Georges Messier, took up the problem. His was a hybrid development. By combining Col. Deport's oleo-pneumatic gun recoil with samples of the American Lockheed automobile hydraulic-actuating cylinders, he built probably the first modern hydraulically retractable landing gear. The Olaer Company, which the author directed, was working on similar problems for automobiles at that time and decided to enter the airplane field. To have the best chance against competition by electric controls using high voltage, it seemed necessary that an equivalent high "voltage" hydraulic system, foolproof and unaffected by wear, tear, cold, and age, be first scientifically developed.

Advantages of High Pressures

The following illustrations may help to clarify the analogy between high voltage and high pressure in hydraulics:

A few volts permit the handling of a good-sized telephone bell; a few pounds' pressure are just good enough to actuate a windshield wiper; 1000 lb will hold its own against a 20-v motor. The future will certainly bring into competition systems of several hundred volts, such as are already being applied in ships with installations of several thousand pounds per square inch. In other words, high pressure is comparable to high voltage, thus affording an efficient way of producing and transporting energy without the corresponding trouble of handling great volumes of oil or conducting many amperes of electricity.

The enormous advantages of high voltage are thus balanced, and hydraulics will be free to develop its potentialities of easy maintenance, light weight, and flexibility. The value of these qualities is particularly potent in the high-pressure hydraulic accumulator which is able, in a fraction of a second, to start off the heaviest engines.

Having adopted this point of view and before determining the optimum operative pressure, it was essential to learn the reaction of European aeronautical engineers and test pilots compelled to fly with apparatus under such apparently eruptive pressures. It is hard to believe the great difficulties encountered by the author in promoting the idea that the damage caused by the explosion of an accumulator is related to the amount of energy thus liberated, e.g., the energy stored in a 50-cu-in. accumulator at 5000 psi is not much greater than 1 gal at 1000 psi.

The best illustration of the present status of the art in the United States is Harold Adams' very interesting work,[2] in which the optimum operating pressure is calculated, and which proves that above 3000 psi there is practically no saving of weight, either in tubing or in actuating cylinder walls, if the same load factor is maintained for both high- and low-pressure hydraulic systems.

While the author is in full agreement with Mr. Adams' calculations concerning the parts involved, he has found that above 3000 psi there is still a marked saving in cylinder heads and tube fittings, as well as in the actual weight of oil involved. In addition to this, higher pressures should be of great interest for the following reasons: The smaller the apparatus, the less will be the modifications necessary in the structural design of the plane, thus saving an incredible amount of weight, space, and last but not least, headaches. One is led to the conclusion that too low a pressure, even 3000 psi, limits the free development of optimum structural design.

Furthermore, a constant pressure drop in the line of a few hundred pounds is necessary to transmit the energy from the pump to the actuating cylinder. Those hundred pounds become a relatively smaller percentage in a 9000-psi system than in one of 3000 psi. The corresponding tubing, being necessarily thicker, resists external stress and vibrations so well that the factor of safety can be reduced to the one adopted for cylinders, thus giving nearly 50 per cent weight saving. Once again, there is a point of comparison with the high voltage in electrical-power transmission.

TABLE 1 WEIGHT SAVING COMPARISON BETWEEN 5000-PSI AND 1000-PSI HYDRAULIC SYSTEMS

	Weight saved, lb	Per cent saved
Tubings, fittings, and supports	5	50
Oil	30	75
Pump	0	0
Selector valve	1	50
Landing-gear cylinders	5	60
Dive-flaps cylinder booster of pressure	11	70

As an illustration of weights saving, Table 1 summarizes the case of an airplane weighing 7000 to 8000 lb, with a hydraulic

[2] "Design and Shape Problems in High-Pressure Hydraulic Systems," by Harold Adams, *S.A.E. Journal*, September, 1940.

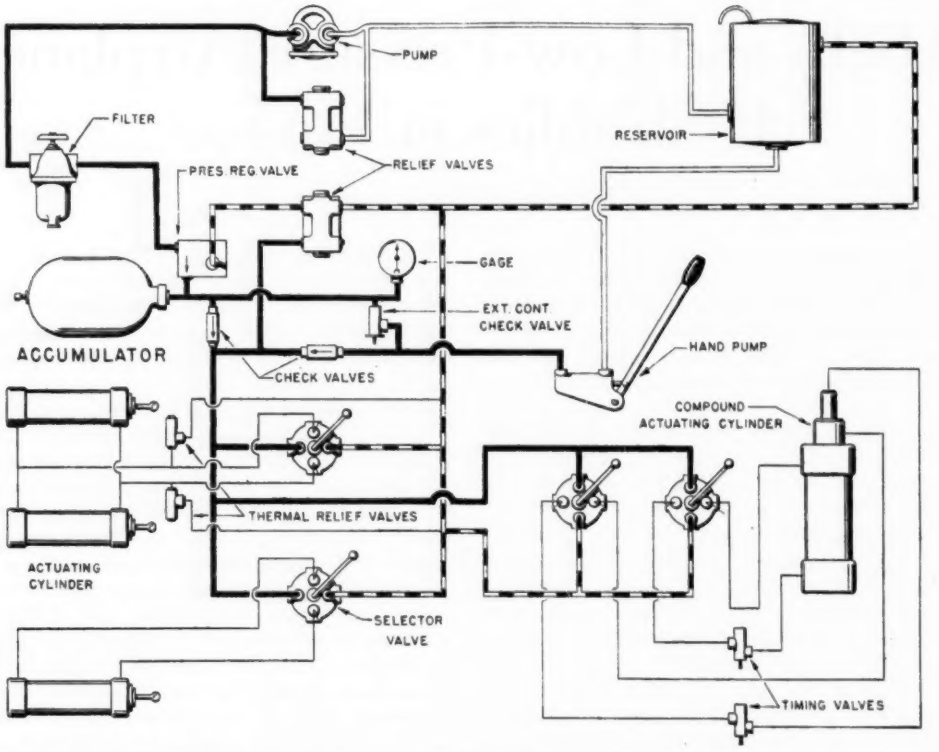

FIG. 1 SCHEMATIC DRAWING OF TYPICAL OLAER MERCIER HYDRAULIC SYSTEM SHOWING INSTALLATION OF ACCUMULATOR AS IN REGULAR USE IN FRANCE IN 1936, AND AS IN USE ON AMERICAN AIRCRAFT IN 1943
(When a variable-delivery pump, Dowty, England; Olaer Mercier, France, is used, the pressure-regulator valve is suppressed.)

system utilizing 5000 psi, compared to one at 1000 psi (Fig. 1). In this instance, the total weight saving appears to be over 60 per cent.

In Europe, prior to 1935, to the best of the author's knowledge no planes had flown with a hydraulic system operated at a pressure appreciably over 1000 psi.

It was difficult to get the French Bureau of Aeronautics to have little more than faint sympathy for such evident madness as the proposal of the Olaer Company. However, after 2 months of completely successful trials at 8000 psi, it was agreed, much to the relief of the bureau, to drop the pressure to 4000 psi. In 1935, the Morane Saulnier fighter 405–406, equipped with Olaer-Mercier hydraulic system at 4000 psi, took off from the Villacoublay Airport, piloted by an amazingly confident man, Michel Detroyat.

HIGH-PRESSURE SYSTEMS ADOPTED FOR MILITARY AIRCRAFT IN 1936

Interesting items at that time were the automatic thermostatic actuation of the selector valve, controlling the position of the radiator-actuating cylinder and the follow-up flap control, permitting their immobilization at any degree of their travel. There were, also, separate piston-type accumulators with metallic glands, permitting independent emergency movements of flaps and undercarriages.

In 1936, the Fokker Gl light bomber adopted the same system at an operative pressure of 4500 psi. Both types of planes have since been manufactured in regular line production. The basic scheme of the hydraulic system of both of these planes is the same. In the Fokker, the following functions were controlled by the Olaer-Mercier system: Retractable landing gear with mechanical lock hydraulically operated by special cylinder, landing flaps with a safety valve allowing for automatic adjustment at high speed, dive flaps, bomb doors, cockpit opening, and cooling flaps.

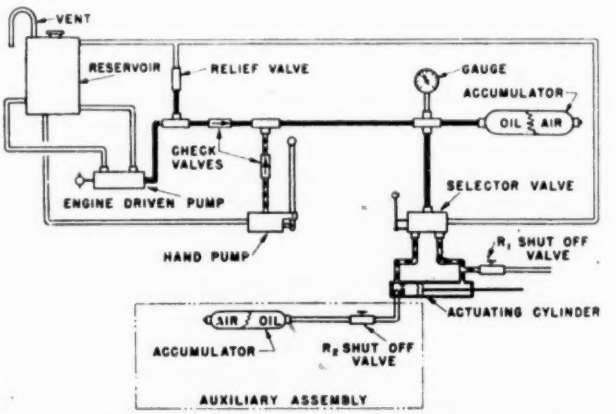

FIG. 2 SCHEMATIC DIAGRAM SHOWING ELEMENTS OF TYPICAL OLAER MERCIER INSTALLATION WITH SELF-REGULATING PUMP
(Note independent circuit and emergency outlet. In case of pressure failure in line 1, pilot opens valve R_2 and, if necessary, R_1 to lower landing gear. In use in Holland, Switzerland, Italy, France, 1936.)

Special mention must be made of the emergency hydraulic pressure conducted to the hydraulic-flap and landing cylinders, utilizing an automatic transfer valve on the cylinder head, isolating the normal hydraulic circuit in case of its failure (see Fig. 2). The energy for this was provided by an air bottle or an accumulator preloaded at 5000 psi, thus doing away with the hand pump. Bristol, in England, and others use a similar transfer valve to connect a gas-charge-producing cartridge device. At the same time, Caproni in Italy acquired the Olaer license in order to equip its series of light bombers 310. The chief char-

acteristic of this modified installation was a complete dual hydraulic system up to the jack, with two independent pumps, one on each engine, the pilot thus having the choice of shifting from one to the other, provision having been made for automatic transfer valves. Since then, the high-pressure hydraulic system has been adopted in Switzerland, and in Czechoslovakia by Skoda for its Avia 35. In 1938, the French fighter Dewoittine 520 also adopted Olaer. The different components of this system were on view, in operative condition, at the hydraulics meeting in Los Angeles, November, 1941, under the chairmanship of Commander Harry Marx of the Bureau of Aeronautics, and of Mr. Bashark of Wright Field.

The parts shown consisted of a complete retractable landing gear, composed of a magnesium wheel, specially coated with metallic salts, resisting 1000 hr of exposure to salt spray (which coating process is now in use in Germany and was recently found satisfactory by Northrop laboratories), and of brakes of the inflated-bag type having an extremely large brake drum located inside of the wheel contour, thus enabling the dispersion of the heat generated when landing at very high speed, i.e., 100 mph. This last-mentioned characteristic was found necessary, if not always for actual landing, at least for taxiing rapidly along the ground to shelter in war operations.

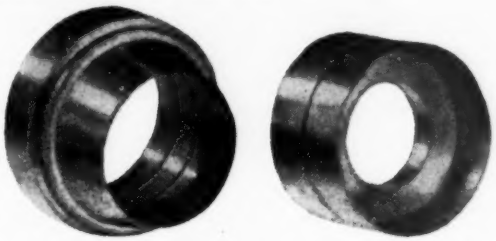

FIG. 3 OLAER MERCIER METALLIC GLAND FOR PRESSURE UP TO 30,000 PSI AND TEMPERATURE RANGE FROM —100 F TO +400 F
(In use in France, Holland, and Switzerland since 1936.)

Shock struts were provided with the Olaer metallic glands (Fig. 3), adequate to resist excessively low temperatures such as found in Russia and Alaska. A complete retracting system, with the nut-cracker link actuated by a cylinder having no fixed point on the airplane structure, was simultaneously developed by Bristol in England, and by Olaer in France. Here the mechanical lock is included in the hydraulic cylinder (Fig. 4), and operated by a subsidiary piston actuated by the pressure existing in the cylinder itself, thus suppressing external connections. This feature has since been adopted by the Messerschmitt fighter.

As to the simultaneous problems of fittings and flexible hose, they were very easily solved by the Ermeto fittings (Weatherhead) as long as the wall thickness of the tube is over 0.04 in., and the ordinary Alemite flexible hose, provided the inside diameters remained under $^3/_{16}$ in. For operations at very low temperatures, a carefully designed horn-shaped metallic tubing gives a foolproof solution, so long as the displacement of the units to be connected is not too great.

OTHER NOTABLE DEVELOPMENTS IN EUROPE

It may be worth while to mention some other characteristic devices developed in Europe. To replace the mechanical push-pull control, the Exactor system, initiated in England and since licensed in the United States, has taken a leading place. Messier developed a similar system, characterized by keeping the oil under pressure in both circuits, forward and backward; the total of the pressure in both lines is kept constant due to a single spring acting on two independent compensating pistons.

Except for the Letombe Viet air compressor, which is after all

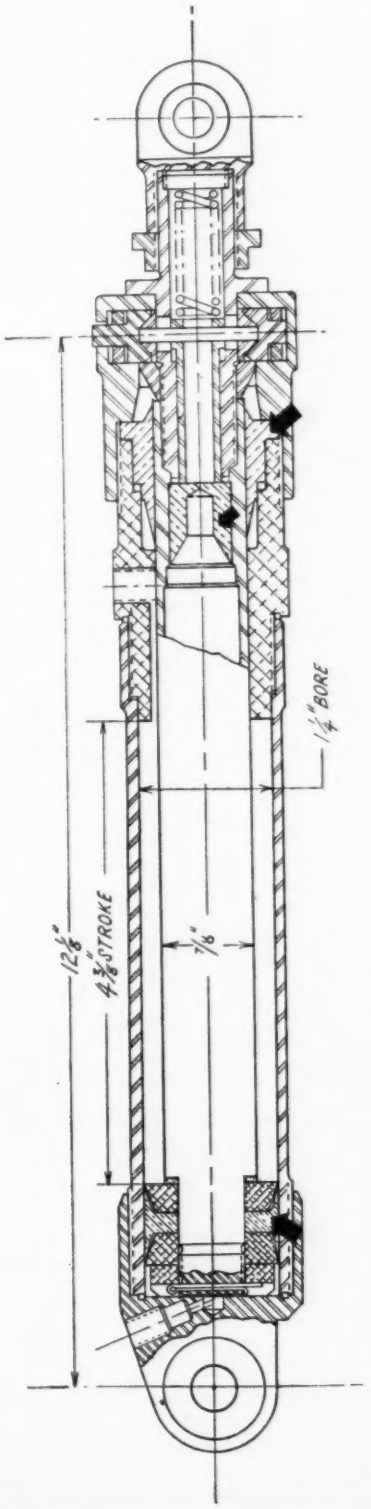

FIG. 4 TYPICAL LANDING-GEAR-ACTUATING CYLINDER FOR CURRENT TYPE PURSUIT AIRPLANES, WEIGHING ABOUT 6000 LB
(The Olaer Mercier metallic gland, indicated by arrows, replaces the old-fashioned packing subject to aging, leakage, and rapid deterioration unless periodically renewed. The gland acts as a bearing, occupies less space, and weighs no more than the cap required to fix the old packing and the retainers. It flexes sufficiently to adapt to the cylindrical form of the piston itself, demands but slight refinement of tolerance.)

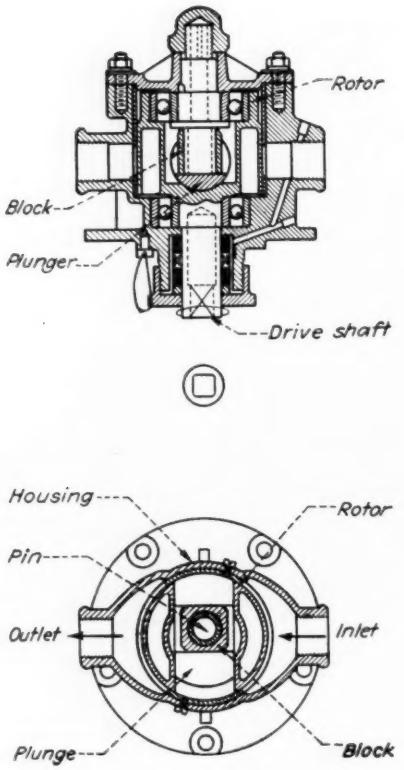

FIG. 5 ROTO PLUNGE RECIPROCATING PUMP, ENGLAND

not a pump, the first application of reciprocating pumps was made in England under the name of the "Roto-Plunge" pump, manufactured by T. H. and J. Daniels Company (Fig. 5). Later on Vickers Aviation Company, Ltd., in England (which has no connection with the Vickers Company of Detroit) produced a two-cylinder pump for use in aircraft (Fig. 6).

In 1935, Bristol developed a three-stage gear pump with a normal delivery of $2^3/_4$ gpm at 1500 psi, at a speed of 2400 rpm. Between 1930 and 1933, de Boysson in France developed a very fine radial-piston pump for turret control. This pump, adopted by Messier, is shown in Fig. 7. Some 5 years ago, an automatic clutch device, controlled by hydraulic pressure,

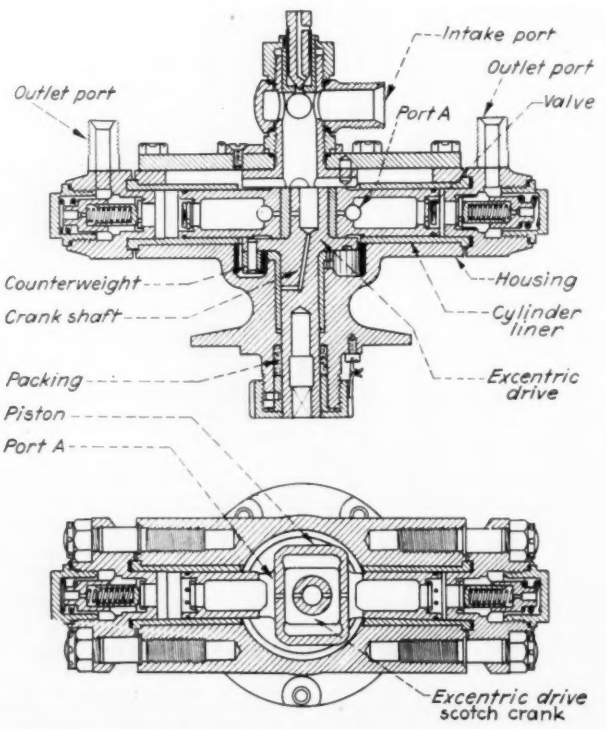

FIG. 6 VICKERS, LTD., HORIZONTALLY OPPOSED TWO-CYLINDER RECIPROCATING PUMP

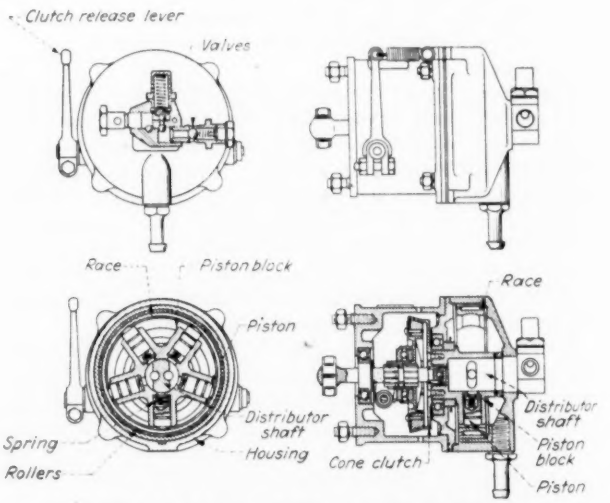

FIG. 8 DE BOYSSON MESSIER PUMP, FRANCE

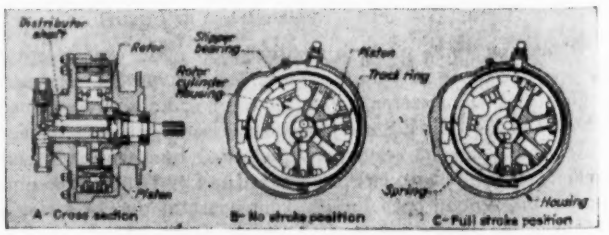

FIG. 9 CROSS SECTION DOWTY, ENGLAND, LIVE-LINE PUMP

was evolved jointly by de Boysson and Messier (Fig. 8). On the same general principle, Dowty adopted a pump which a few years ago was transformed into a self-regulating pump by the addition of a spring limiting the torque (Fig. 9). This is known today as the "Live-Line" system in which the only, but very interesting, improvement over the Olaer self-regulating system consists in the elimination of the accumulator, a bigger pump taking care of the instantaneous flow requirements. This carries the risk that, in case of pump or engine failure, no energy is available.

The Olaer pump (Fig. 10), developed in the period 1935–1938, and since adopted in several European countries, is somewhat similar to the well-known Vickers wobble-plate type, described fully in a paper by Dale Herman.[3] Its characteristics are (1)

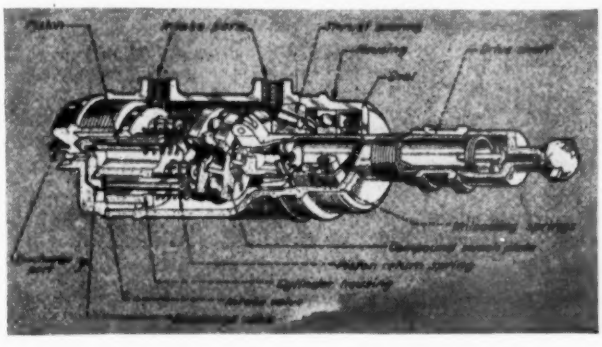

FIG. 10 OLAER MERCIER PUMP, 5000 PSI, WEIGHT, 2.2 LB
(In use in France, Holland, Italy, and Switzerland.)

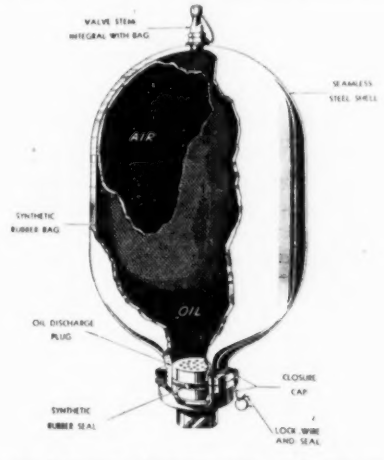

FIG. 11 OLAER MERCIER ACCUMULATOR AS BUILT IN THE UNITED STATES

supercharging, thus avoiding cavitation at high speed; (2) self-regulation by a spring concentric to the axis; and (3) lightness of weight, 2.2 lb for a 1/4-gpm, 5000-psi pump. The basic design for all these pumps, as also for many of the ultramodern hydraulic devices, can be found in the hydraulic controls used on battleships for the last 40 years. Hele-Shaw (England) and Waterbury (England) have contributed largely to their development. Happily for us aviation hydraulics engineers, the prohibitive weight of these known devices makes their use in aviation impossible. The hydraulic cylinders, utilizing rubber or leather glands, are more or less similar to the American practice.

Fig. 11 shows the Olaer-Mercier bag-type accumulator, and Fig. 4 the Olaer jack, also developed in 1936, the latter having an internal self-locking device and metallic glands as shown in Figs. 3 and 4.

The similarity holds good for European and American globe, check, regulating, pressure-reducing, safety, and selector valves.

In Europe, faith in hydraulics led to the development of hydraulic valve locks to prevent eccentric movements. Bristol and Olaer use a valve operated by a connecting rod which, by shutting off the line when the weight of the airplane telescopes the oleo strut, makes it impossible for the undercarriage to retract on the ground. A variant feature of this device prevents the outflow of oil from the jack when external force tends to displace the piston. Bristol applies his double hydraulic lock on bomb doors. This lock consists of spring-loaded poppet valves independent of the jack. The Olaer system is based on a sliding head of the jack itself, which closes the hydraulic circuit when the head tends to telescope into the cylinder due to external forces. When the internal pressure is again applied it pushes out the head thus reopening the oil circuit.

WAR INTERRUPTS WORK ON EXTENSIVE HYDRAULICS APPLICATIONS

There were three more interesting developments in process at the outbreak of the war in Europe. One, in collaboration with the French Navy, for watertight compartments, was later proposed for very large airplanes. If the weight increase, necessitated by the increasing distance between the hydraulic units and the increased energy to be transmitted on the "bigger and better" planes now on their way, were not provided for, the planes would soon carry more tubing than freight. A patented solution to this was found in providing, close to each hydraulic cylinder, two accumulators, one of high pressure to store the local energy, and the other of low pressure to absorb locally the outlet flow required during rapid actuation, as well as a local selector valve, controlled electrically at distance by the pilot or, in case of emergency, by hand. An enclosed hydraulic circuit, independent of the atmospheric pressure and particularly noteworthy for stratospheric flying, is thus obtained automatically by the elimination of the oil reservoir rendered unnecessary by the presence of the low-pressure accumulators. The combination of an electrical remote-control system, with hydraulic-actuating cylinders, may be compared with the nervous system of the human body in controlling the flow of blood to the muscles for actuation. This organic union might well encourage the electrical engineer to accept hydraulics "for better or for worse," or at any rate until rotary high-speed servomotors take its place.

Another development of note was a hydraulic steering device for the front wheel of the Fokker D23, a tricycle landing gear similar to the follow-up rudder control of ships, which sooner or later will be applied to airplanes.

A still further interesting point was the hydraulic control of two or more landing flaps, operating simultaneously without any mechanical connection. Instead of controlling the amount of fluid to be admitted to or exhausted from each of the operative jacks, the problem was reversed. If a disequilibrium should occur, the pilot would correct it in the normal way by means of the stick, thus automatically bringing into action a special distributing valve, which in turn corrects the amount of fluid needed for an exact symmetrical displacement of the flaps.

Of course, some additional features are required to permit the correction being made while lowering or raising the flaps. A leak in any part of the line would be taken care of automatically, because the control is not affected by the distribution of the oil, nor by the movement of the flaps themselves when not absolutely symmetrical, but by the stability of the plane itself.

[3] "The Evolution of the Hydraulic Pump as Applied to Aircraft," by Dale Herman, appearing on pages 583–588 of this issue of the Transactions.

A two-position actuating cylinder was used to permit different landing and taking-off flap positions.

ACKNOWLEDGMENT

The author wishes to express his appreciation for the courtesy and help of Commander Harry Marx, U.S.N.R., who is in charge of hydraulics at the Bureau of Aeronautics of the Navy; of Mr. Edward Greer of Greer Hydraulics Co.; and of Simmonds Aerocessories, Inc., for the use of the illustrations in this paper.

Maintenance of Aircraft Hydraulic Systems in the Field

By R. E. MIDDLETON,[1] BURBANK, CALIF.

This paper deals with certain aspects of the aircraft-accessories maintenance problem, under wartime conditions, and sets forth some suggestions as to how manufacturers of aircraft hydraulic equipment might assist in its solution. The comparative merits of hydraulic systems and electrical-mechanical systems for operating airplane accessories are discussed from the standpoint of maintenance and repair.

IN contrast to peacetime when Army aircraft could be serviced under the best possible shop conditions by a thoroughly trained and experienced staff, highly complex and delicate aircraft accessories are today overhauled, repaired, and adjusted oftentimes in the open, exposed to extremes of weather and with only the most limited tools and equipment. It is true that all large well-equipped air bases have proper maintenance facilities but under combat conditions, so long as an airplane will fly, it is usually operated from outposts far removed from such shops.

Through the courtesy of the Army Air Forces, the author has had an opportunity to become quite thoroughly acquainted with the conditions under which airplanes being used in the Alaskan theater of operations are being serviced and kept in proper flying condition. This study involved observation of the maintenance and service operations at various bases, including actual combat squadrons.

Improvement Necessary in Servicing Hydraulic Equipment

This study of conditions in the field demonstrated the eagerness of the Army Air Forces' personnel to avail themselves of all constructive advice and help forthcoming from civilian technicians and representatives of equipment manufacturers. In the case of hydraulic equipment, which is doing a fine job in the field, the results are being accomplished with wholly inadequate field service provided by manufacturers of this type of equipment, and in spite of certain quite serious handicaps. In general, manufacturers have not furnished the caliber of field service essential to the most advantageous operation of the equipment and the least interference with operation of the airplane, at all times. Of course, one important reason for this is the tremendous expansion in the Army Air Forces without corresponding increase in available personnel, with a thorough knowledge of hydraulics.

It is believed that the greatest field for improvement in the operation of hydraulic systems under service conditions lies in the expansion by hydraulic-equipment manufacturers of the facilities for educating service personnel; and in furnishing the proper tools, equipment, and service manuals pertinent to the maintenance, adjustment, and repair of these accessories.

Of course, it would not be accurate to assume that similar service difficulties are not encountered in electrical-mechanical systems for operating accessories. During the tour in Alaska it was possible to observe many instances where electrical equipment of various kinds was being removed, repaired, or replaced. Actually, the percentage of such replacements appeared to be higher than the percentage of replacements of hydraulic equipment. In connection with such comparisons, it should be borne in mind that the total quantity of hydraulically operated accessories now in use on standard military airplanes exceeds considerably the total of electrically operated accessories. Therefore, even though the percentage of replacements of hydraulic equipment is low, the actual number of such replacements may still be greater than the actual number of replacements of electrically operated equipment.

More Rugged and Serviceable Designs Will Help

The following suggestions are made to manufacturers of hydraulic equipment in the interest of remedying at least partially some of the failures of hydraulic equipment to give the best possible service. By improving field conditions, one of the greatest obstacles to present and future progress in the use of hydraulics in aircraft will be removed.

It is the author's belief that hydraulic-accessories manufacturers have not in the past assumed their full responsibility for the successful and trouble-free operation of their equipment in the field. In many cases, the design of such equipment does not provide the reliable and rugged construction which is necessary for it to stand up under varying and adverse atmospheric, weather, and ground conditions which prevail in many theaters throughout the world where American-built aircraft are called upon to operate. In partial justification, it is true that sufficient time has not been available for developing and testing design features of the equipment which may later cause trouble. Obviously in many cases the airplane itself has had to be the proving ground for the equipment. Consideration must also be given to the extreme urgency under which manufacturers have been operating. They have been called upon to produce equipment within the most stringent delivery schedules. Nevertheless, it is believed to be entirely feasible for the accessories manufacturer to work out a comprehensive program which will allow sufficient time to find and correct the majority of the weak points of his equipment through careful test and improvement.

The facts demonstrate that in the few cases where such procedure has been followed, even to the point of apparent overcaution in proving equipment before it is installed in airplanes, the greatest serviceability in the field has been achieved.

Another important design consideration relates to the tools and methods required for maintenance and service. Many instances are on record of units which required special wrenches, holding fixtures, and adjusting tools, for their proper adjustment and repair. These may be quite acceptable where the units can be serviced in well-equipped base repair depots, which can maintain supplies of such tools, fixtures, and gages. Under war conditions, in practically no case is sufficient equipment available at the points where airplanes are actually being operated in service, and where it is necessary for mechanics to keep them flying.

Whether it is hydraulic, electrical, or mechanical, the ac-

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

cessory equipment which literally can be taken apart and put together again on the upturned bottom of a packing case, with the ordinary mechanic's tool kit, will in general be successful. Certainly it will have to be rugged equipment. Experience would appear to prove that hydraulic equipment is much more susceptible to design which is capable of this type of servicing than are electrical-mechanical devices, which are more delicate, more needful of special tools, and more difficult to repair in the field.

Another major point in a program of service improvement is the assumption on the part of the accessories manufacturer of a greater share of the responsibility for actual servicing of the equipment in the field. The first step is for each manufacturer, within his ability to do so, to assure that full information and instructions are made available to all squadrons flying airplanes in which his equipment is installed, and also to make a greater effort to furnish the necessary tools and spares at points where they are needed. It is believed that this can best be accomplished through the efforts of qualified service representatives of the accessories manufacturers who, under the auspices of the Air Service Command, can work with the Army and Navy personnel. They can serve as advisers, guides, helpers, and liaison between the service organizations, which must use and maintain the equipment, and the factories which, because they are so far removed from the battle fronts, usually tend to lose sight of their great responsibility and the tremendous job that must be done in keeping the equipment working and the airplanes flying.

As has been amply demonstrated by the aircraft manufacturers, a sufficient number of qualified service representatives can be invaluable in aiding the personnel of the armed services to become thoroughly familiar with the highly specialized, intricate and, at best, rather delicate accessory equipment. They can go far toward attaining the degree of co-operation between the accessories manufacturers and the actual users of the equipment, which will not only insure long life but also reliable operation.

Centrifugal Casting of Steel

By S. D. MOXLEY,[1] BIRMINGHAM, ALA.

This relatively new method of casting is being applied to great advantage in the economic production of high-quality engineering parts. The three methods generally used are true centrifugal casting, semicentrifugal casting, and centrifuging. The author gives a comprehensive description of each method, the work for which it is best adapted, the machines used, details of molds, and physical properties of the resulting products.

THE casting of metals centrifugally is basically "pressure casting." In static molding, feeding is done by atmospheric pressure and gravity, and the pressure under which the metal is cast is dependent upon the height of the gates and risers. In centrifugal casting, the metal is forced against the mold wall and into the cavities under much higher pressures resulting from centrifugal force imparted by the revolving mold.

Generally, the methods of centrifugal casting are (1) true centrifugal casting, (2) semicentrifugal casting, (3) centrifuging.

The "true centrifugal" method consists of spinning the casting about its own axis and using centrifugal force to hold the metal on the wall of the mold, thus forming the inside without the use of a center core. When a mold is spun about a horizontal axis, the interior cavity formed by the molten metal is a true cylinder, regardless of the shape of the outside of the casting. Its inside diameter is determined by the volume of metal poured.

Fig. 1 shows a cylindrical flask lined with sand and provided with suitable end fixtures. If the mold is spun at sufficient speed and metal is poured into it, a cylindrical tube, as indicated, is cast.

If more than one inside diameter is required in a casting, the larger inside diameters may be formed by cores extended from the ends of the mold, leaving the smaller diameter to be formed by centrifugal force. Fig. 2 shows a conventional mold for making cast-iron pressure pipe. Note that the inside diameter of the socket is larger than the inside diameter of the pipe and is made with a core.

This method has been used in the mass production of cast-iron pipe for more than 20 years. During that period both sand-lined mold and metal-mold processes have been in successful commercial use, and their economic soundness has long since been proved. Higher physical properties have been obtained, and this has resulted in a reduction in the required thickness and weight of the pipe for a given service. Alloy-steel gun barrels are centrifugally cast in horizontal metal molds by a process developed over a long period of years at Watertown Arsenal.

True horizontal centrifugal casting is well adapted to the manufacture of short and long tubes in various sizes where the inside cavities are cylindrical. Steel tubes, ranging from several inches in diameter up to 50 in. diam, can now be made by the author's company in lengths of 16 ft. Typical products of this method are pipe, various kinds of tubing, radial-engine cylinder barrels, hollow ship shafts, weld-neck castings, bearings, sleeves, etc.

Vertical True Centrifugal Casting

True centrifugal casting is also done by spinning the mold about a vertical or an inclined axis. When this is done the resulting interior cavity is a paraboloid. The shape of this paraboloid is dependent upon (1) the speed of rotation of the mold, (2) the diameter of the closing fixture at the top of the mold, and (3) the angle of inclination of the axis of rotation. Assuming a fixed diameter at the top of the inside cavity, and a fixed angle of inclination, the depth of the paraboloid is increased by an in-

Contributed by the Metals Engineering Division and presented at the Spring Meeting, Birmingham, Ala., April 3–5, 1944, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

crease of speed. Likewise, the paraboloid will be shortened with slower speed.

Fig. 3 shows radial-engine cylinder barrels being cast by the horizontal and the vertical methods. At the right the mold is spun about a horizontal axis, and the inside cavity is cylindrical. At the left the mold is spun vertically and the inside cavity is parabolic in shape. At a certain speed of rotation the inside cavity will take the shape of paraboloid *A* as shown, while at some lower speed the inside cavity will be formed on the line of paraboloid *B*. In either case, the top diameter of the inside cavity will be larger than the bottom diameter. These castings ($8^3/_4$ in. OD × $11^3/_4$ in. long) are now being made horizontally at speeds of 975 rpm and lower, and vertically at speeds approaching 1200 rpm. The mathematics for calculating the shape of the inside paraboloid is relatively simple and is in the record.[2] Fig. 4 shows a comparison of an actual paraboloid as cast with the shape of cavity as calculated.

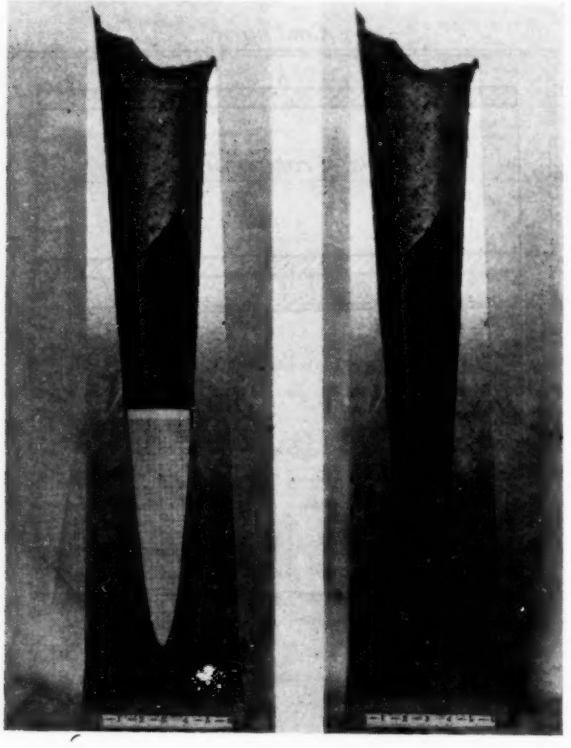

FIG. 4 COMPARISON OF ACTUAL PARABOLOID AS CAST WITH CALCULATED SHAPE OF CAVITY

Advantages. The horizontal and vertical methods of producing castings have many advantages. In static castings a large proportion of the critical defects are subsurface imperfections, detectable only by expensive and time-consuming methods. When spun, the impurities such as dirt, sand, and slag, having lower specific gravity, are forced to the inside surface of the casting by centrifugal force. Any gas or air pockets are likewise eliminated. The elimination of these foreign inclusions results in a sounder casting, and the product is more uniform. A centrifugal casting is more dense than a static casting. It is doubtful that the method of casting steel would change the specific gravity of the metal, but being free of these foreign inclusions or voids would naturally make a casting more dense, or rather, heavier per unit volume.

[2] R. F. Wood, U. S. Patent No. 1,533,780.

Directional solidification is very important in any method of molding. In true centrifugal casting, this occurs naturally, since the metal is cooled from the outside toward the center. Inspection of the castings is greatly simplified, since such defects as are found are in nearly all cases on the inside or outside surface of the castings, thus making them more readily detectable.

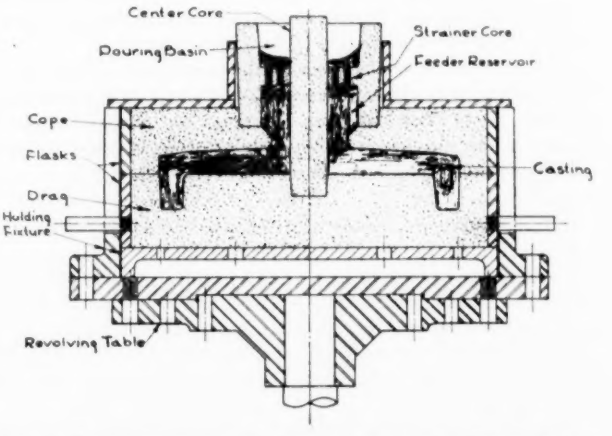

FIG. 5 SEMICENTRIFUGAL CASTING OF FLYWHEEL WITH CENTER CAVITY

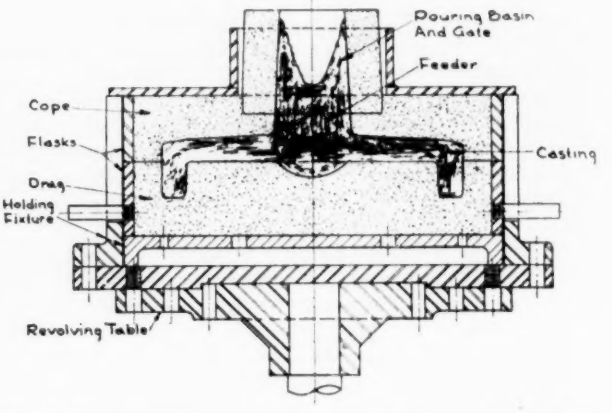

FIG. 6 SEMICENTRIFUGAL CASTING OF FLYWHEEL WITH SOLID CENTER

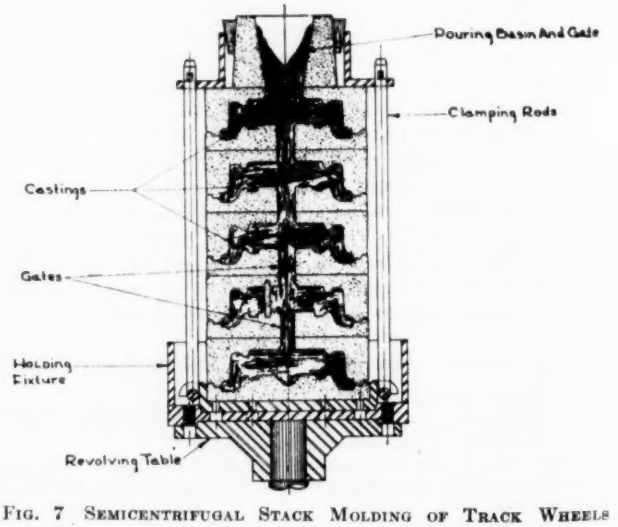

FIG. 7 SEMICENTRIFUGAL STACK MOLDING OF TRACK WHEELS

The elimination of inside cores greatly reduces the costs in the foundry as well as in the cleaning shed.

The elimination of gates and risers greatly increases the yield and in some cases 100 per cent yield is obtained. Cases in which 100 per cent yield is obtained include cast-steel hollow ship shafts, various tubing, cast-iron pipe, etc., where inside machining is not required. In castings such as radial-engine cylinder barrels where the inside machined surface is highly important, the wall is poured thicker than required. This extra thickness on the inside serves very much as an inside gate or feeder and is later removed by machining. Thus in such cases the actual yield is lower. The centrifugal method is highly adaptable for mass production of identical castings.

Semicentrifugal Method

Semicentrifugal casting consists of spinning a casting about its own axis—usually about the vertical axis. If the casting has a center cavity, this cavity is often formed with a center core, and the casting is fed by a center gate passing down around this core. Fig. 5, demonstrating this method, shows a cross section through a sand mold mounted on the revolving table of a vertical casting machine. This is a flywheel casting and is typical of the semicentrifugal method.

Fig. 8 Semicentrifugal Casting; Stack Molding of Tractor Wheels
(Mold made up ready for placing on casting machine.)

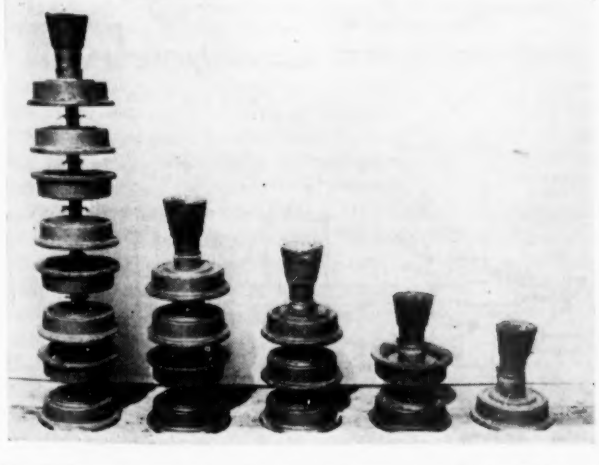

Fig. 9 Semicentrifugal Casting, Illustrating Stack Molding of Tractor Wheels

In many cases, the center is cast solid and the center cavity, if any, is machined out, or removed by an oxyacetylene torch. This is shown in Fig. 6 where the same flywheel is cast with a solid center.

Metal molds and a combination of metal and sand molds are also used. Stack molding, where a number of castings are made in one pour, is well adapted to this method. This is illustrated in Fig. 7. Fig. 8 shows a built-up stack mold ready to place on the casting machine. Fig. 9 serves to illustrate the possibilities of stack molding. On the right is a wheel casting made one in a mold, while at the extreme left it will be noted that eight castings are made on the stick. The only limitation on the number of layers used in stack molding is the convenience and economics of the handling operations. Usually a greater number of castings made on a single stick increases the foundry yield, and this factor must be considered against the problems of handling, pouring, shakeout, and other foundry problems.

Very often it is found advisable to change somewhat the design of the casting to favor gating, feeding, and directional solidification in order to obtain more uniformly sound castings. Ordinarily, this can be done without altering the usefulness of the casting, if the engineer and foundryman will cooperate.

In good practice, the gating, feeding, and provision for directional solidification are different in centrifugal molding. The gates and feeders must be designed to suit this type of molding. The foundry technique also must be changed to suit the method. Most successful foundries have found it necessary to engineer carefully each job that is to be spun, and many jobs are found better suited for static molding.

The speed of rotation in semicentrifugal casting is lower than that used in true centrifugal casting, and hence the centrifugal pressure is less. However, this rotation keeps the liquid metal in motion. This action aids in flowing the metal into all of the cavities of the mold, and in more completely feeding the casting. It further insures against blows and voids caused by contraction during solidification. This produces sounder and more uniform castings.

This method is particularly adaptable for casting wheels, gear blanks, and other circular shapes.

Centrifuging

In the "centrifuging method" the molds forming the useful castings are positioned near the periphery of the revolving table. The metal is poured into a gate located on the axis of rotation and is fed into the molds by radial sprues. Centrifugal force is used merely to provide liquid pressure. Usually, two or more castings are made in each mold.

One of the earliest applications of this method is the old-time inlay-casting machine used in dentistry, as shown in Fig. 10. A plaster-of-Paris mold was attached to one end of an arm. The other end of the arm was pivoted to and supported by a pedestal; the arm being free to revolve around the pivot. Molten gold was poured into the mold and the mold was rapidly spun around the pivot by hand. The centrifugal force of spinning forced the molten gold into the intricate cavities of the mold resulting in a very sound casting accurately shaped.

A typical example of centrifuging is shown in Fig. 11, where five bogie-wheel hub castings are made in one mold. The center gate with the five radial sprues to feed the castings is shown.

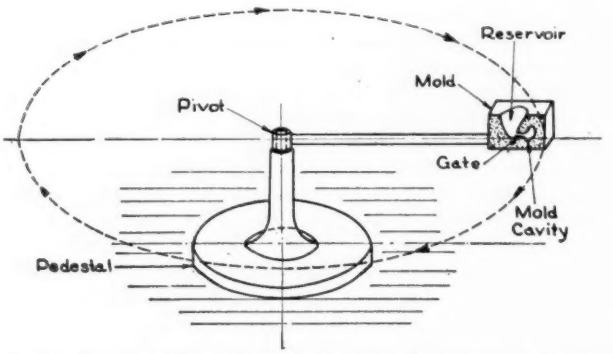

FIG. 10 DENTISTS' INLAY-CASTING MACHINE, ILLUSTRATING CENTRIFUGE CASTING

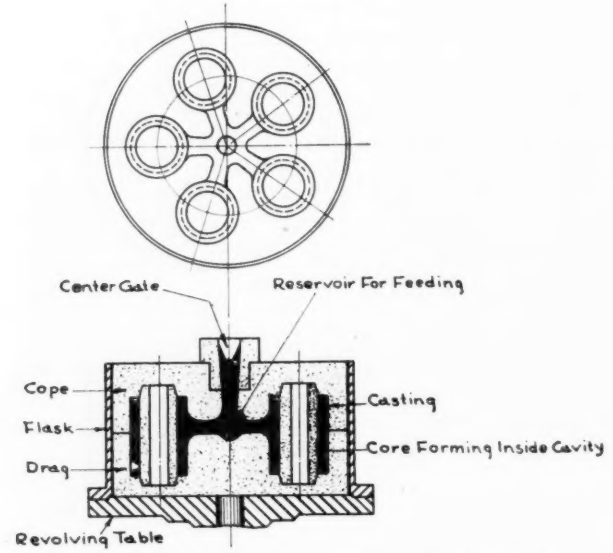

FIG. 11 CENTRIFUGE CASTING OF BOGIE-WHEEL HUBS

In this case a core is used to form the inside cavity of each casting. This method is also well adapted to stack molding, and many odd-shaped castings are made by this process. This is illustrated in Fig. 12 which shows bracket castings made by this method in one layer, and the same castings made by stack molding in eight layers.

The advantages of centrifuged casting are substantially the same as obtained in semicentrifugal casting. Yields above 85 per cent have been reported on jobs where formerly in static casting they were less than 50 per cent. On single-mold casting by the semicentrifugal method, yields have been increased from approximately 30 per cent to more than 70 per cent. The casting machines can be of simple construction, and therefore not too expensive, either in first cost or in maintenance. Floor-type units may be used which can be moved from one location in the foundry to another at little cost or inconvenience.

MACHINE CONSTRUCTION

Many different designs of centrifugal-casting machines are used. Those used in "true centrifugal" castings are of two types, i.e. (1) indirect-driven, and (2) direct-driven. In indirect-driven machines, the mold usually rests on four rollers. Two or more of these rollers are connected to an electric motor or other driving unit. Sometimes top rollers are used. A suitable pouring basin with spout, or orifice, is provided on the pouring end of the machine. This orifice, or trough, projects slightly inside the pouring end of the revolving mold. The principle of design is the same with relatively long casting machines as with short ones. Fig. 13 illustrates the usual design of this type of machine.

In making short-length castings, the mold is sometimes bolted to a face plate which is mounted on a shaft, and thus the mold is directly driven. This type design is shown in Fig. 14. There are many variations, but these two general types serve the purpose here. With both types of machines sand and metal molds are used.

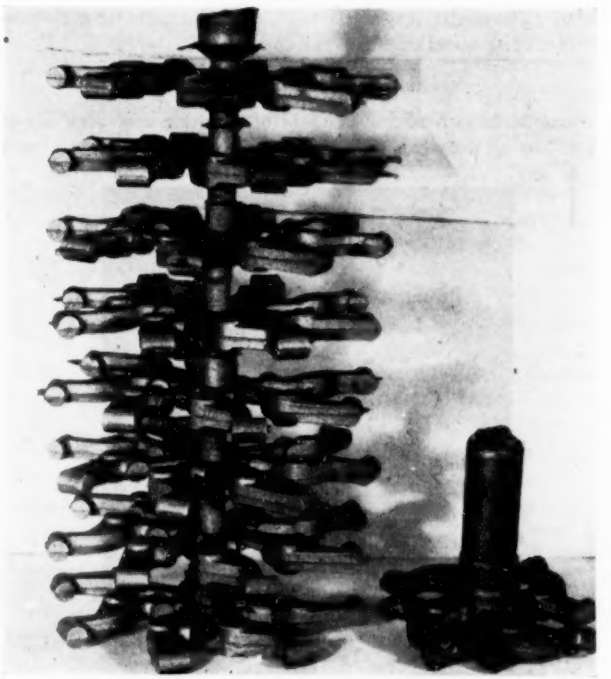

FIG. 12 BRACKET CASTINGS MADE BY CENTRIFUGING IN ONE LAYER (RIGHT); AND BY STACK MOLDING IN EIGHT LAYERS

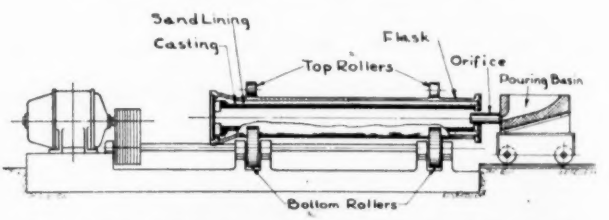

FIG. 13 TRUE CENTRIFUGAL MACHINE FOR LONG CASTINGS

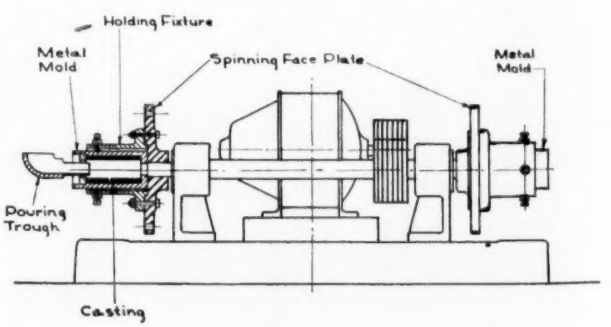

FIG. 14 TRUE CENTRIFUGAL CASTING MACHINE WITH MOLD DIRECT-DRIVEN

The machine used in the semicentrifugal method is identical with the one used in the centrifuge method. It consists usually of a vertical spindle on which a table is mounted, the flask being centered and securely clamped to the table, as shown in Fig. 15. Sometimes floor-mounted units with bevel-geared drives are used. This type of machine is illustrated in Fig. 16.

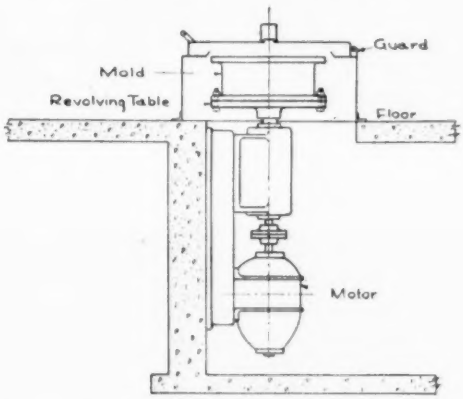

FIG. 15 PIG-TYPE CENTRIFUGAL CASTING MACHINE

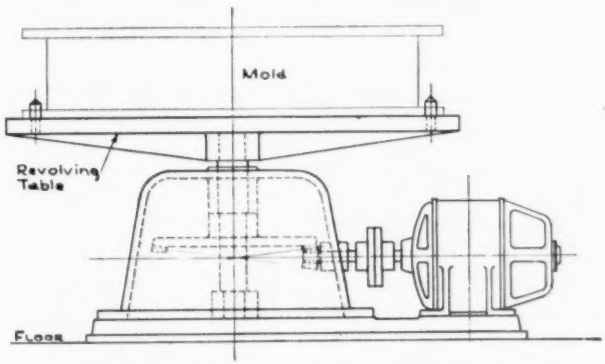

FIG. 16 FLOOR-TYPE CENTRIFUGAL CASTING MACHINE

Drives. Many types of motors have been used to drive centrifugal casting machines. Usually a speed range of 3 or 4 to 1 will meet all the requirements, and any driving unit with this range will be adequate.

TYPES OF MOLDS USED

Both metal and sand molds are being used extensively in producing castings by this method. Carbon or graphite molds have also been used for casting nonferrous metals. Each kind of mold has its place in centrifugal casting, and the type of casting to be produced usually determines the kind of mold best suited.

Permanent molds are best adapted (1) where large quantities of identical castings are to be made, (2) where the outside contour of the casting is such that it can be readily withdrawn from the mold after casting, and (3) where a fast cooling rate from the outside inward with attendant fine grain is desirable. They are also better suited for castings which have relatively uniform wall thicknesses, or without abrupt changes in wall thickness.

Permanent molds are usually made of cast iron or steel. When cast-iron molds are used, it has been found desirable to have a cross-sectional area of the mold 4 to 5 times that of the casting produced. The life of a permanent mold is dependent upon many factors and foundry techniques which have not yet been fully explored. Usually metal molds are kept at temperatures between 400 F and 800 F, during the casting operation. It is the usual practice to coat the mold with some form of facing between casts to protect it.

Sand molds are generally preferred (1) in the casting of long tubes where the metal must flow relatively long distances over the mold surface, (2) where the shape of the casting is such that the mold must be broken down to remove it, (3) where it is essential to be able to vary the dimensions and shapes of similar castings, (4) where relatively few identical castings are to be made, and (5) where a relatively uniform cooling rate through a thick section is desirable. Sand molds more commonly used are dry-sand, skin-dried, and oil-sand, and they are usually faced to prevent cutting. The cooling time of castings made in sand molds is much longer than in metal molds, thus the casting is free of chilled surfaces and is likely to have fewer casting strains. The sand used for centrifugal molding must be much stronger than in static molding to resist the added pressure and vibration caused by spinning. Usually it is found advisable to have a sand with higher permeability than that used in static molding.

Quite often a combination of metal molds and sand molds is used. Where it is desired to core holes of various shapes in castings, cores are used with the metal molds for this purpose. Often it is desirable to relieve the chill in certain portions of the casting, and this is done by using dry-sand cores. In some cases, there is a serious cutting action on the mold where the metal enters during the casting operation. A dry-sand splash core inserted in the metal mold to prevent this cutting action will materially lengthen the life of the metal mold.

MANY SPEEDS USED IN CENTRIFUGAL CASTING

In the manufacture of centrifugal castings a wide variety of mold speeds is used. The terms usually referred to are "peripheral velocity," and number of "times gravity" centrifugal force, or pressure, against the mold wall. The casting speed is linked with a number of other factors, such as pouring time, size and shape of casting, wall thickness, method of centrifugal casting being used, and others.

A general rule in the manufacture of relatively thin-wall tubes by the horizontal true centrifugal method in sand-lined molds is a speed of rotation which will produce a centrifugal force of 75 times gravity. Although this rule is generally accepted, it might be said that a favorable speed would be the lowest which would prevent "raining" during the pouring operation and yet provide enough force to squeeze out the foreign inclusions in the metal.

In practice the rotational speed of metal molds usually will be found lower than with sand molds, approximately 60 times gravity. This is because the chilling effect of the mold causes the molten metal to "pick up" more readily than in the refractory sand mold.

In the manufacture of cast-iron pipe in sand molds, the general rule is 75 times gravity. The general rule in the manufacture of cast-iron pipe in water-cooled steel molds is from 900 to 1250 fpm peripheral velocity, depending upon the size and thickness of the pipe to be cast.

An examination of the rotational speeds used by the various successful steel foundries leads to the conclusion that speed is not critical. Certainly it can be said that the ideal rotational speed cannot be determined at present, in the light of the many variables involved in true centrifugal casting of metals.

Likewise, there is a wide variation of rotational speeds used in semicentrifugal casting and in centrifuging. By both of these methods castings are being successfully made with peripheral speeds on the outermost part of the casting of from 100 to 1000 fpm. Here again, factors such as gating, pouring time, size and shape of casting, and type of mold used are to be considered. In

some cases the mold is filled with molten metal before revolving. In other cases the mold is poured at slow speed and then brought up to full casting speed.

Typical examples of centrifugal castings made by the author's company are shown in Figs. 17 to 23.

Physical Properties

The present emergency has given sharp impetus to the development and the production of centrifugal steel castings, not only as an improvement over static casting methods, but to produce parts formerly thought possible only by forging. Most of the physical properties of these castings have been found to compare favorably with those of forgings and, in many cases, to be better, depending upon how the casting is used.

The physical properties of centrifugal castings are practically the same as sound static castings. However, the ability to consistently produce sound homogeneous castings has made it possible to cast engineering parts that were not thought possible a few years ago. Once the foundry routine is adjusted, greater uniformity of product is usually obtained.

Compared with forgings it may be said that some centrifugal castings can be produced nearer to finished dimensions with consequent saving in machining cost. To illustrate, Fig. 24 shows

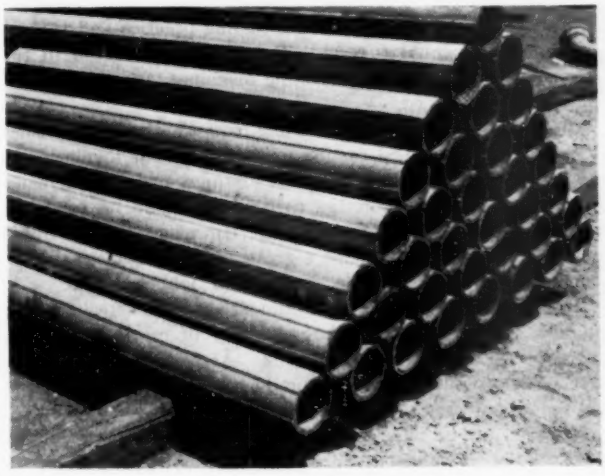

Fig. 24 Fluted-Tubes Stators

fluted tubes cast in 16 ft 0 in. lengths, later fabricated into small electric-motor stators. The as-cast tube is $4^{3}/_{4}$ OD and $4^{1}/_{16}$ ID. The OD tolerance of the casting is $\pm^{1}/_{64}$ in.; ID is $\pm .08$.

In forgings the physical strength and ductility values are higher in the direction of rolling than those taken across the direction of rolling. In a sound steel casting these values are equal in all directions, and in many cases advantage can be taken of this characteristic. Cone[3] has reported bursting tests of forged vs. centrifugally cast airplane cylinder barrels. The forgings split longitudinally at lower pressures than the bursting pressures of cast barrels. The cast barrels also showed greater "bulge" deformation. McCarroll[4] has also reported centrifugally cast gears to have better over-all properties than forged gears.

It should be pointed out that the chief advantage of this process is its ability to produce *high-quality* castings rather than low-cost castings. Adequate equipment and competent personnel for making chemical and physical tests on the product are essential. Rigid routine control on metallurgy, melting, sand conditioning, and the other factors of the process must be maintained to insure high-quality castings.

Conclusions

No one experienced in the art would venture to say that these methods of molding will revolutionize the steel-foundry industry or replace the great bulk of work done by forging. The size and shape of the casting place definite limitations on the process. However, the centrifugal method of casting is ideally suited for producing a vast variety of work. It is a relatively new method that is rapidly finding its place in the economic production of high-quality engineering parts.

Discussion

J. B. Caine.[5] This paper describes a noteworthy contribution to this increasingly important method of forming metals. To the writer, at least, the economic importance of this new process should not be overlooked. It is incontestable from the theoretical standpoint that the most efficient method of forming a shape slightly more complicated than a round or flat is by casting. The reason that steel castings have not been able to compete in price with other methods of forming relatively simple shapes in quantity has been the necessity of making an individual mold for each casting and that steel shrinks during solidification. This solidification shrinkage necessitates the use of such large risers to supply liquid steel to the solidifying casting that the steel foundry must pour twice as much metal in the average mold as that required for the casting.

If the design of the part permits the use of permanent molds and the true centrifugal process, an individual mold for each casting is not required, and, as the author states, yields approach 100 per cent. Casting is then the most efficient method known of forming these parts. If the part is more complicated, the semicentrifugal and centrifuging processes, although requiring an individual mold for each casting or group of castings, increase the all-important yield and therefore improve the competitive position of castings.

There is at least one other advantage that the author has not stressed, namely, the use of centrifugal force to impel molten metal into thinner sections than can be cast statically. With increasing emphasis on strength-weight ratios, it will be necessary to cast thinner and thinner sections to take full advantage of high-strength cast steels. A corollary of this is, of course, the use of centrifugal force to cast fine detail and within tolerances measured in thousandths of an inch.

Nathan Janco.[6] This paper is an excellent summation of the centrifugal process of casting steel, and its progress up to the present time. The various methods of centrifugal casting are clearly outlined, as well as some of the details of the actual production methods. The paper certainly should be of considerable interest to practical foundrymen, as well as to mechanical engineers concerned with the design of steel parts.

In the production of semicentrifugal castings, or castings produced by the centrifuging method, it is essential that conditions for directional solidification be set up, in order to obtain perfect castings. In a great many cases this can be accomplished only by pouring the metal into the mold while the mold is revolving. However, if the metal is poured into the mold at the usual speeds

[5] Metallurgist, Sawbrook Steel Castings Company, Lockland, Ohio.

[6] Chief Engineer, The Centrifugal Casting Machine Company, Tulsa, Okla. Mem. A.S.M.E.

used for spinning, the erosive action of the metal upon the sand-mold surface will be excessive and dirty castings will result. This is extremely important as it is to no avail if metallurgically perfect castings are produced and then have to be scrapped because they are dirty. During the past few years, this difficulty has been overcome by pouring the metal into the mold while the mold is rotating at speeds between 10 and 25 rpm. After the mold is full, or partially full, it is accelerated to the proper spinning speed. This has been found to be very successful in the elimination of dirty castings. A greater speed range than 3 or 4 to 1 is necessary in a centrifugal casting machine in order to accomplish the desired result.

The writer's experience concerning rotative speeds agrees with that of the author. A general average of the speeds used for the various types of centrifugal casting work, and which covers a very large percentage of all types of castings is as follows:

True Centrifugal Castings:

1 Sand-lined molds; speed, 60 to 75 times gravity.

2 Metal molds; speed, 40 to 60 times gravity.

3 Sand or metal molds, vertically spun; (generally castings whose length does not exceed 2 times the casting inside diameter); speed, 75 to 125 times gravity.

Semicentrifugal or Centrifuging Methods: Speed 600 to 1000 fpm; average, 800 fpm.

Centrifugal castings produced by the precision casting method, or "lost-wax" process, are castings which generally have very thin metal sections and usually are spun at rotative speeds below 600 fpm. In this case no advantage is being taken of the pressure of metal resulting from centrifugal force. The centrifugal casting machines are used only to provide a method of keeping the metal in motion, and thus permit the metal to run into thin sections and to obtain sharp definition.

The density and other physical properties of a perfect centrifugal casting do not differ from those obtained from a statically cast test bar which is a perfect casting. The principal advantage of centrifugal casting is that it is practical to produce castings in quantity which have physical properties approaching the best obtained in a test bar and yet achieve a high metal yield. To obtain such results by static casting methods is likely to be difficult and expensive.

E. C. Jeter.[7] There is a definite opportunity for the expansion of the already wide field of centrifugal castings. Sometimes, however, certain groups are prone to become overenthusiastic and to apply this method to a wide variety of parts, many of which would better have remained as forgings or as static castings.

Some of these are of such a design that centrifugal casting methods could not guarantee freedom from defects, and thus centrifugal castings would not be good enough from a quality standpoint. Physical-property requirements might be above those which can be met by centrifugal castings, although there probably would not be many such cases.

Other parts might be of such design that static castings would be of high enough quality and more economical. The simplicity of design might indicate that a forging would be more economical than either a centrifugal or a static casting. Unless castings are of such design as to be centrifugal "naturals," such as flanged cylinder barrels and symmetrical castings of that type, a static casting might be good enough or be more economical, unless for some reasons of design a very great saving in gates and risers is obtained.

In the final analysis the centrifugal method of casting should be applied intelligently to the parts for which it is best suited. Promiscuously making a wide variety of castings, many of which are not adapted to centrifugal casting methods, will do more harm to this field than any other one thing.

Anton Johnson.[8] The author has described comprehensively the various methods of centrifugal casting practice and the applications best suited to each. Details are also given in the paper of types of centrifugal casting machines, and the jobs for which each is adapted.

Confirming the author's concluding remarks, the writer wishes to state that centrifugal casting methods will not revolutionize the steel-foundry practice of static castings, owing principally to the fact that large-tonnage castings can now be produced statically, with resultant high yields. However, the centrifugal casting method can be applied a great deal more widely than is commonly believed possible, even in a jobbing shop. The writer's company operates a medium-sized electric steel jobbing foundry, which produces a large variety of castings with an average weight of 20 lb per casting. As high as 25 per cent of the monthly output has been produced by the semicentrifugal and the centrifuging methods?

Will the author please advise what is the dry permeability of the sand in centrifugal practice, and why a higher permeability is used than in static practice? Also, what method is used in pouring stack molds, i.e., are they stationary when poured, and then spun? If spun, what has been the author's experience, if any, with misruns or cutting of molds?

Some Characteristics of Rotary Pumps in Aviation Service

By R. J. S. PIGOTT,[1] PITTSBURGH, PA.

Only within recent years have rotary pumps been accorded a semblance of the technical consideration which has been expended upon the piston or plunger reciprocating type, and the centrifugal and turbine types, between which two groups occurs its sphere of greatest usefulness. The rotary can handle all pumpable viscosities at any pressure up to 1000 psi. It has other qualities such as the ability to handle liquids with considerable gas or vapor present. The present paper is devoted to a discussion of characteristics of gear- and vane-type rotary pumps which make them widely adaptable to lubrication-oil, fuel-oil supply, and other aircraft uses in which they predominate.

THE group of positive-displacement pumps generally known as rotary pumps lies between the piston or plunger reciprocating pumps, which are also positive displacement, and the centrifugal and turbine pumps, which are not. Rotary pumps have never received the amount of technical attention accorded the two other large groups, chiefly because, like the bat, they occupied a position between the "birds and the beasts." However, this stepchild of the pump family has come in for much more attention during the last 10 years than formerly, since it has been finally discovered that, given the same degree of design skill, the rotary pump is quite as good as, and in many cases better, than the other two general types, when applied in its proper sphere. The following generalizations can be made which apply to the whole field of applications:

Centrifugal pumps are best on low-viscosity liquids, such as water or light oil, and relatively large quantities at low or moderate pressure. The efficiency falls off badly at 2500 sec S.U. viscosity, and centrifugals are of no use whatever above 5000 sec S.U. The efficiency also falls off rapidly with reduction of size below 100 gpm, unless particularly fine design and smooth finish of impellers and passages are employed. The reciprocating pump is good on either high- or low-viscosity liquids, for all pressures, especially for high pressure, and for any size above 1 gpm. The centrifugal is always cheapest and smallest, in the field where it is best fitted. The reciprocating pump is always largest and most expensive, but has the high-pressure field (1000 psi up, at moderate to large size, all viscosities) almost to itself. There lies in between a field which the rotary may often fill better than either; it can handle all pumpable viscosities in any size, at any pressure up to 1000 psi. Two particular designs are satisfactory up to 3000 psi in small sizes, the radial-plunger and the axial-plunger designs. Durability is, in general, less than that of reciprocating pumps.

The rotary can also handle liquids with considerable gas or vapor present; the reciprocating pump is apt to develop difficulties under these circumstances, and the centrifugal gives up completely.

The rotary has now taken a prominent position in machine-tool operations, including presses for all sorts of oil-pumping duty, and may handle a variety of queer liquids like glue and tomato sauce, that are not very manageable with the two older and more considered types.

But in airplane service, practically all the pumps used are rotaries, mostly gear and vane types for lubrication and fuel supply, with some axial plunger types for hydraulic operations. We therefore become immediately interested in a study of inlet-side losses, as well as in general performance with and without air or vapor present in quantity. There have been serious failures of such pumps at high altitudes, particularly when air or vapor is present.

It is high time some of the hydraulics of such pumps were given the attention needed to provide good designs and installations for the purpose, i.e., successful high-altitude operation.

So little seems to be clearly perceived about capacity and efficiency that it even appears necessary to restate some principles which should be obvious.

The principal types of rotary pumps are as follows:

1 Gear: (*a*) Spur or helical external gear (any lube pump, aeronautic). (*b*) Straight or helical internal gear (Feuerheerd, Hill, Pigott).

2 Vane (Pesco, Chandler Evans, Vickers).

3 Oscillating piston (Kinney).

4 Screw: (*a*) Two screw (Quimby). (*b*) Three screw (Imo)

5 Plunger: (*a*) Radial plunger (American Engineering, Oil Gear, Northern). (*b*) Axial plunger (Waterbury, Vickers).

6 Lobular (Roots, Northern).

The following discussion applies to all types, but since we are for the moment most interested in the aviation applications, the examples and test data will be largely from gear and vane types.

Displacement of Gear Pumps

Many formulas for the displacement of spur and helical external-gear pumps have been used and published. All of those with which the author is familiar are based upon incorrect theory of what constitutes clearance volume, and some in rather general use are as much as 15 to 20 per cent in error.

The proof of this statement is that for years pump manufacturers have published test curves showing, for example, volumetric efficiency of 85 per cent at zero pressure difference. How can there be any leakage, or "slip," if there is no pressure difference? A pump always delivers substantially its full displacement at zero pressure difference, unless it is so badly designed as to be cavitating, or there is gas or vapor present.

Referring to Fig. 1, in a spur-gear pump, the full tooth-space volume of both gears is delivered around the outer side of the gears from suction to discharge side. The volume that is returned to suction from the discharge side is that which is sealed off from both sides, at the instant when two pairs of teeth first contact (seal point, see Fig. 1*a*). It is quite apparent that this volume has no relation to the volume under one tooth when fully meshed with the mating teeth on the center line between gears;

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

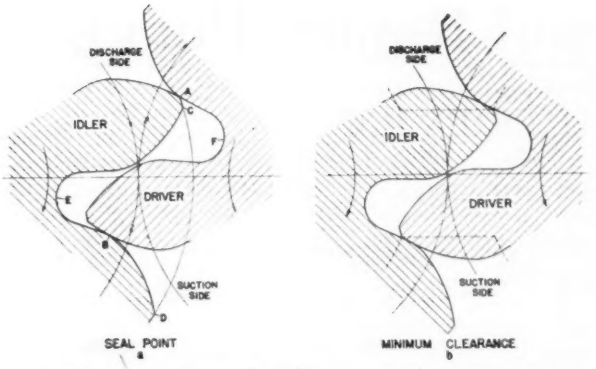

FIG. 1 SPUR-GEAR PUMP, SEAL-POINT, AND MINIMUM-CLEARANCE DIAGRAMS

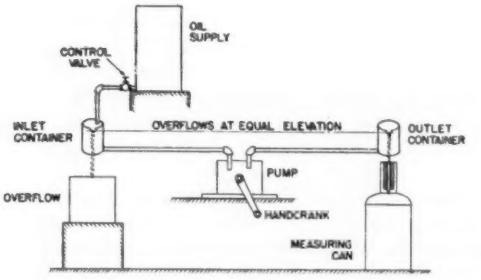

FIG. 2 HAND-CRANK DISPLACEMENT TEST

the latter is the usual clearance volume used for most displacement formulas.

Referring to Fig. 1*b*, the two pairs of teeth are now symmetrically placed on either side of the center line; this is the position of minimum volume and is 1 to $1^1/_2$ per cent less than that at the seal point, depending upon the number of teeth and the angle of attack. This seal-point area, and that of the tooth space, can be accurately planimetered, say on 10-times-scale drawing. The proof that this operation gives displacement and clearance volume correctly is as follows:

Fig. 2 shows a pump set up for the "hand-crank test." The two reservoirs are arranged with weirs for holding the static head the same on suction and discharge; the intake side is slightly oversupplied from another tank, so that there is always a slight overflow at the weir. The pump is then slowly hand-cranked, say 100 revolutions, and the overflow from the discharge-tank weir is measured in a suitable container, i.e., a glass graduate, or a standard test can. Since there is no difference in static head, and no measurable flow loss in the pump, at very slow rotation, there can be no slip.

The results of many hand-crank tests check planimeter values within 0.1 to 0.2 per cent, much better than usual pump-test deviations. It is important to have the displacement value as nearly exact as possible, since all systematic analyses of slip and mechanical losses depend upon it, and the effect of air or other compressibles can be calculated correctly only when the displacement and clearance volume are accurately known.

A convenient proof of no slip is to perform the hand-crank test on two liquids of widely different viscosity, for example, kerosene and an S.A.E. 30 lube oil. Since the slip is inversely proportional to viscosity and directly as pressure, the two values for displacement will always differ, if there is any pressure difference in the pump due to internal losses dependent upon speed of rotation. This can be shown by cranking too fast. When the two values agree, there is no slip and no pressure difference; the value is then exactly the displacement.

SLIP AND MECHANICAL LOSSES

The losses in any rotary pump can be divided into two classes, which can easily be segregated in an ordinary performance test. We can, from the test and the displacement, obtain delivery in gallons per minute, displacement gallons per minute, water horsepower, displacement horsepower, and brake horsepower.

If we divide total losses into slip and mechanical losses, we can get two general values of considerable usefulness. These two values aid in detecting what details of a pump should be changed to obtain improved results.

Slip, obtained from (displacement gallons per minute—delivery gallons per minute) can be correlated with pressure difference across the pump, viscosity, and speed. Mechanical losses comprise bearing and shaft-packing friction, viscous shear in running fits at teeth or vanes, and sides of rotor, and for convenience, the hydraulic inlet and outlet losses, such as port skin friction, losses due to turns in ports, or diffusion streams, and centrifugal

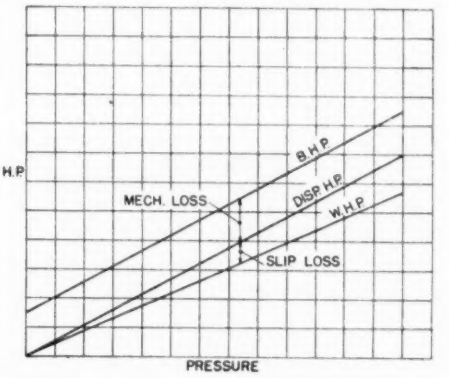

FIG. 3 CONSTANT SPEED AND VISCOSITY, VARYING PRESSURE

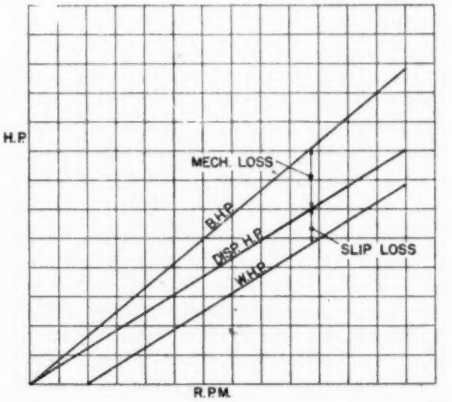

FIG. 4 CONSTANT PRESSURE AND VISCOSITY, VARYING SPEED

effects. Every positive-displacement pump pumps the full displacement volume, but some leaks back to suction, after the work has been done on it. Slip horsepower loss is therefore merely the difference between displacement horsepower and water horsepower as delivered. Friction horsepower, or mechanical loss, is the difference between brake-horsepower input and displacement horsepower. Fig. 3 shows the analysis for a pump running at constant speed and viscosity of liquid, varying pressure. Fig. 4 shows the same for varying speed, pressure difference, and viscosity constant.

After some struggles, we succeeded in calculating the slip and friction of rotary pumps closely enough to predict what the per-

formance should be on test, within a few per cent. It is a somewhat tedious job, but mathematically simple. Some general forms indicate the nature of the losses.

Since all rotary pumps are capillary-sealed, i.e., close fits, the flow for most liquids above water in viscosity and at pressures less than 500 psi will be in the viscous region and follow the general formula

$$\Delta p = \frac{0.00173\ \mu l v}{b^2}$$

where

Δp = pressure drop, psi
μ = viscosity, Reyns (= centipoises × 0.000672)
l = length of capillary path, ft
v = velocity, fps
b = clearance, ft

If the value of $\frac{2b\rho v}{\mu}$ is greater than 1200, the flow is turbulent and follows the law

$$\Delta p = \frac{0.000054\ f l \rho v^2}{b}$$

where f is the friction factor and ρ is the density in lb per cu ft.

If the clearances are not in excess of 0.010 in., and ordinary ground finishes are used, the passage may be considered rough, f becomes constant at 0.054, and viscosity has no effect. For finer finish and larger clearances, roughness is low enough to make f vary with Reynolds number, and the author's curves[2] for this purpose may be used. The maximum effect of viscosity with perfectly smooth passages would be 0.25 power of μ.

The teeth of gears not in pressure contact, such as may be found in the internal-gear pumps at the out-of-mesh position, and the rounded tips of vanes have substantially a line seal, consequently, they may be treated as rounded-approach orifices; they will be in the turbulent region at considerably higher viscosity or lower pressure than the relatively long path seals. Sides of gears, vanes or rotors, and square tops of external-gear-pump teeth will nearly always be in viscous flow.

In pumps operating at fairly high rotative speed, low or moderate pressure and very viscous liquids, there is a noticeable temperature effect, owing to the high rate of viscous shear in the capillary-seal areas, and to heat added by the energy loss from slip.

This effect may be great enough to reverse the expected and usual reduction of slip, with increase of viscosity, by heating the liquid in the clearance spaces and thus reducing the viscosity therein. For example, a pump running at 1150 rpm, peripheral speed of gear 34 fps, 100 psi pressure, the slip reaches a minimum at about 1500 sec Saybolt viscosity, and thereafter increases with viscosity of the pumped liquid.

From the foregoing, external-gear-pump slip will be largely in the viscous region for aviation lubrication pumps and slip will therefore vary chiefly as p/μ. In any case, the majority of the pumps in aviation service operate at pressure ranges from 10 to 100 psi and on viscosities of not less than 30 cp (hot), so that the slip is not very large anyway, usually 3 to 6 per cent.

The mechanical losses are more troublesome to calculate, and since there is not much interest in the matter for airplane pumps except perhaps the hydraulic pumps, it will not be detailed here.

[2] "The Flow of Fluids in Closed Conduits," by R. J. S. Pigott, *Mechanical Engineering*, vol. 55, 1933, pp. 497–501, 515; also Kent's "Mechanical Engineer's Handbook," John Wiley & Sons, Inc., New York, N. Y., 1936.

Inlet-Side Losses

The inlet-side losses become extremely important for both oil and fuel pumps in high-altitude flying, and hitherto this interesting and valuable field of investigation has been almost completely neglected. A vacuum gage at the inlet connection of a pump gives slight indication of the minimum absolute pressure within the running parts of the pump.

Referring to Fig. 5, it is seen that one of the forces opposing

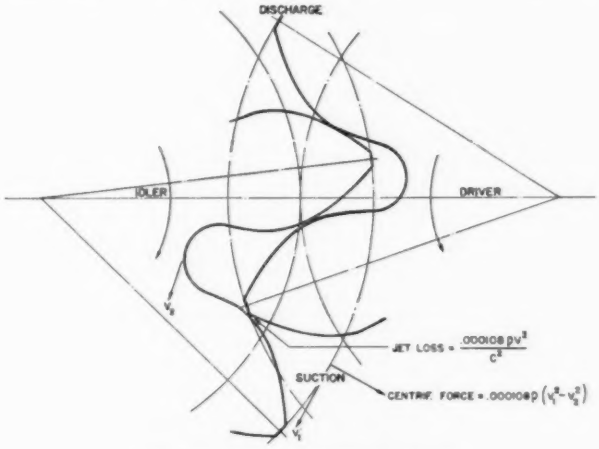

Fig. 5 Spur-Gear-Tooth Loss

flow is the centrifugal force of the ring of oil in the teeth; the second loss is the jet head required to flow the oil between the tip of one tooth and the side of the mating tooth, so as to supply the increasing volume of the space enclosed by these teeth. A third loss is the suction chamber, or port loss, and consists of the skin friction, and the diffusion of the stream from a round pipe to a much larger square section in a very short distance.

While the author has calculated these losses with quite reasonable success, fortunately it is unnecessary to depend upon any estimates, as the inlet-side loss is very easily measured.

The theoretical analysis shows, however, that the suction-side loss does vary at different positions of the gear teeth or vanes, and the measured loss by test is an intermediate value between the maximum and minimum calculated loss.

Two test methods will yield the total inlet-side losses directly. It is necessary that the liquid used have a very low vapor pressure, and be substantially free of dissolved gases. Ordinary lubricating oil, S.A.E. 10 to 50, has a very low vapor pressure, but may contain dissolved air up to 8 or 9 per cent by volume, at 1 atm and 68 F. A convenient stripping method is to restrict the inlet of the pump by means of a valve, and operate the weigh system with the pump cavitating 50 or more per cent of its normal capacity, circulating the whole body of oil in the system 5 to 10 times. Then make the cavitation tests immediately, before any appreciable air is reabsorbed. This method does quite well for most tests, but since air is slowly reabsorbed, and moreover does not strip completely, the method is not rigorous but represents rather closely the best that may be obtained in flight. A better method for air-free determinations is to use a vacuum tank weigher and operate the whole system under vacuum, sealing at possible leak points such as pump-shaft packing and valve stems with suitable oil supply. By this method, all air is positively stripped out. One method of test is to run the pump at constant differential pressure, increasing speed until the pump begins to cavitate. Fig. 6 shows such a test. Up to the cavitation point, since slip varies with $\Delta p/\mu$, and both Δp and μ are constant, the slip is constant, and the delivery line parallels the displacement.

At the point where the delivery line first departs from parallelism to the displacement line, the remaining pressure difference between the absolute pressure, measured at the inlet flange, and the barometer, is equal to the required pressure to deliver full flow to the pump.

By restricting the inlet with a valve, the pumps can be made to

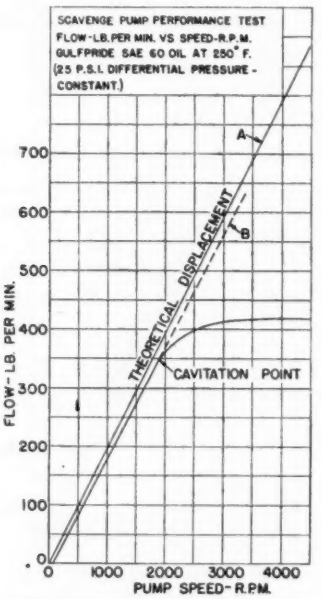

FIG. 6 SCAVENGE-PUMP PERFORMANCE TEST

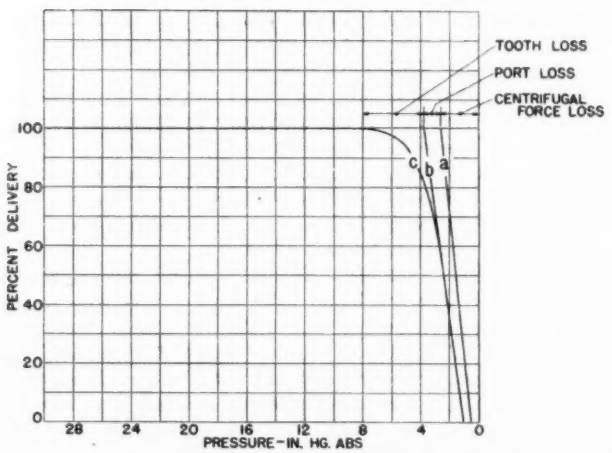

FIG. 7 CAVITATION TEST, CONSTANT SPEED

cavitate at a lower speed, and a plot made of pump loss versus speed.

The other method is to operate at one or more fixed speeds, constant pressure differential, and restrict the inlet until the pump cavitates, and this can be continued down to the point of pump instability. This method yields the same results and also gives performance curves exactly as the pump behaves in high-altitude flying. Moreover, it is a more convenient plot for performance testing with entrained air present, as also occurs in flight. This method of test is shown in Fig. 7. The centrifugal force is shown at a. Its value decreases from the full amount, $\Delta p = 0.000108\rho(v_1^2 - v_2^2)$ with "solid" oil, to 20 to 30 per cent of this amount at zero delivery. The reason is plain—as the pump goes into cavitation the amount of oil does not fill the tooth space. The remainder is oil vapor (no air is present). The effective density is therefore reduced and with it the centrifugal force. Centrifugal force does not decrease to zero at zero delivery, because if the differential pressure across the pump is maintained, the slip remains the same and returns to suction, and the clearance volume is also returned to suction, so that the pump at zero delivery must actually still be pumping slip and clearance volume in order to maintain pressure.

For example, in Fig. 7, the full centrifugal force is 2.77 in. Hg with the tooth spaces full of oil. The slip is 5.69 per cent of displacement, clearance volume 25.8 per cent of displacement, a total of 31.49 per cent. This value must be reduced to tooth volume as follows, remembering tooth space is displacement plus clearance: $\frac{31.49}{1.258} = 25.0$ per cent.

That is, the tooth space is 25 per cent oil, 75 per cent air or oil vapor. Neglecting vapor weight, the effective density is then 25 per cent of that full of oil, and the zero delivery centrifugal force will therefore be $2.77 \times 0.25 = 0.69$ in.

The calculated port loss added to the centrifugal force (line a) gives line b which coincides with the test line c from zero delivery up to about two thirds of full delivery, when the test line c shows a further loss, i.e., the tooth loss (see also Fig. 5). This curve shows an effect that is logically to be expected. Calculation of this loss from the simultaneous values of increasing volume and the area of the opening between the teeth, including side pockets (if any) shows that the initial tooth loss is high at the seal point, decreases rapidly as the teeth come out of mesh, and vanishes when the teeth are fully out of mesh; about 45 deg with seven teeth, for example. When inlet absolute pressure exceeds the full tooth loss, this region of high loss has a pronounced effect, but as the inlet pressure is reduced, cavitation starts in the full-mesh region in each pair of teeth and extends farther and farther as the inlet pressure is reduced an additional amount. The result is

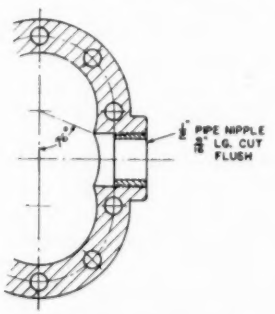

FIG. 8 SPUR-GEAR PUMP, CONDITION NO. 1

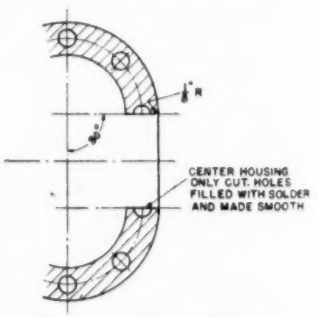

FIG. 9 SPUR-GEAR PUMP, CONDITION NO. 1-A

that the high-loss region is less and less well filled, consequently, the average tooth resistance drops off and finally vanishes altogether. At this time most of filling is done in the open region after the teeth are out of mesh, where there can be no tooth resistance.

These calculations are made mainly to disclose the nature and variation of the three losses; quantitative results are easily obtained by test. But such calculations show the path for improvement.

For example, one immediate indication is that the arc of gear exposed to entry of fluid on the suction side has importance. Many gear pumps are built, as shown in Fig. 8, with very little arc exposed to suction side. When opened up to 90-deg exposure, the reduction of break-point was from 7 in. to 5 in. Hg. The optimum arc exposed is 90 deg to not over 135 deg, from the center line of the gears, shown in Fig. 9.

Effect of Clearance Volume and Air

Clearance volume in a rotary pump corresponds, in a piston pump, to the space between piston and cylinder head at the end of the stroke, together with the volume of the ports from the cylinder to the valves. There is, however, a difference in operation; in the piston or plunger pump, the clearance volume is never delivered to the discharge chamber, whereas in a gear pump, the whole tooth space (which includes the clearance volume) delivers to the discharge chamber, and the clearance volume then takes a fraction of this volume back again to the suction.

If a liquid, no gas present, is handled, the clearance has no effect on the delivery; it is simply displacement minus slip. But if air or other compressible gas is present, the clearance has a pronounced effect upon performance, much the same as in a compressor.

The tooth space supplies all the oil that will reach the discharge chamber, but a volume of oil leaks back as slip, mixed of course with the compressed air, and a volume of oil and air is also returned to the suction in the clearance volume. All quantities as fractions of tooth space:

Q_t = tooth-space volume per unit of time delivered to discharge side (= 1.000)
Q_c = clearance volume oil returned to suction
Q = delivery of pump
a_t = air/mixture at tooth inlet side pressure p_t
a_2 = air/mixture at discharge pressure p_2
a_1 = air/mixture at inlet pressure p_1
p_1 = inlet pressure, in. Hg abs
p_t = tooth pressure inlet side, in. Hg abs
p_2 = discharge pressure, in. Hg abs
s_t = slip, a function of $\dfrac{\text{pressure difference}}{\text{viscosity}}$ $\left(= \dfrac{s_d}{(1 + c_d)}\right)$
c_t = clearance volume $\left(= \dfrac{c_d}{1 + c_d}\right)$
s_d = slip, c_d = clearance } in the usual term, fraction of displacement

The air delivered to the discharge side is compressed to a reduced volume.

$$a_2 = \frac{\left(\dfrac{a_t p_t}{p_2}\right)}{(1 - a_t) + \left(\dfrac{a_t + p_t}{p_2}\right)}$$

It is evident, then, that the clearance volume fills with a mixture of very much higher oil concentration than that which entered the teeth. The value for oil returned in the clearance is

$$Q_c = c_t - \frac{c_t\left(\dfrac{a_t p_t}{p_2}\right)}{(1 - a_t) + \left(\dfrac{a_t p_t}{p_2}\right)}$$

The delivery, in fraction of tooth space, is

$$Q = Q_t - s_t - Q_c - a_t$$

$$= (1.000 - c_t - s_t) - a_t + \frac{c_t\left(\dfrac{a_t p_t}{p_2}\right)}{(1 - a_t) + \dfrac{a_t p_t}{p_2}}$$

The first parenthesis is the normal full liquid delivery of the pump, no air present. The second portion is the effect of air.

To avoid confusion, it should be made clear that slip is still a function of p/μ, and it is not affected by the air present, provided the flow is viscous. In turbulent flow, the pressure drop for a given liquid flow goes up in proportion to the volume of air present, but rationalizing from the usual formulas and tests shows that it has no effect in viscous flow. We are concerned almost exclusively with viscous flow in the capillary seals of aviation pumps, on account of the small hydraulic depth and relatively high viscosity. Under these circumstances, the slip can be taken as constant, regardless of air present in the mixture, provided pressure difference and viscosity are constant.

Calculating for a series of values of a_t from 0.05 to 0.40, we get delivery, Q. Having deliveries, we can now take the pump inlet loss from a curve such as Fig. 7 for the particular pump involved, which added to p_t will yield p_1.

Having found p_1, we can convert the selected values of a_t to a_1 the air percentage at the inlet (where it will ordinarily be possible to measure it by test). Then by plotting p_1 versus a_1 and Q versus a_1, we can take simultaneous values of Q and p_1 for selected values of a_1, such as 5, 10, 15 per cent and cross plot in the form we want as shown in Fig. 10. This form of plot is the most convenient for test results likewise. In this figure, the vacuum test of the actual pump for cavitation air-free is for a pressure pump operating at 2700 rpm, 90 psig discharge pressure, aviation 120 oil at 185 F. For any other speed or discharge pressure, the figures of course change, since slip or displacement change; a change of oil temperature or viscosity alters the plots very little, since the slip is small in any case.

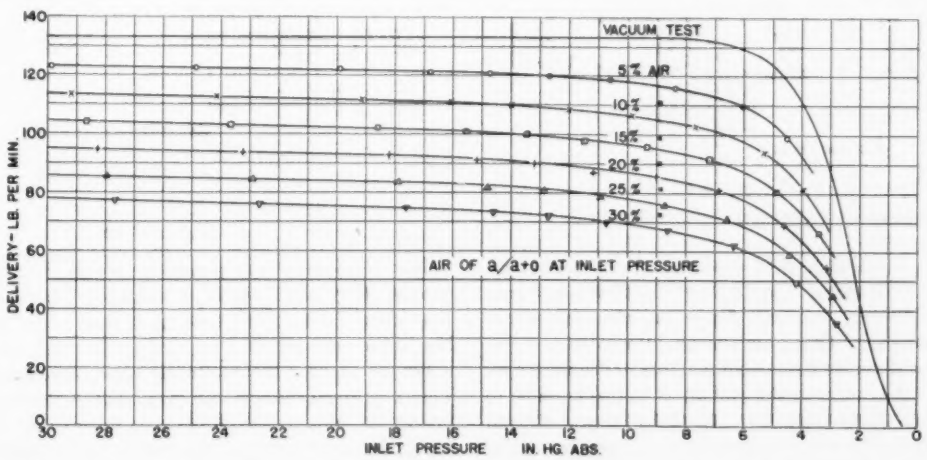

Fig. 10 Calculated Performance, Standard Spur-Gear Pressure Pump, 90 Psi Discharge Pressure

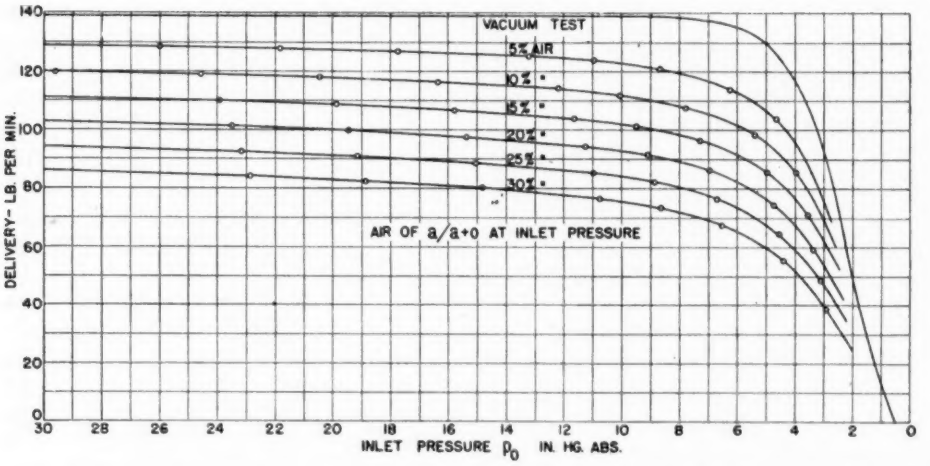

FIG. 11 CALCULATED PERFORMANCE, STANDARD SPUR-GEAR PRESSURE PUMP, 20 PSI DISCHARGE PRESSURE

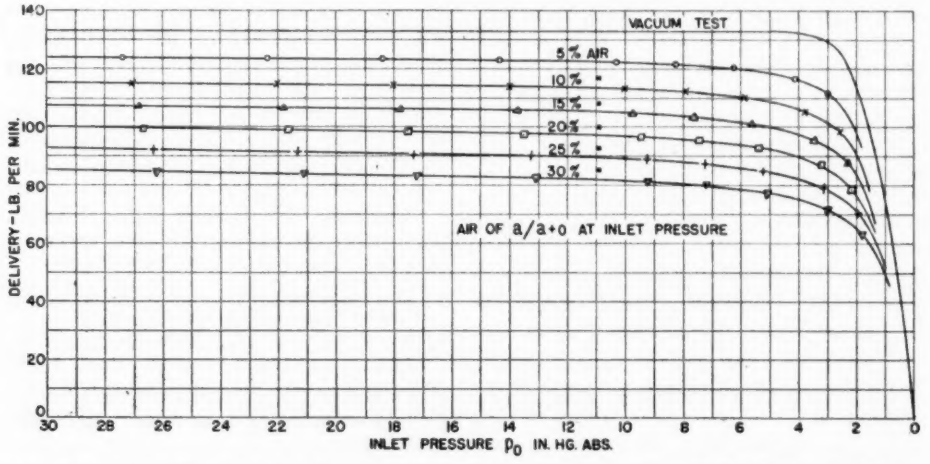

FIG. 12 CALCULATED PERFORMANCE, INTERNAL-PORTED EXPERIMENTAL PUMP, 90 PSI DISCHARGE PRESSURE

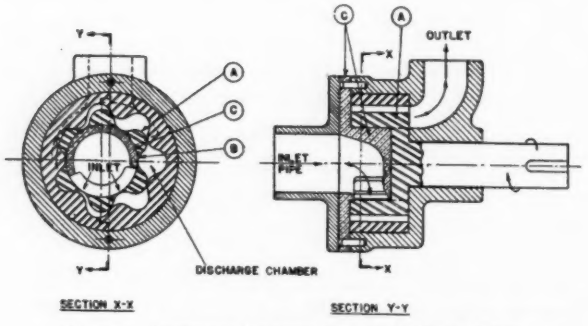

FIG. 13 INTERNAL-PORTED INTERNAL-GEAR PUMP

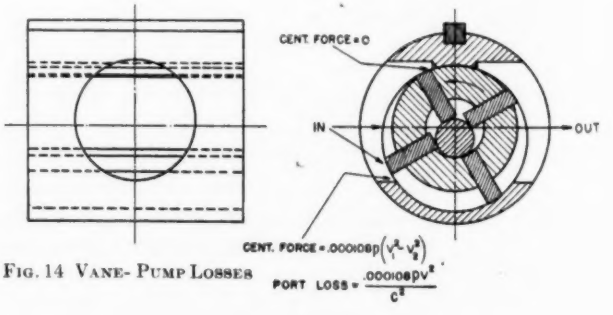

FIG. 14 VANE-PUMP LOSSES

Fig. 11 shows a recalculation of the same pump for 20 psi discharge pressure, scavenging. Fig. 12 shows the 90-lb conditions for a pump, same delivery, but only 5 per cent clearance and a much lower intake loss. This pump is an internal-gear type, shown in Fig. 13, and avoids the centrifugal loss in the intake by taking in the oil at the center of the pinion; it is also possible to get very low values of clearance with the internal-gear design, since the tooth practically fills the tooth space; in a spur gear, clearance cannot be reduced below about 12 per cent.

VANE PUMPS

The situation in vane pumps is very nearly parallel to the gear pumps; they both take in oil at the periphery, so are subject to centrifugal force; both have port loss. But there is no tooth loss in the vane pump.

Fig. 14 shows a diagrammatic view as commonly constructed. The centrifugal force at the beginning of the suction "stroke" is practically zero, as the oil between rotor drum and sleeve has no depth, but at the end of the stroke as the blade is just meeting the lower abutment, the depth is nearly twice the eccentricity so

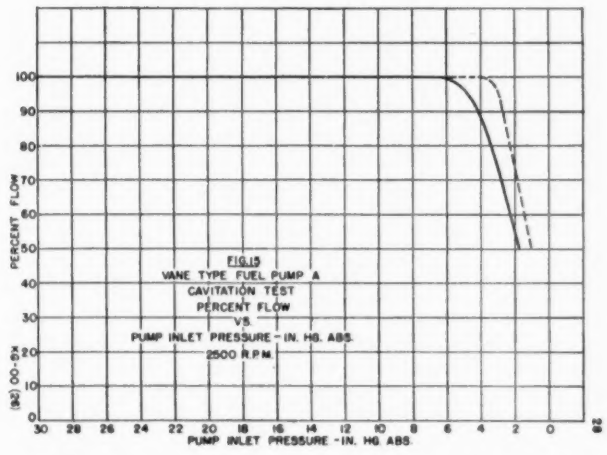

FIG. 15 VANE-TYPE FUEL PUMP A, CAVITATION TEST

that the centrifugal force is nearly double that of a gear pump of corresponding diameter. The port, which is in the sleeve, is usually a round hole and therefore the area for filling, under the edge of the descending blade and the lower edge of the port, is decreasing much faster than the required rate of filling of the space between rotor blades and sleeve. Consequently, the port loss becomes quite substantial.

The cavitation test on such a pump is shown in Fig. 15 and is worse than that of a gear pump of the same diameter and speed. There is, moreover, little need for so much loss. A simple change in the port for better terminal velocities lowered the losses 30 per cent. This pump is typical of several made by different manufacturers, and it is obvious that the designers have not yet paid enough attention to the hydraulics of the operation.

SOME GENERAL DATA

The following is a summary of the pump situation at the present time:

Taking a pump of $1^1/_2$ in. gear or sleeve diameter, or a centrifugal of the same eye diameter, and running at 2700 rpm on aviation oil, the losses are about as follows, at the point of cavitation:

1 External gear pump, 7 in. Hg best, many designs now in actual flight up to 11 in. Hg.

2 Vane pump, 5 in. Hg best, most designs now in use 6.5 to 7 in.

3 Internal-gear pump, Fig. 13, 3.0 in. Hg.

4 Centrifugal boosters, as in use 3.5 to 5 in. Hg.

It is perfectly obvious that if we are to fly these pumps satisfactorily at 50,000 ft, which is the present aim, the total losses in suction piping from tank and to the interior of the pump must be less than 3.43 in., the barometric pressure at that altitude.

Since the piping may have losses from 1 in. Hg at full flow to as high as 7 or 8 in. in some bad cases, not much is left to fill the pump. Clearly the pumps must be designed for a total loss on the suction side of the pump which, including any pipe losses from the tank, does not exceed the barometric pressure at the maximum altitude desired.

We have several ways of attaining this end:

1 Design the pumps for low inlet loss.

2 Design the piping for lower loss than is now common, eliminating all sharp ells, restrictions, and quick disconnects, possible.

3 Put the pump drowned at the sump or tank, and avoid all inlet piping.

4 For those cases where a considerable change of piping and pump is not a feasible fix for designs now flying, use low-loss boosters at the sump or tank.

It is of course true that we can always take some advantage of the reduction of inlet loss when the pump operates below its cavitation point, which is usually the condition where failure will occur (see Figs. 10 and 12, for example), and that is where the pumps usually are operating in flight, since some entrained air is always present in the oil and probably always will be. The path for successful selection of a pump is therefore rather clearly indicated. Let us use the pressure pump as an example; to fly at 50,000 ft means 3.43 in. barometer. For a normal short line from tank to pump, we can assume the line can be designed for, say, 1.0 in. loss at 110 per cent of normal new engine flow. That will leave 2.43 in. for the pump loss. About 10 per cent air at tank at present should be allowed for a poor tank at low level of oil, and the pump can then be selected that will deliver the required 110 per cent of new engine flow, with 10 per cent air at the tank, and at 2.43-in. pump loss, from curves such as Fig. 7.

Even without any tests, these losses may now be quite accurately and safely calculated so that the design can be assured of success before building the job.

The foregoing discussion on pumps has only touched on major points; it is hoped that this sort of study will be carried further by those directly interested in building engines, pumps, and planes.

Discussion

R. A. JEHEBER.[3] Referring to the section entitled, "Slip and Mechanical Losses," there are some statements which the writer feels are somewhat oversimplified and do not reveal what is actually happening in many cases. These are: "Every positive-displacement pump pumps the full displacement volume, . . . Slip-horsepower loss is therefore merely the difference between displacement horsepower and water horsepower as delivered. Friction horsepower, or mechanical loss, is the difference between brake-horsepower input and displacement horsepower." Figs. 3 and 4 of the paper are based on these statements.

The writer bases his opinion on past experience with reciprocating pumps; it should apply to rotary pumps as well, as they are the same type, that is, positive displacement. Several years ago when the majority of liquids pumped (mostly water) were practically incompressible, the author's statements would have corresponded closely to the truth. Developments in oil-refinery practice, however, soon showed that the word "slip" contained more than one type of loss.

If we start from the common accepted definition of "slip" as used by the author (displacement in gallons per minute minus delivery in gallons per minute), we can divide this slip into two main types as follows:

1 *Full Power-Loss Slip.* In other words liquid which leaks back to the suction after full discharge pressure has been built up in it. Examples of such slip are leakage past valves or pistons (in reciprocating pumps), or clearances (in rotary pumps) from full discharge pressure to suction pressure.

2 *No (or Low) Power-Loss Slip.* In this category we have such types as the following:

(a) Liquid which falls back to the suction before pressure builds up (for example, the liquid which falls back through the suction valves of a reciprocating pump while they close, before the build-up of pressure. Another example, rather extreme to illustrate the point, would be a four-plunger pump with one suc

[3] Director of Research, Mack Manufacturing Corporation, Plainfield, N. J. Mem. A.S.M.E.

tion valve stuck open so that one plunger, although it travels back and forth, does not do any effective work; assuming ideal operation for the other three plungers this positive-displacement pump would pump only three quarters of the full displacement volume).

(*b*) Liquid which cannot be drawn in because it has been displaced by air or vapor (an extreme example of this would be to connect air instead of the liquid to the suction valve[s] of one plunger. In a four-plunger pump, this would again mean that this positive-displacement pump would pump no more than three quarters of the full displacement volume).

(*c*) Liquid which cannot be drawn in because of expansion of the liquid trapped in the clearance space. To illustrate, let us imagine a pump handling compressible liquids which expand in the clearance space so that its plungers travel one quarter of their suction stroke before the suction valves can open; here again this positive-displacement pump would pump no more than three quarters of the displacement volume.

There are of course some volumetric losses which fall partly in the first and partly in the second category, such as, for example, liquid which leaks back while the pressure is only partly built up. In a 1000-lb differential-pressure pump, for instance, the amount which leaks back from 250 lb differential pressure might be one-quarter loss of the first type and three quarters loss of the second type.

This second type of slip is far from negligible for such liquids as hot oil or propane close to the boiling point where they are quite compressible and may also pull vapor.

As a matter of fact this was brought forcefully to the writer's attention in some tests with large reciprocating-plunger pumps where the effect of this second type of slip was so great that the brake horsepower required to drive the pump was less than the displacement horsepower based upon geometrical displacement (geometrical displacement of the pump in gallons per minute times differential pressure of pump in pounds per square inch divided by 1715). In plunger pumps there is not much argument as to what constitutes the geometrical displacement.

It might be said that this is a special case of a pump which functions partly as a compressor. This may be true, but there are enough modern applications in oil-refinery work and high-altitude flying to warrant its recognition.

The author is fully aware of this second type of slip, or should we say, volumetric loss; he recognizes some of it in other parts of his paper as "effect of air or other compressibles" also "effect of clearance volume and air;" only he does not call it "slip." This would suggest that the disagreement could perhaps be one of definitions and words rather than one of principle. Possibly the author has in mind making a correction to a "reduced displacement" which would be equal to the geometric displacement minus a certain value representing this second type of slip. If this is the case, it would be interesting to know how the various factors are evaluated in such a correction.

It is agreed with the author that theories used in the pump industry should undergo a general overhaul so that they can be adapted to problems encountered in present-day practice.

W. L. Weeks.[4] During the past 2 years or so the Wright Aeronautical Corporation has worked very closely with the author's organization on problems of air entrainment and of refinement of oil-pump design.

Since the investigation of inlet ports and tooth-loss effects, made by progressively cutting away the inlet side of a submerged pump, was one of the jobs they did for us, it is natural that we are in general agreement with this paper.

[4] Project Engineer, Wright Aeronautical Corporation, Paterson, N. J.

In the successful effort in making his paper a digest, some points are necessarily condensed. With some slight urging, the author might expand a few points. For instance, a more detailed concept of the centrifugal-loss line *a* in Fig. 7 might be of interest. The author might explain that, while for purpose of general discussion, this line may be considered straight, it actually is a slightly curved one as calculated for conditions beyond the start of cavitation. To us it is an interesting even if not a highly important point.

Another item which is interesting in some phases beyond the present exposition is the one the author calls "jet loss."

When we started the research with Gulf, we already knew inlet ports could be bad if too narrow. As a matter of fact, we had widened them in some pumps where the location of studs would permit. But the pump's volumetric efficiency at altitude still left much to be desired. At that time we had no evidence that the spur-gear pump was not as good a type as any, for the job; and we had investigated others.

The question of volumetric efficiency being tied in with pump gear-tip speed gave us an incentive to check empirical figures we had heard on tip-speed practice. All told, we felt that every factor in the action of a spur-gear pump should have its possibilities exhausted by research.

We soon found that our program dovetailed very well with some analytical studies the author had made. The now completed research leaves the spur-gear-pump ceiling quite predictable and the limitations of this type pump well established before we adopt other types.

A very clear picture of various loss factors is given in this paper, but one which concerned us a year ago is slighted. It deserves consideration.

The author has pointed out that loss by centrifugal force can be evaluated. He shows that loss in the unmeshing process of the gears, labeled "jet loss," is not only a difficult one to evaluate, but that it can easily be avoided by making the inlet port reasonably wide.

In the research with the mutilated and submerged oil pump, one factor we tried to clarify was that called shock loss, namely, the loss caused by the struggle of the liquid to get in behind a gear tooth as it speeds across, and even partly against, the path of liquid flow through the inlet port.

Referring to Fig. 7 of the paper, and the "test line *c*," it may be said that even in the flow plot of a pump with a very wide inlet port, this line *c* is still a fairly easy curve, showing a loss imposed aside from the computable port and centrifugal ones. And yet, with such a wide inlet port, the author says (and we certainly subscribe) the "jet loss" is practically negligible. A reasonable deduction might be, then, that test line *c* represents the loss due to shock of sudden change of direction of liquid entering the rotors, even during exposure of wide-open tooth spaces. In fact this interpretation is indicated in the report of the tests thus: ". . . . the shock losses are practically independent of the gear exposure." Also, in the discussion section of the report, where housing-inlet, centrifugal, and acceleration losses (the latter, the author has spoken of, in his present paper as jet loss) are treated, the last item is shock loss. But, although given last place in discussed losses, this loss is evaluated in the over-all, as follows: "The major portion of the loss indicated by the tests, after deducting the calculated centrifugal and inlet friction losses, is that due to shock brought about by sudden changes in the velocity and direction of oil flow." We certainly agree with the report statement.

It is believed the author will agree that the flow curves from the internal-ported gear-type pump, shown in section in Fig. 13, show more delay in cavitation than can be explained by centrifugal aid to rotor filling, and designedly low inlet-port loss, when

compared with the flow curve from a wide-ported spur-gear pump. This could be explained by the fact that, although in both types of pump the teeth move practically crosswise of oil flow, the cross-sectional shape of the pinion (or inner rotor) teeth and the profile of the teeth of the outer rotor in the I. P. pump are much cleaner in point of flow lines, than are spur-gear teeth to radial entry of liquid.

Does the author feel that this comparison further supports the status given to shock loss, or what we like to call tooth turbulent-entry loss, in spur-gear pumps, as stated in the test report?

In no sense is the foregoing questioned correlation pertinent to the status of the internal-ported pump in the aviation industry. If its outstanding volumetric efficiency at extremely low inlet absolute pressures is 99 per cent due to centrifugal aid to rotor filling, we do not care in the least. This new and cleverly developed type of pump has become available almost exactly when we are convinced that the inherent limitations of the spur-gear type shows it to be unsatisfactory for service at altitudes of 40,000 ft and upward. Although the author has not pushed this new development particularly, the writer takes the opportunity to say that we cannot afford to neglect its potentialities.

Author's Closure

Referring to the discussion by W. L. Weeks, possibly he has confused the losses in the inlet port with those which may occur in the inlet chamber between the pipe port and the gears. The normal losses in the port and the inlet chamber are, in all cases, relatively small for any reasonably well-designed pump, but the amount of the pinion arc that is exposed to the suction chamber is quite important. This situation has been discussed in the paper and is also covered by Mr. Weeks.

With regard to his point that the jet loss, by which the author means the flow between the tip of one tooth and the flank of the next, can be eliminated by making the inlet port reasonably wide, while this is not subject to exact determination, in general, the statements made in the paper and those by Mr. Weeks are in agreement. The jet loss still exists in reduced amount when the pump is in cavitation, but by exposing more arc of the teeth in the unmeshed region, a greater time is allowed for filling the incompletely filled teeth, and therefore the loss occurring in the meshed region may not be appreciable or even detectable. It is somewhat difficult to get exact terminology to describe these situations, but in Fig. 7 of the paper, the port loss as indicated in this figure includes any loss due to the pipe opening into the pump, the skin friction in the inlet chamber, and any velocity-head-type loss due to changes of direction of the stream from the usually circular inlet pipe to the usually rectangular configuration where the oil enters the gears. It will be seen from the diagram that the port or intake-chamber loss forms a relatively small percentage of the total when the pump is either not cavitating or is in low order of cavitation, but assumes a somewhat larger percentage of the total after the tooth loss has substantially vanished in the high order of cavitation. It is possible that Mr. Weeks has misunderstood the application of the term "jet loss." The author was thinking almost exclusively of the high-speed jet occurring between the tip of one tooth and the flank of the next, which is actually the bulk of the tooth loss. The other velocities elsewhere, particularly in the port and intake chamber, are relatively rather low.

With regard to Fig. 13 of the paper, part of the gain shown by this design of pump is of course elimination of centrifugal force. Another fraction of the gain is due to proper shaping of the gear-tooth ports for good pickup, just as in a centrifugal pump; and another fraction of the gain is due to the great reduction in clearance. His point is correct, that the proper shaping of the intake edge of the gear teeth, so as to introduce the liquid radially from the intake cup without shock, is quite important. The difference between a plain radial port and the ports as now shaped amounts to as much as $1^1/_2$ to 2 in. Hg. It is the author's feeling that the improvement in this pump is not traceable to any one cause but to several of the structural changes that have been accomplished. These are about as follows:

1 Elimination of centrifugal resistance.

2 Good turn conditions and faired shapes in the inlet cup.

3 Proper proportioning of the port area in the gear, together with proper angle of the inlet edge to reduce, as far as possible, any shock loss or change in direction of the fluid as it enters the teeth.

4 The reduction of clearance from approximately 20 per cent to around 5 per cent.

In response to Mr. Week's kind remark about the potentialities of this design, the author has rather avoided pushing this design too much, since this is a technical paper, and presumably quite unbiased. However, it is within the bounds of propriety to say that, at the present time, this pump has the lowest inlet loss of any we have investigated, including some centrifugal boosters.

In reply to Professor Schweitzer's oral comments the author is in agreement that, in some sense at least, displacement is a conventional term. However, the reason why we have adopted displacement in the form given in the paper is: (1) It is in exactly the same status as the displacement of a reciprocating pump and in all of the commercial rotary pumps, and therefore has very widespread use. (2) The distinction between slip and mechanical loss can only be made correctly upon the basis of this form of displacement. They do not correlate properly with the geometric displacement described by Professor Schweitzer which in effect corresponds in the present paper to the tooth space. Mr. Hambling of the Thornton Laboratories in England also applied Professor Schweitzer's method of using the geometric displacement, with the result that all analyses based upon volumetric efficiency give very deceptive values.

With regard to the assumption that slip may occur elsewhere than from the discharge side to the inlet, two points should be made as follows:

In the analysis as made in the paper and in 90 per cent of the pumps, there is no external shaft leakage because for a commercial pump the shaft is packed. The only case where shaft leakage is permitted is in aviation pumps where leakage along the shaft either passes back to a sump or travels through to another pump in the same case. It is believed Professor Schweitzer's assumption that some of the leakage may have come from oil carried into the tooth space on its way from suction to discharge, and leak out before it reaches the discharge, is an incomplete rationalization. It must be realized that, while some of this leakage is taking place all along this path, what material does leak out is from an intermediate-pressure region and the tooth must be refilled from some other source or the leakage would not take place. Now it is obvious that between the point where this particular quantity of oil has leaked back before completing the path from suction to discharge chambers, there is also pressure difference between this pressure and the discharge, and leakage comes down from discharge to this point to replace that which has leaked out at the lower pressure point. The net result is, therefore, that the entire displacement work is done on the total difference of pressure, and all leakage is truly represented by calculation on the total pressure difference between inlet and discharge. It is therefore clear that the work done on the liquid in the pump is always that of pumping the entire displacement against the difference of pressure between inlet and discharge and is not in any way affected by what place, in the pump, any particle of oil came from to join the leakage. This situation is not an approximation, it is entirely rigorous.

Effect of Combined High Temperature and High Humidity on the Corrosion of Samples of Various Metals

By W. L. MAUCHER[1] AND B. W. JONES,[2] SCHENECTADY, N. Y.

The atmosphere around and in oil refineries is corrosive; and when these refineries are located in hot humid locations, this atmosphere attacks various metals actively. Four groups of eighteen selected metal specimens were subjected to this corrosive atmosphere in a refinery along the Gulf Coast. Two groups were located indoors and two groups outdoors for about one year. This paper is a report of how these specimens withstood this hot, humid, corrosive atmosphere.

VARIOUS metals when subjected to the combination of high temperatures, high saline humidity, and to the gases which are found around and in the various oil refineries along the Texas Gulf Coast exhibit a very high rate of corrosion. This condition has been the cause of much destruction to enclosing cases, structural members, and to electrical parts which are magnetic. This gas also rapidly attacks current-carrying parts such as copper, cadmium, silver, and other materials, so that the maintenance personnel in these plants would welcome any suggestions that would reduce this type of corrosion.

The present paper is a report of some work done to ascertain the degree of corrosion which this condition would have on eighteen selected materials or platings. Four groups of these eighteen selections per group were placed in four selected locations of an oil refinery which was adjudged to be the most severe plant in that area as regards corroding. Each specimen was hung on a porcelain-enameled hook so that the specimen did not touch any other member. No. 1 location was inside a power plant; No. 2 location was outside this same power plant, where the samples were subjected to the rain and sun; No. 3 location was inside a chilling pump house; and No. 4 location was outside this same chilling pump house.

A competent person inspected these seventy-two specimens at the expiration of 7, 14, 35, 72, 129, and 225 days at the test sites, and Tables 1 to 4, inclusive, are his report. These specimens were returned to the laboratory after 1 year exposure and W. L. Maucher who originally prepared them also inspected them on their return. Tables 5 and 6 are from his report. Therefore, these two reports give a comprehensive description of what occurred during this period of 1 year in a saline atmosphere containing a substantial concentration of sulphur acids, such as hydrogen sulphide and sulphurous and sulphuric acids, and we should be able to draw a few useful conclusions from the results. The list of metals as shown in the next column might be generalized as follows: (*a*) Five simple elements; (*b*) electroplated coatings on copper; (*c*) chromium alloys; (*d*) copper alloys; and (*e*) nickel alloys.

LIST OF 18 DISTINCTIVE SPECIMENS OF METALS

Specimen number	Material
1	Rolled copper
2	Rolled copper with 0.001 in. silver electroplate per side
3	Rolled copper with 0.001 in. lead electroplate per side
4	Rolled copper with 0.001 in. tin electroplate per side
5	Rolled copper with 0.001 in. cadmium electroplate per side
6	Rolled nickel
7	Type 410 12 per cent chrome steel passivated
8	Nichrome V
9	Lead
10	Type 302 18-8 stainless steel passivated
11	2S aluminum
12	2S aluminum anodized for 20 min
13	Cold-rolled steel
14	Fine silver
15	Monel
16	Everdur
17	Red brass (85 Cu, 15 Zn)
18	25 per cent chrome steel passivated

1 Of the four electroplated coatings on copper, the tin appeared to stand up best. The cadmium was completely gone and the silver showed heavy attack, as evidenced by the scaly black deposit which was probably silver sulphide. The lead plating did not look so bad on the surface but on closer inspection, deep pits of the copper base metal were noted.

2 Rating the chromium alloys in their order of merit, 18-8 stainless steel and Nichrome V average up about the same and rate about the best in this test. The 25 per cent chrome steel was somewhat worse, and 12 per cent chrome steel was decidedly inferior to the other three.

3 While aluminum, untreated, showed a uniform corrosion coating and the anodized aluminum had scattered pits, it is felt that this metal showed up nearly as well as did the 18-8 stainless steel. Considering price, it is the consensus of opinion that aluminum, anodized or otherwise properly treated for paint, and then given two or more coats of suitable aluminum paint, would provide one of the most corrosion-resistant combinations.

4 The test on copper and copper alloys showed conclusively that the high-copper metals have a low resistance to corrosion in this kind of atmosphere and should not be used unless protected by some protective coating.

5 A comparison of monel and nickel indicate that nickel was not attacked as much as was monel.

6 The extremely bad corrosion of the unprotected cold-rolled steel indicates the severity of the corrosive atmosphere at this location and emphasizes the necessity for maintenance painting on any steel parts.

7 Lead showed up outstandingly well but because of its low physical properties would not lend itself to many applications.

8 The interesting observation on silver was that, although it was heavily attacked, there was no sign of pitting or noticeable etching. The metal underneath the corrosion film was very smooth. On large knife switches, the silver surfaces continued to carry their currents satisfactorily.

TABLE 5 LABORATORY INSPECTION RESULTS OF ONE YEAR OF EXPOSURE TO CORROSIVE GASES

SPECIMEN NUMBER	LOCATION A OUTSIDE #3 POWER PLANT	LOCATION B INSIDE #3 POWER PLANT
1	Heavy black corrosion incrustation. Metal etched and pitted.	Heavy incrustation of dark corrosion products. Metal etched.
2	Medium black corrosion. No pitting. Some silver plate still present.	Thin, uniform dark corrosion coating. No etching or pitting.
3	Uniform black corrosion. Some pitting.	Same as No. 2
4	Uniform black corrosion. No noticeable pitting.	Thin, uniform gray corrosion coating. No etching or pitting.
5	Cadmium plate all gone. Similar in appearance to #1.	Uniform yellow corrosion coating. No pitting or etching.
6	Uniform green and black corrosion. No pitting.	Uniform light green corrosion coating. No pitting or etching.
7	General rusting over all. Shallow pits.	Numerous scattered rust spots. Metal etched.
8	Thin green-gray corrosion over all.	Same as No. 6
9	Missing	Thin dark corrosion film. No pitting.
10	Scattered rust spots over all. Shallow pits.	No appreciable corrosion. Metal slightly dulled.
11	Moderate gray uncrustation. Uniformly etched.	Numerous pits scattered over surface.
12	Light corrosion with scattered shallow pits.	Practically perfect. One pit noted.
13	Badly corroded. Metal thinned by extreme rusting	Over all rust
14	Uniform black corrosion scale. No noticeable pitting	Thin uniform smooth black scale. No pitting
15	Heavy black incrustation. Metal etched but not pitted (not as good as nickel.)	Moderately heavy black incrustation. Metal etched.
16	Same as No. 1.	Same as No. 1.
17	Same as No. 1.	Slightly better than No. 1 or No. 16 but of the same order.
18	Scattered rust over all. Shallow pits.	No attack. In excellent condition.

TABLE 6 LABORATORY INSPECTION RESULTS OF ONE YEAR OF EXPOSURE TO CORROSIVE GASES

SPECIMEN NUMBER	LOCATION C OUTSIDE CHILLING PUMP HOUSE	LOCATION D INSIDE CHILLING PUMP HOUSE
1	Heavy incrustation of dark corrosion products. Metal etched.	Black film overall. Somewhat etched.
2	Medium incrustation. No pitting. Some silver plate still present.	Uniform black coating. No etching or pitting.
3	Medium incrustation. Deep pits in basis metal.	Tarnished but otherwise O.K.
4	Fairly heavy incrustation. Shallow pits of basis metal.	No appreciable change. In excellent condition.
5	Medium incrustation. No cadmium plate left. No appreciable pitting.	Uniform yellow color. Otherwise O.K.
6	Moderate uniform corrosion products. No pitting.	Slightly tarnished. Otherwise in perfect condition.
7	Heavy rust overall. Metal etched with shallow pits.	Same as No. 4.
8	Thin gray surface film. No pitting or etching.	Same as No. 4.
9	Moderate uniform gray film over all. No pitting.	Tarnished and a few shallow pits.
10	Numerous scattered small rust spots which show shallow pits underneath.	Same as No. 4.
11	Moderate gray incrustation. Metal etched.	Same as No. 4.
12	Scattered corrosion pits.	Same as No. 4.
13	Very heavy rust.	Rust over all.
14	Thin uniform smooth corrosion scale (.0004" thick). No pitting.	Uniform black tarnish coating. No pitting or etching.
15	Moderately heavy corrosion products over all. Metal surface etched.	Tarnished but not appreciably etched or pitted.
16	Same as Copper (#1).	Same as #1.
17	Same as Copper (#1).	Similar to #1 & #16 but slightly better.
18	Missing	General rusting and pitting.

R. B. MEARS.[3] We were very much interested in the paper by Mr. Maucher and Mr. Jones. Naturally, we were gratified by the good resistance to attack exhibited by the bare and anodically coated aluminum samples. These results are supported by a considerable amount of other data obtained both by our own laboratories and elsewhere. These other tests unite in revealing that many aluminum-base materials are highly resistant to outdoor exposure conditions, even in damp or seacoast locations. It is also well known that sulphur compounds do not attack any of the commercial aluminum-base alloys. Thus the high resistance of the aluminum-base alloys to atmospheric conditions coupled with their specific resistance to sulphur compounds indicates that oil-refinery people could well afford to give serious consideration to the use of aluminum alloys.

Data from extensive atmospheric exposure tests conducted by A.S.T.M. Committee B-3, Subcommittee VI, for periods up to ten years are now available. These tests were conducted at seven different outdoor exposure sites, including exposures at Altoona, Pa.; New York N. Y.; State College, Pa.; Phoenix, Arizona; Sandy Hook, N. J.; Key West, Fla.; and La Jolla, Calif.

Aluminum alloys 2S, 3S, and Alclad 17S-T proved highly resistant at all locations. Rather similar tests conducted by the Aluminum Research Laboratories indicate that some of the newer sheet alloys such as 52S, 53S, Alcald 3S, and Alclad 24S-T are also highly resistant in outdoor exposures.

Aluminum alloys have been used to some extent in roofs for oil tanks handling sour crudes. About 60 unpainted aluminum-alloy (3S) roofs have been used. In all cases it is understood that these roofs resisted both the outdoor atmospheric exposures and the moist air containing H_2S in the tank interiors very satisfactorily.

Because of the high resistance of aluminum alloys to sulphur compounds and to ammonia (or ammonium hydroxide), aluminum-alloy tubes can often be used advantageously in heat exchangers and condensers in refineries. For such applications, the use of Alclad 3S alloy tubing or of cathodic protection by zinc attachments is advantageous in minimizing the effects of corrosive cooling waters.

Aluminum wires are used for telephone lines in atmospheres containing hydrogen sulphide, because of their high resistance to attack by sulphur compounds.

Aluminum alloy (17S-T) nails are extensively employed for use in wooden structures in oil fields, again because of their resistance to sulphur compounds.

Large processing equipment for gas purification can often be made of aluminum alloys advantageously. Here the high resistance to both CO_2 and H_2S is valuable.

AUTHORS' CLOSURE

We appreciate Dr. Mears's discussion concerning the behavior of aluminum and its alloys under test and service conditions related to those which prevailed in this investigation. It is gratifying to note that the data obtained by the authors are in substantial agreement with Dr. Mears's extensive observations and experience.

An Investigation of Radial Rake Angles in Face Milling

By J. B. ARMITAGE[1] and A. O. SCHMIDT,[2] MILWAUKEE, WIS.

The object of this investigation was to determine the effect of negative and positive radial rake angles in milling cutters upon the power required for the cutting action, the tool life of the cutter, the surface finish, and temperature of the workpiece. Tests were conducted with 2-in. face mills which had two brazed carbide tips. All cutters had the same dimensions except for the radial rake angles which included 30 deg, 15 deg, 6 deg positive; 0 deg, 6 deg, 12 deg, 20 deg, and 30 deg negative. The axial rake angle was 0 deg on all of the cutters. Cutting speeds were varied in seven steps between 106 and 785 fpm; different feeds were used with each speed and the depth of cut was constant at 0.125 in. Test bars were made of normalized S.A.E. 1055 hot-rolled stock. This steel was used throughout the investigation except for the tool-life tests in which S.A.E. 1020 was also used. Equipment and procedure used in the tests are discussed and the results illustrated by several graphs. Clearly defined conclusions are drawn from the investigation.

Discussion of Previous Investigations

NUMEROUS articles recommending negative radial rake milling have appeared in technical publications and bulletins, most of them reporting on over-all performance. The following is stated in one such reference (1):[3] "While the cutting force with a 10-degree NEGATIVE rake is higher than that of a 10-degree positive rake cutter at low speeds, there is always a point at which they are equal, and if a sufficiently high speed is used, the force on the NEGATIVE rake cutter is less than on the positive rake cutter."

At the 1943 Annual Meeting of the Society, a paper was given by Hans Ernst (2), in which were shown several graphs of test data and diagrams with a single-point-tool dynamometer. The results indicated an increase of tool force at high speeds for a 10-deg positive radial rake angle and a decrease of tool force at high speeds for a 10-deg negative radial rake angle. It was stated: "Careful investigations over a wide range of speeds and with various work materials have shown that the power required with negative rake angles decreases steadily with increase in speed. In fact, it has been found in several cases that beyond a certain speed, the specific power consumption with negative rake angles is actually less than with positive rake angles."

At the same meeting, in a companion paper (3), Wallace E. Brainard showed that the tool forces do not vary with the cutting speed from 200 to 1500 fpm. In his investigation, he used an electrical strain gage to determine the tool forces.

For negative radial rake angles, 50 per cent increase in horsepower over present machines and cutting speeds from 375 to 1000 fpm are recommended by R. G. Owen (4). It is also stated that a feed of 0.0005 in. per tooth will dull a cutter after 3 to 5 min cutting time.

C. H. Bodner (5) suggests a heavy cutter body and finds negative blade angles of 10 deg for axial and radial rake the best, in spite of the fact that they require more power to drive the machine tool than positive angles. Climb-milling on machines without backlash and a feed of 0.006 in. per tooth are also recommended.

In a paper by Fred W. Lucht (6), which was presented at the 1943 Annual Meeting of the Society, the following information was given:

"As a rule, positive rake angles result in less power consumption and permit deeper cuts and heavier feeds than do negative rake angles, but the latter should be employed only when necessary to strengthen the cutting edge. Carbide blades 30 to 50 per cent thicker than those used for cast iron permit optimum results when milling steel. A minimum feed of 0.005 in. per tooth is also recommended for steel."

Procedure and Equipment for High-Speed Milling Tests

For this milling investigation a special setup had to be developed to measure the power at the cutting edge accurately at both low and high speeds. All tests were carried out on a Milwaukee 2-K vertical milling machine which had a wide range of feeds and speeds and permitted a maximum cutting speed of 785 fpm with a 2-in. face mill. For checking purposes, an Esterline-Angus recording wattmeter was connected with the milling-machine-drive motor. The surface temperature of the test specimen was measured immediately before and after cutting with an "Alnor" low-range thermocouple. Surface finish on the test bars was checked with a profilometer.

During this investigation, the power required by the tool was measured with a calorimeter from which the heat in the chips was determined. This method proved to be simple and reliable.[4] The measuring of tool forces has been generally effected by the use of mechanical, optical, and electrical means, while the temperature of the cutting edge during the cutting operation has been measured by thermoelectrical devices. In the reported test, distilled water is employed as a means of measuring the quantity of heat generated by a combination of friction and deformation during the cutting operation. Because of the effect which water may have in a milling operation, it was decided to cut the test bars dry and measure only the heat of the chips in the calorimeter. When work is transformed into heat or heat into work, a quantity of work is the mechanical equivalent of a quantity of heat.

Discussion and Interpretation of Results

The main advantage of the calorimetric method used in these tests is that it permits in a simple way the measurement of power at the cutting tool at any cutting speed. Prof. G. Schlesinger

Bottom: Surface temperatures of workpiece measured with thermocouple immediately after taking cuts plotted in upper graph. Room temperature is constant at 70 F.)

(7) has stated that in customary shop tests in metal cutting, variations in the results up to 20 per cent may occur. There are inevitable differences in the elements of the test which are due to the following:

1 The efficiency of the motor which may vary from 5 to 8 per cent because of irregular heating due to load variations during the testing period.

2 The efficiency of the gears which may vary from 3 to 8 per cent because of difficulties in keeping the lubrication factors constant and to the heating caused by a change of load.

3 The variations of 5 to 10 per cent in the test material.

4 Variations in the heat-treatment of the tool, which may vary between 5 and 20 per cent in high-speed tools. (The authors have found that the same percentages will apply to brazed tungsten-carbide tips.)

Data plotted in the accompanying graphs constitute the average of at least three individual tests and are based upon the measurements taken with the calorimeter. This excludes errors due to motor and gear variations. Test bars were taken from the same piece of material and were normalized. A close check was maintained in order to eliminate those bars which would repeatedly give results more than 5 per cent above or below the average temperature value measured in the calorimeter for identical tests.

Care was taken to use carbide tips from the same batch and to have them carefully brazed and ground. Another source of error is the wear to which the carbide tip is exposed as soon as it begins to cut metal. During the power tests, tips were inspected after each cut on a test bar. Cutters were eliminated if they showed any sign of wear under the illuminated magnifying glass, and in most cases were used on three test bars removing 0.3 cu in. of metal and not on more than six test bars. During these tests, the cutters were considered to be sharp. A very close check on the cutting edge was also possible because a rise in the calorimeter readings and the surface-temperature readings would always indicate a hard spot in the test bar or wear and chipping of the cutting edge. In some cases this could also be noticed by a rise in the wattmeter reading and could be seen with the magnifying glass as wear on the cutting edge.

Changes in the power required by the two-lip milling cutter in relation to the rake angle were investigated first. The initial series of tests was conducted at a cutting speed of 427 fpm and varying feeds with the 6-deg positive radial rake and 0 deg, 6 deg, 12 deg, 20 deg, and 30-deg negative radial rake angles. A second series of more than 1000 tests was run under identical conditions except that the cutting speed was increased to 523 fpm.

In order to study the effect of the negative radial rake angles at lower speeds, tests were conducted at 285, 192, and 106 fpm cutting speeds. At these speeds the surface of the specimen would show conspicuous chatter marks for all negative radial rake angles larger than 6 deg. Considerable vibration was induced in the machine. At 106 fpm the surface of the specimen was also badly torn and cracked by the negative radial rake cutters.

Several series of tests were conducted at 638 and 785 fpm, and the results were found to agree substantially with those at the lower speeds. From the computed average temperature of the chips, it can be seen that the melting temperature of S.A.E. 1055 was not approached in any test. Observation indicates that

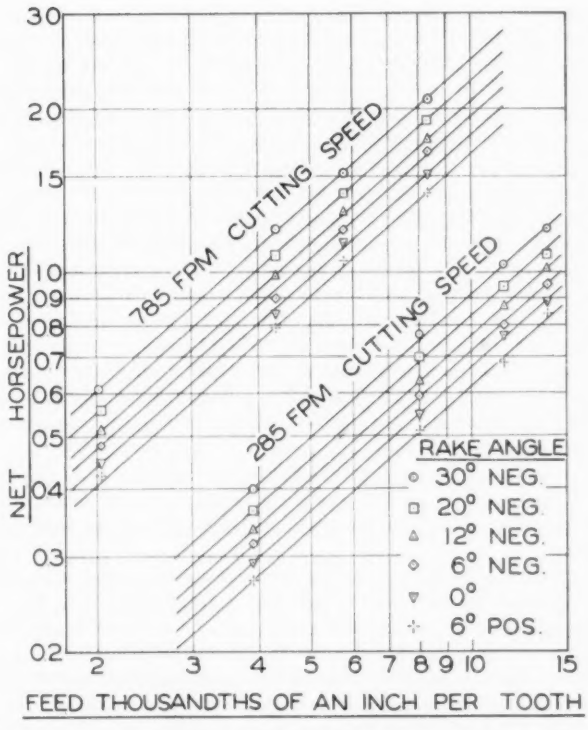

FIG. 3 COMPARISON OF NET HORSEPOWER REQUIREMENTS OF DIFFERENT RADIAL RAKE CUTTERS OPERATING AT CONSTANT CUTTING SPEEDS, 0.125 IN. DEPTH OF CUT, AND VARIOUS FEEDS AS COMPUTED FROM HEAT IN THE CHIPS

(Material, S.A.E. 1055; normalized; Bhn 205.)

the average temperature is the actual temperature of the chips only at fine feeds, while a heavier chip has a different temperature on each side, the higher one on the side away from the tool. This is indicated by the difference in color in individual chips.

When cutting tests are made at heavy feeds and at high speeds, chips and minute particles from the workpiece come off simultaneously. These small particles usually become so overheated, because of their smaller heat-carrying capacity, that they fly off as sparks, while the heavier chips are blue on the side away from the tool and still have the silvery steel color on the side which has just been separated from the workpiece.

From the temperature rise of the calorimeter the average temperature rise of chips, the horsepower per cubic inch per minute, and the net horsepower could be determined.

Values for average chip temperature and horsepower per cubic inch per minute thus arrived at are plotted in Figs. 1 and 2. It can be seen that the chip temperatures increase as the radial rake angle becomes more negative. Because these negative radial rake angles required more net horsepower, it follows that there was more heat generated during the cutting operation. The plotted temperatures further substantiate this statement. Chip temperatures were computed from the calorimeter readings for a constant specific heat. Actually, the specific heat of steel must be assumed to increase at high temperatures and the true chip-temperature values are lower than those plotted.

From the surface temperatures of the workpiece which were measured with the "Alnor" low-range thermocouple immediately before and after the cutting of the test bar, it can be seen that workpiece temperatures depend less upon the radial rake angle than upon the feed (see lower part of Figs. 1 and 2). The temperature of the workpiece and chips varies inversely as the feed. This general tendency was also found to be true in the tool-life tests when the same test bar was used continuously until the cutter had failed.

The net horsepower values, as computed from the calorimeter temperature rise, in relation to the feed per tooth as used in the tests are plotted with a logarithmic scale in Fig. 3, for a cutting speed of 785 and 285 fpm. This relationship between the values for different radial rake angles at other cutting speeds was found to remain substantially the same.

For a given radial rake angle, the increase in net horsepower with an increase in feed has a relationship which is always definite and can be determined from the logarithmic graphs as

$$\text{hp} = CnNf^a$$

in which

C = constant depending upon the radial rake angle
n = number of cutter revolutions per minute
N = number of teeth in cutter
f = feed in inches per tooth
a = exponent determined as 0.85 from values plotted on log-log paper

Net horsepower values computed by the foregoing formula were found to agree within close limits with actual test results. This was a further check that the tool forces were not reduced by negative radial rake angles or high cutting speed, but remained constant for a given chip cross section and changed with the radial rake angle, as shown in Figs. 12 and 13.

During these tests conducted at 427, 523, 638, and 785 fpm cutting speeds, various feeds, and a constant depth of cut, the following observations were made:

1 In taking the first six cuts with sharp cutters on a test bar the power requirement of the cutter with positive radial rake is less than that for cutters with negative radial rake angles.

2 After the negative and positive radial rake cutters have cut an equal amount of metal and all show wear on the cutting edge, the negative radial rake cutters will require less power.

3 In comparison with positive radial rake cutters, the cutter with negative radial rake angles will stand up longer and show less wear.

4 A cutter with negative radial rake angles is more effective at higher cutting speeds because of its inherent additional strength at the cutting lip.

5 Cutters with 20- and 30-deg negative radial rake angles left more pronounced chatter marks on the workpiece and frequently induced machine vibration.

6 Observations for tests run at 427, 523, 638, and 785 fpm agree substantially for tests run at 285 and 192 fpm cutting speed. However, surfaces showed conspicuous chatter marks for all negative radial rake angles above 6 deg even at low feeds.

7 At 106 fpm the surface of the specimen was badly torn and cracked by all negative radial rake cutters. In every specimen, the edge at which the cut was completed was ragged and chipped below the surface plane, indicating that the edge of the test bar had been broken rather than milled off. Induced vibration of the machine was very noticeable during these low-speed tests with the various negative radial rake cutters.

8 The surface temperature of the workpiece decreases with increasing feed rate and is proportional to the temperature of the chips.

The horsepower per cubic inch of metal removed per minute by the cutters with different radial rake angles at a cutting speed of 785 fpm is plotted in Fig. 1. The highest values were obtained with the 30-deg negative radial rake cutter and the lowest with the 6-deg positive radial rake cutter. In spite of the fact that data points are somewhat scattered due to the inevitable test variations, it can be seen that there is a tendency of the horse-

power per cubic inch per minute to decrease with increasing feed. This really means that the work required to remove a cubic inch of metal is less with a coarse feed than with a fine feed. One good reason for the better power economy at coarser feeds is the fact that a coarse feed F, which is twice the fine feed f, is separating a smaller suface in relation to the volume removed. As can be seen in the simplified diagram, Fig. 4, the fine feed will separate a surface area of $2(f + d) \times l$ which is $(d \times l)$ larger than the surface area of separation for the coarse feed which is $(2f + d) \times l$. But in each case the same volume of metal will be removed and a coarse feed will result in more economical power consumption.

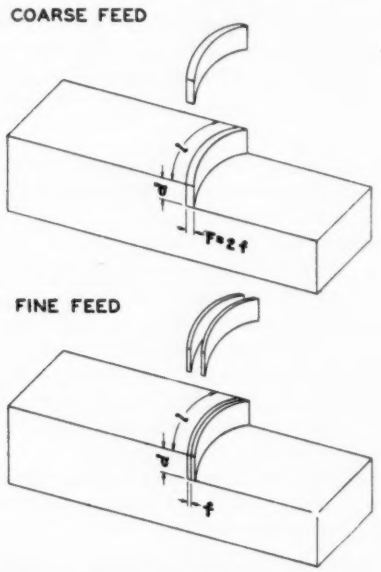

FIG. 4 RELATIONSHIP BETWEEN ONE COARSE CHIP AND TWO FINE CHIPS IN REMOVING SAME AMOUNT OF METAL

The advantage in power economy gained with heavier feed is illustrated in Fig. 5, in which the feed in inches per tooth is plotted on the abscissa, 1 f being the feed which is so fine that there is only minimum deformation in the workpiece and chip. For this reason the cutting force is assumed to be directly proportional to the area of the surfaces of separation and to the volume of metal removed. On the right-hand ordinate are given values for the cutting force per chip and also area of the surfaces which are separated when cutting a particular chip. Volume of the chip is indicated on the left-hand ordinate. If it were possible to separate the metal chips from the workpiece in one plane only, e.g., without disturbing the adjacent layers in the metal, the increase in the cutting forces with increase in feed per tooth would be very small and would coincide with the increase in the area of the surfaces of separation. The volume of metal removed will increase more rapidly as can be seen from the upper line.

However, besides separation of the metal planes, compression, bending, friction, and other phenomena in a metal-cutting operation which can be observed as deformation also occur. Since this deformation in the chip and in adjacent layers of the workpiece is proportional to the feed, the tool forces become greater with an increase in feed.

When the volume of metal being cut is removed in fine chips of 1 f thickness, the force line would coincide with the volume line because of the large proportional increase in the areas of separation.

The ordinate b-c between the first and second curve can be considered as representing the increase in the cutting force due to deformation of the heavier chips. If the force of separation were the only force necessary to cut metal, then the cutting force would be directly proportional to the surface areas of separation, and the increase in cutting force would equal a-b. It is evident that one thick chip is more economical than several fine chips in removing an equal volume of metal from the difference in the ordinate of the same chip for the force and volume curve. The volume curve would indicate the sum of the forces necessary to remove 10 fine chips of 1 f thickness, while the force curve represents the actual force necessary to remove one thick chip of 10 f thickness. The difference, c-d, in the height of the ordinate equals the decrease in force in the latter case.

For this particular feed of 10 f, the increase in volume of the metal removed is 1000 per cent in comparison to a feed of 1 f, while the increase of the cutting force is only 720 per cent. If there were no deformation in the chip and workpiece, the cutting force would have increased only slightly less than 10 per cent be-

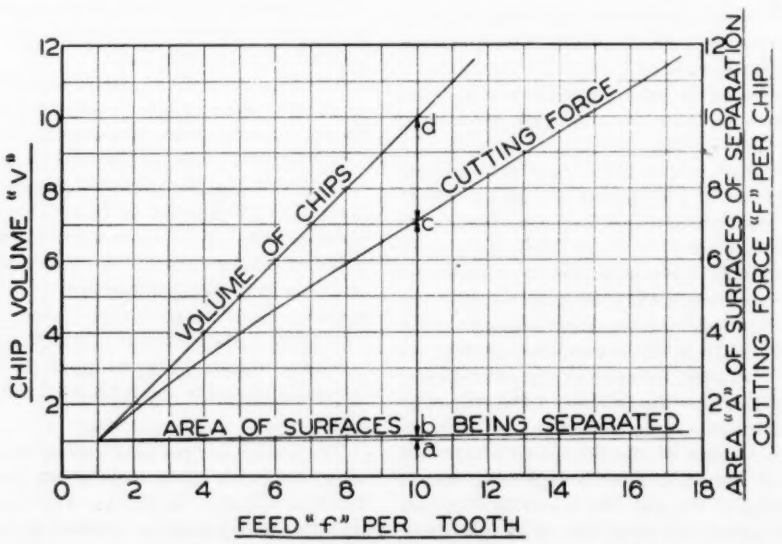

FIG. 5 RELATIONSHIP OF VOLUME OF CHIPS REMOVED, AREA OF SURFACES OF SEPARATION, AND CUTTING FORCE TO FEED PER TOOTH OF CUTTER

cause it would have equalled the small increase in the area of surfaces being separated. Therefore, this one chip of 10 f required almost 7 times as much force due to deformation as was required for its separation.

But no matter how fine a chip is cut, there is always more work done in deforming the metal than in separating it. As just pointed out, separation of metal is only a small part of metal-cutting. This can be seen from the appearance of heavier steel chips, which will often retain the steel color in the cutting plane and be heavily oxidized on the side away from it, indicating that more heat was generated through deformation than cutting of the chip.

From the heat values of the calorimeter, the average temperatures of the various chips were computed. Increasing the chip thickness will lower the average temperature because, with increasing feed, the volume of the chips increases more rapidly than the cutting forces. Therefore, the average temperature of the chips will vary inversely as the chip thickness.

The graph in Fig. 5 has been plotted with values of depth of cut and feed corresponding to the ones used in the tests, as have the force values. If another ratio of depth of cut to feed were to be used, the line for the areas of separation would be steeper for a smaller ratio and have still less slope if the ratio between depth of cut and feed were larger.

Comparative Tool-Life Tests

During the tests for power consumption, it was found that the positive radial rake cutters would frequently fail after the first cut on the test bar. For this reason numerous comparative tool-life tests were made following the procedure subsequently described. Since the cutters with 20- and 30-deg negative radial rake angle induced too much vibration, very few tool-life tests were run with them. Cutters with 15- and 30-deg positive radial rake were excluded from the tool-life tests because they failed too easily.

Three readings on test bars of S.A.E. 1055 (the same as used in the tests for power consumption) were taken first. Then 16 cuts which removed 28 cu in. of metal were made on S.A.E. 1020. Following this, three test bars were again cut for comparison. Depth of cut was 0.125 in. for all tests; the feed was constant at 15 ipm with a cutting speed of 523 fpm.

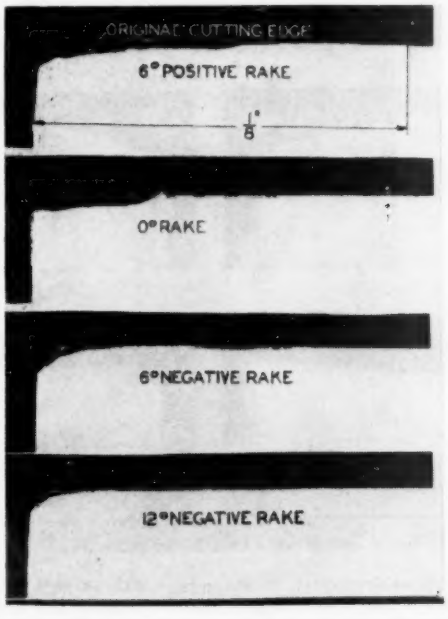

Fig. 6 Silhouettes of Cutting Edges of Various Cutters in Plane Parallel to Axis of Rotation Taken on a Jones and Lamson Optical Comparator

(Each cutter has removed 28 cu in. of S.A.E. 1020 cold-rolled steel and 0.59 cu in. of S.A.E. 1055 at a cutting speed of 523 fpm, a feed of 0.0075 in. per tooth, and 0.125 in. depth of cut.)

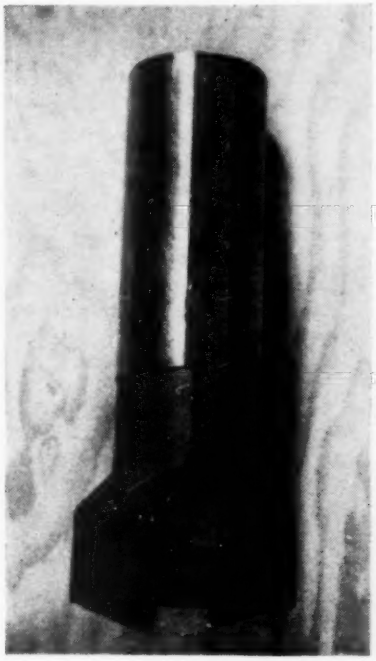

Fig. 7 Two-Bladed Face-Milling Cutter Which Was Used in Tests and Was Provided With Blades of Various Radial Rake Angles

The following observations and measurements are typical and representative of the results in the comparative tool-life tests:

1 After the same amount of metal had been cut with each cutter the increase in power consumption was as follows:

6-deg positive radial rake cutter	34 per cent increase in power
0-deg radial rake cutter	24 per cent increase in power
6-deg negative radial rake cutter	16 per cent increase in power
12-deg negative radial rake cutter	12 per cent increase in power

2 The wear on the cutting edge of the 6-deg positive, 0-deg and 6-deg negative radial rake cutters was due to minute chipping of the carbide tips. On the cutting edge of the 12-deg negative radial rake cutter only fine abrasion was visible, see Fig. 6.

3 Average profilometer readings in microinches on the surface of the test bars at the beginning and end of test were as follows:

Cutter	Reading at beginning	Reading at end
6-deg positive radial rake	140	53
0-deg radial rake	23	26
6-deg negative radial rake	45	80
12-deg negative radial rake	22	80

4 The average surface temperature rise of the specimen would increase between 200 and 400 per cent for the last cuts taken with the partly failed and worn cutter.

Comparative Tool-Life Tests of Cutters Provided With Double Radial Rake Angle Tips

It was established without doubt by numerous tests at cutting speeds ranging from 100 to 800 fpm that the tool forces are higher

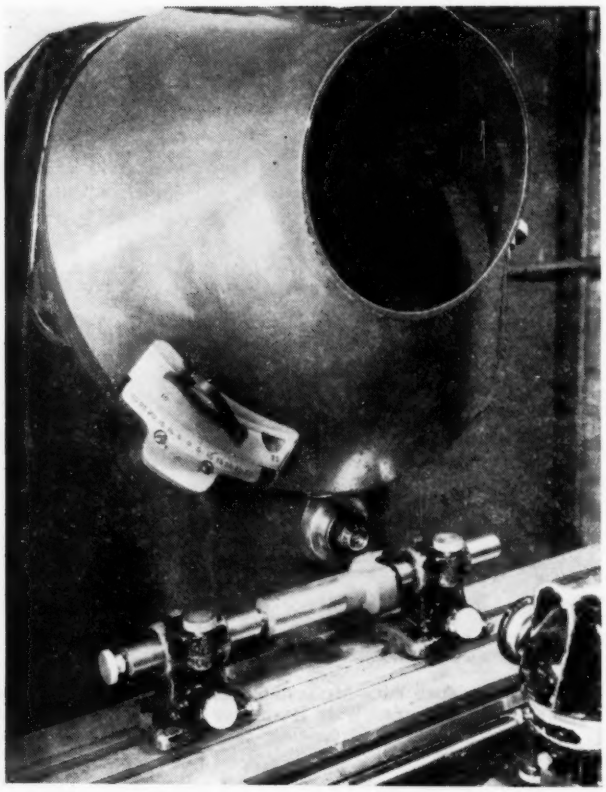

FIG. 8 JONES AND LAMSON OPTICAL COMPARATOR USED FOR INVESTIGATION AND RECORDING OF TIP FAILURE

for cutters with negative radial rake angles than for positive radial rake angles. However, the cutters with negative radial rake angles will stand up much better and their power requirements will increase more slowly than those with positive radial rake angles. This increase in power consumption during the cutting operation is due to the wear to which any cutter is exposed while in operation. Only because of the more rapid wear may it actually happen that a positive radial rake cutter will entail higher cutting forces than one with negative radial rake angles.

From Fig. 5, it is evident that the cutting forces are invariably several times greater due to deformation of the metal than to separation in the cutting plane. This deformation is always present no matter which angles are provided on the cutter and will be more evident with negative radial rake angles than with positive radial rake angles. A very sharp tool would induce little deformation in the chip or workpiece but tool life would be very low if one would go to the extreme and use a metal-cutting tool similar to a razor blade.

There are therefore two major requirements for a cutter which will give satisfactory cutting action and tool life:

1 A cutting edge which will stand up and not wear or chip readily.

2 A tool shape which will reduce the deformation in the chips and workpiece.

As the cutting speed and hardness of the workpiece material increase, these two requirements assume greater importance. The first requisite can be satisfied with negative radial rake angles and carbides on the cutting tips; the second is achieved by simultaneously providing a positive radial rake angle for improving chip flow.

In accordance with the foregoing conclusions, it was found that cutters which had positive secondary radial rake angles with negative primary radial rake angles imposed at the cutting edge gave better tool life and required less power than cutters with negative radial rake angles. In the text the term "primary" radial rake refers to the radial rake angle at the cutting edge. "Secondary" radial rake refers to the radial rake angle behind the primary radial rake angle (see Fig. 9, *A* and *C*.)

Similar designs for rake angles on single-point tools have been used by DeLeeuw, E. G. Herbert, and Klopstock and are discussed in their application to high-speed tools by O. W. Boston (8). The use of negative and positive rake angles on carbide lathe tools for the machining of steel has recently been reported by Einar Almdale (9).

For the experimental investigation of the double radial rake angles, the first two cutters tested had been given a negative primary radial rake angle of 12-deg, 0.005 in. wide at the cutting edge of a 15-deg positive secondary radial rake tooth. This cutter was tested at 523 fpm cutting speed and compared with cutters of 6-deg positive radial rake angle and 12-deg negative radial

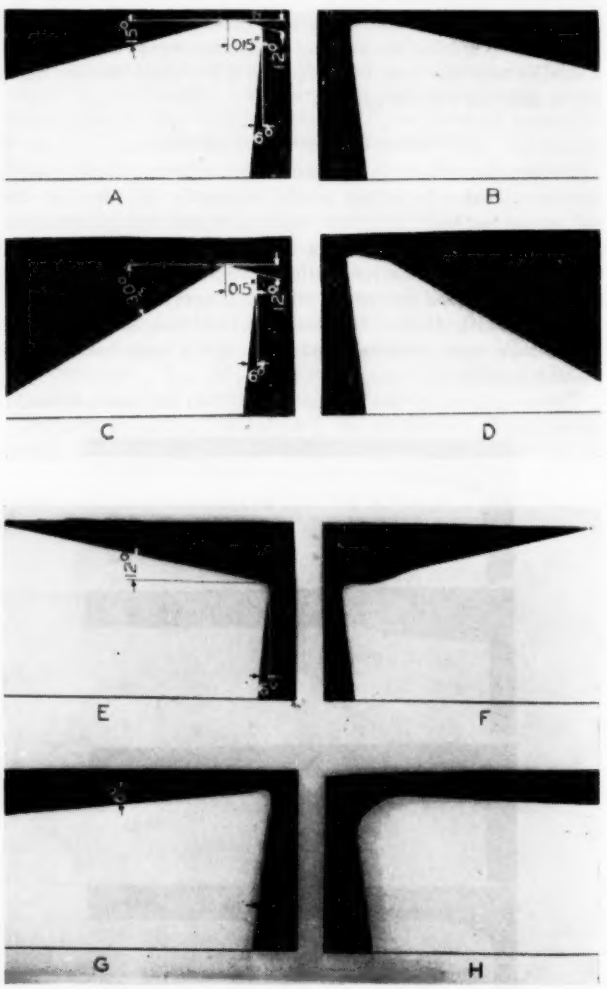

FIG. 9 CROSS-SECTIONAL SILHOUETTES OF CARBIDE CUTTING TIPS IN A PLANE NORMAL TO AXIS OF ROTATION BEFORE AND AFTER THEY HAD REMOVED EQUAL AMOUNTS OF METAL

(Double radial rake cutter blades are shown in *A*, *B*, *C*, and *D*. The 12-deg negative radial rake angle is the primary radial rake angle and the 15- or 30-deg positive radial rake angle behind it is the secondary radial rake angle. Negative and positive radial rake angles are shown in *E*, *F*, *G*, and *H*. Illustrations at left show the angles of a sharp cutter blade, while those at right show type of wear which was most frequently encountered in tips provided with the respective radial rake angles.)

rake angle. The feed per tooth in this test was 0.0075 in. and it was observed that the cutter with the double radial rake angles used less power than the cutter of 6-deg positive radial rake angle. It was also standing up better, but not as well as the cutter with 12-deg negative radial rake angle. After the cutter had removed a comparatively small amount of metal, a crater started to form behind the cutting edge and eventually caused the edge to fracture.

The next comparative test was made with the same cutters except that the negative primary radial rake angle of 12 deg on the double radial rake cutter was increased in width to 0.007 in. The result was practically the same as in the first series of tests.

A third series of tests was conducted with identical cutters. The ones with double radial rake were given a negative primary radial rake of 12 deg, 0.020 in. wide, and the feed per tooth was 0.0105 in. In these tests, the double radial rake cutter required approximately the same power as the 6-deg positive radial rake cutter at the beginning of the test. Later, after it had machined the same amount of metal as the others, its power requirements were less than either of the other cutters. At this point the 6-deg positive radial rake cutter had failed completely and the 12-deg negative radial rake cutter had worn more than the double radial rake cutter. A comparison of the actual power consumption shows that after the double radial rake cutter had machined 16.8 cu in. of metal its power requirement was equal to that of the 12-deg negative radial rake cutter at the beginning of the test. Workpiece temperature was also lower than for the other cutters.

After these tests a large number of cutters with 30-deg positive secondary radial rake angles provided with a negative primary radial rake angle were tested. The positive secondary radial rake angle of 30-deg behind the negative primary radial rake angle of 12-deg brought about an additional decrease in tool force, power consumption, and tool wear, Figs. 9, 12, and 13.

The most obvious indication of improved cutting action was the shape and color of the chips. Those made by a double radial rake angle cutter showed little deformation, Fig. 14. They were almost flat (cutting S.A.E. 1020) and the color ranged from straw for the 15-deg positive secondary radial rake cutter with 12-deg negative primary radial rake to white for the 30-deg positive secondary radial rake cutter with 12-deg negative primary radial rake, Fig. 16.

SURFACE FINISH AND TEMPERATURE OF WORKPIECE

In order to obtain a measure of the surface finish of the workpiece produced by milling cutters with various radial rake angles, profilometer readings were taken of the finish of each S.A.E. 1055 test bar or every third one in the tests which were repeated more than three times. In either case the first test bar cut with a new cutter and the last one of the test or series of tests were always checked for surface finish with the profilometer.

After comparing several thousand readings of surface finish produced at different speeds and feeds, the following statements can be made:

The best surface finish of 8 to 50 microinches is attained at cutting speeds from 500 to 800 fpm and a small feed of 0.0005 to 0.001 in. per tooth. At these feeds no difference could be established between the surfaces produced by the different cutters with various radial rake angles. However, when the feed was increased from 0.003 to 0.012 in. per tooth, the negative radial rake cutters gave a better finish than the cutters with positive radial rake. The best finish at these speeds was produced by the 12-deg negative radial rake cutter and had profilometer readings from 20 to 70 μ in. while the 6-deg positive radial rake cutter produced a finish from 30 to 145 μ in.

For a series of tests made at 427 fpm, the cutter with the 12-deg negative radial rake angles produced the best surface finish.

At speeds of 285, 192, and 106 fpm, with feeds from 0.0036 to 0.0130 in. per tooth, the surface finish was a little better with the 6-deg positive radial rake cutter than with the negative radial rake cutters. All the surface finishes were very poor, ranging from 90 to 245 μ in. for the 6-deg positive radial rake cutter to 170 to 290 μ in. for the 12-deg negative radial rake cutter.

It was found that the 6-deg positive radial rake cutter would produce a better surface at the higher cutting speeds after the cutting edges had become slightly worn.

The surface temperatures of the test bars were measured immediately before and after the cut. It can generally be stated that temperature of the workpiece is influenced by the radial rake angles of the cutter but is more dependent upon the cutting speed and feed. Surface temperature of the workpiece will vary directly as the cutting speed and inversely as the feed, see lower part of Figs. 1 and 2. The cutter which cuts with a smaller force, e.g., the 6-deg positive radial rake angle, will also entail a lower surface temperature as long as its cutting edge is sharp. As soon as its cutting edge is slightly worn, the surface temperature of the workpiece will increase beyond the temperatures generated by cutters with negative radial rake angles which have removed an equal amount of material. A cutter with negative radial rake angles, because of better wearing qualities, will generally give a somewhat lower surface temperature in workpieces than a positive radial rake cutter.

The foregoing statements apply only in those cases in which

(Top: Washerlike chips cut at a feed of 30 ipm. Center: Chips cut at 30 ipm by same cutter after a corner angle of 20 deg had been added. Bottom: Chips from same cutter, 20-deg corner angle, operating at 60 ipm feed.)

the chips will not be deposited upon the workpiece and will not transfer heat to the workpiece after their separation from the stock.

PRACTICAL APPLICATION OF DOUBLE RADIAL RAKE ANGLE

Performance of the double radial rake angle cutters with the experimental setup indicated a definite superiority over cutters with a single positive or negative radial rake angle. To check the action of double radial rake angles in a production setup, an 8-in-diam cutter, Fig. 17, was designed for the machining of mild steel. This cutter was made for comparison with existing cutters with negative radial rake angles and therefore was provided with 12 teeth. Blades made of solid carbide were ground and lapped so they could be held by wedges in ground slots in the cutter body. No axial rake angle or corner angle was provided. The positive secondary radial rake angle of the blades was 30 deg, and a negative primary radial rake of 6 deg, 0.015 in. wide, was ground on the cutting edge.

This cutter was operated at a cutting speed of 465 fpm and a feed of 30 ipm, which resulted in a maximum chip thickess of 0.0113 in. A $4 \times 4 \times 12$-in. block of S.A.E. 1020 cold-rolled steel with a Brinell hardness of 160 was used as the workpiece. Flat circular chips similar to spring washers and almost white in color were cut, see top of Fig. 18. After the cutter had machined approximately 300 cu in. of metal, signs of wear were detectable chiefly from the tendency of chips to assume a bronze tint. Interference of chips between the cutting blade and workpiece led to chipping of the cutting edge.

To increase cutter strength, a corner angle of 20 deg was ground on the blades. Chip clearance was improved by setting the blades out farther. The cutting edge was given a negative primary radial rake of 6 deg, but the width was increased to 0.025 in. This cutter was operated at various cutting speeds with feeds ranging from 35 to 60 ipm. Consequently, the maximum chip thickness was varied between 0.019 and 0.023 in. per tooth. Depth of cut was held constant at 0.125 in.

Chips cut with the second cutter were flat, semicircular, and almost white in color, see center of Fig. 18. After signs of wear began to appear on the cutting edge, the chips began to show a bronze coloring. One tip of the cutter was slightly damaged after operating for two hours by a chip which was carried around and caught between the blade and workpiece.

As can be seen from the chips in the lower part of Fig. 18, the chief disadvantage in this cutter design was inadequate chip clearance which allowed the chips to hit the cutter body and curl sharply at one end when the feed was 60 ipm.

However, these tests were sufficiently conclusive to prove that the double radial rake angle cutters require less power than the cutter with negative radial rake only and still provide a maximum amount of strength in the cutting edge.

The main advantage of the double radial rake on a face milling cutter will be that one cutter of basic design, e.g., 30-deg positive radial rake, can be used for mild-steel and nonferrous metals by grinding a primary negative radial rake on the cutting edge in the case of steels or a positive primary radial rake in the case of nonferrous metals. A cutter with a 15-deg positive secondary radial rake and a negative primary radial rake will be a stronger cutter and could be used in machining steels with a hardness in excess of 200 Bhn.

Regrinding of the double radial rake cutter will not require the removal of as much of the carbide tip as either a positive or negative rake cutter.

CONCLUSIONS

Negative radial rake angles were found to produce stronger

cutting tips, the cutting edges of which are generally not as liable to fail from impact and shock when entering a workpiece of hard material as are the cutting edges formed by positive radial rake angles.

Power required at the cutting edge is higher for the negative radial rake cutter than for cutters with positive radial rake angles. This holds true for conventional cutting speeds as well as higher cutting speeds up to 785 fpm.

Cutters with negative radial rake angles will stand up longer at the higher speeds than positive radial rake cutters under identical conditions.

Wear and failure at high speeds on the cutting edge of a positive radial rake angle cutter will soon increase its power consumption above that of a cutter with negative radial rake angles.

Best surface finish in high-speed milling is produced with a negative radial rake cutter at cutting speeds between 500 and 800 fpm. A feed of 0.001 in. per tooth or less will give the smoothest surface but will also result in more rapid abrasion at the cutting edge than with coarser feeds.

At 192 and 106 fpm cutting speed, the surface of the test specimens was badly torn and cracked by the negative radial rake cutters. This did not happen at higher cutting speeds.

Average temperature of the chips produced by ordinary feed does not approach the melting temperature of steel even at high speeds.

Heat in the workpiece and chips is due more to deformation of the metal than to separation in the cutting planes.

When removing a chip there is always more work done in deforming the metal than in separating it. The various elements like compression, bending, work-hardening, shearing, and friction enter into what is commonly called "metal-cutting."

A cutter with negative radial rake angles will generally give a somewhat lower surface temperature in the workpiece because it does not wear as rapidly as the positive radial rake cutter. However, as long as the positive radial rake cutter has a sharp cutting edge it will maintain lower temperatures in the workpiece.

A cutter with a 15- or 30-deg positive secondary radial rake angle and provided at the cutting edge with a negative primary radial rake angle 1 to 2 times the width of feed per tooth was found to be a more effective cutter, since it combined the increased strength of the cutting edge afforded by negative radial rake angles and the lower power requirement of the cutter with positive radial rake angles.

When running tool-life tests, it was found that the tool life of the carbide tips may vary as much as 50 per cent for the same cutters under identical conditions. This was due to variations of the quality between batches of carbide inserts of the same brand. Since tungsten from different sources is used by the carbide makers, this may be one of the most likely causes for the variation in cutter performance.

From the net horsepower at the cutter, as determined by the calorimeter, the tool forces were computed for the different rake angles by the formula

$$\text{hp} = \frac{F \times V}{33{,}000}$$

$$F = \frac{\text{hp} \times 33{,}000}{V}$$

This force F is the resultant force of several component forces, and it can be seen in Fig. 12 that it increases with the negative radial rake angle and decreases with the positive radial rake angle. It also shows how much the tool forces on a cutter with 12-deg negative primary radial rake are reduced by the application of a positive secondary radial rake angle of 15 or 30 deg.

The graph in Fig. 13 illustrates that the horsepower is a straight-line relationship to the cutting speed when depth of cut and feed are constant. The force F has a particular value for each radial rake angle and chip cross section. This value does not vary with cutting speed.

Effect of Grain Size and Subzero Treatment on Productivity of Four High-Speed Steels

By S. M. DEPOY,[1] DAYTON, OHIO

In the investigation reported, the effect of grain size and subzero treatment on the productivity of four high-speed steels was studied by means of a series of turning tests on one alloy steel at a preselected uniform hardness. The material being cut, the shape of the tool bit, and the speed, feed, and depth of cut on the turning operation were held constant. Standard and subzero treatments were used at different hardening temperatures to develop different grain sizes and different hardening products. The results obtained show that the grain size, carbide solution, and type of martensite formed in the tool have a very marked effect on its cutting ability. It appears that subzero treatment is much more effective, when large grain sizes are developed.

THE purpose of the research was as follows:

1 To determine the difference in cutting ability between four types of high-speed steel.

2 To determine the difference in cutting ability which may exist between standard-treated cutting tools and those that are subzero-treated between subsequent tempers.

3 To determine the effect of ultimate grain size on the cutting ability of cutting tools.

The equipment and materials used in the research were as follows:

1 Model C Monarch toolroom lathe, 14 in.

2 Battery of Ajax electric salt-bath furnaces.

3 Subzero unit; simple container filled with dry ice and methanol.

The materials utilized consisted of one alloy machinery steel, N.E. 8620, and four types of high-speed tool steel. The source, heat number and chemistry of these materials are given in Table 1.

[a] Specification for high-speed steels in this column were recently adopted by three large automotive manufacturers.

Procedure Followed in Tests

All high-speed steel bits (3/8 in. square × 3 in. long) were hardened in the Ajax salt-bath furnaces using Houghton liquid heat N.D. salt and Houghton liquid heat 2400 C salt in the preheat and high-heat furnaces, respectively. Park No. 100 salt was used in the quenching bath. The following are the treatments used:

Treatment No. 1. Preheat at 1650 F for 30 min; high heat at 2175 F for 2 1/2 min; quench at 1100 F for 3 min; cool in air to 100–150 F; wash thoroughly (hot water not less than 150 F); double temper at 1050 F, 2 hr + 2 hr.

Note: Care was taken that the bits cooled to room temperature between the temper cycles on all treatments.

Treatment No. 2. Preheat at 1650 F for 30 min; high heat at 2225 F for 2 1/2 min; quench at 1100 F for 3 min; cool in air to 100–150 F; wash thoroughly; double temper at 1050 F, 2 hr + 2 hr.

Treatment No. 3. Preheat at 1650 F for 30 min; high heat at 2275 F for 2 1/2 min; quench at 1100 F for 3 min; cool in air to 100–150 F; wash thoroughly; double temper at 1050 F, 2 hr + 2 hr.

Treatment No. 4. Preheat at 1650 F for 30 min; high heat at 2300 F for 2 1/2 min; quench at 1100 F for 3 min; cool in air to 100–150 F; wash thoroughly; double temper at 1050 F, 2 hr + 2 hr.

Treatment No. 5. Preheat at 1650 F for 30 min; high heat at 2325 F for 2 1/2 min; quench at 1100 F for 3 min; cool in air to 100–150 F; wash thoroughly; double temper at 1050 F, 2 hr + 2 hr.

Treatment No. 6. Preheat at 1650 F for 30 min; high heat at 2350 F for 2 1/2 min; quench at 1100 F for 3 min; cool in air to 100–150 F; wash thoroughly; double temper at 1050 F, 2 hr + 2 hr.

Treatment No. 7. Preheat at 1650 F for 30 min; high heat at 2410 F for 2 1/2 min; quench at 1100 F for 3 min; cool in air to 100–150 F; wash thoroughly; double temper at 1050 F, 2 hr + 2 hr.

A duplicate of each standard bit was made, and these duplicates were treated at 105 F below zero (—105 F). The bits were subjected to the subzero treatment between the two tempers. The refrigeration cycle was 3 hr. An Izod impact specimen was treated with each bit, and the relative impact values determined. Microsections were made on each bit, and the grain count was

TABLE 2 HARDNESS, IMPACT VALUE, AND GRAIN COUNT OF BITS TREATED AT —105 F

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

determined by the intercept method. Table 2 records the hardness, impact value, and grain count on each bit.

Following the heat-treatment all bits were ground to conform to the following specifications:[2] Back rake, 8 deg; side rake, 14 deg; front relief angle, 6 deg; side relief angle, 6 deg; end cutting angle, 6 deg; side cutting angle, 15 deg; nose radius, $^3/_{64}$ in. Care was taken that all bits were ground exactly alike.

When the bits were completely finished a 5-in-diam bar of N.E. 8620 of 240 Bhn, was set up in a 14-in. Model C Monarch toolroom lathe, and a preliminary cut made on it to remove the hot-rolled surface, reducing it to 4.950 in. diam. The bar was 23 in. long, having an available machining surface of 20 in. By varying the revolutions per minute (rpm) with respect to the diameter, a surface speed of 200–219 fpm was maintained, according to the following formula:

Surface speed = 0.262 × diam of bar × rpm of chuck

The cutting point of the tool was set on the center of the bar, and the shank of the tool was at 90 deg to the center axis of the bar. The depth of cut was held uniform at 0.050 in., and the feed at 0.0075 in. per revolution. The operation time of each bit was timed with a stop watch. The point of failure of each bit was obvious and abrupt. After failure, each bit was reground and made ready for a repeat test. All 24 bits were tested five times. It should be noted that small pieces of the tool bit were left in the bar at the point of failure. It was necessary to remove these and the "glazed" surface before starting another test bit.

Results of Tests

After tabulating the operating time on each bit, the average time was calculated for the five test runs. In order to present the comparison of the results on the various materials and heat-treatments, an arbitrary figure, which will be referred to as the "productivity" of the tool, was developed. This figure was arrived at by calculating the volume of metal removed, according to the following formula:

Volume of metal removed (cu in.)
= depth of cut × 12 × speed (fpm) × feed × operating time

With the feed depth of cut constant, the formula reduces to

Volume of metal removed = 0.0045 × speed × operating time

or

$$V = 0.0045\,ST = \text{productivity} = P$$

Thus

$$P = 0.0045\,ST$$

From this formula the productivity was calculated for each test run, and the average productivity determined for each bit.

TABLE 3 AVERAGE OPERATING TIME AND PRODUCTIVITY OF TOOLS TESTED

[2] "The Effect of Hardness on the Machinability of Six Alloy Steels," by O. W. Boston and L. V. Colwell, Trans. American Society for Metals, 1943, vol. 31, pp. 955–979.

Interpretation of Results

From examination of Table 3, it is immediately apparent that the low refrigeration treatment is immensely effective. Further, it may be noted that refrigeration is much more effective on the steel when it is austenitized at comparatively high temperatures.[3] It may also be noted that the higher austenitizing temperatures produce a superior cutting tool even when the tool is not subjected to refrigeration. However, this does not mean that high-speed tool steels may be heated at or over the top of the austenitizing range promiscuously. It must be remembered that these treatments were controlled very closely both regarding time of soak and temperature range. A small increment of prolonged soaking time or higher temperature would cause incipient fusion, thus producing a "burned structure." This structure would be extremely brittle and would be practically useless in operation.

Fig. 1 M-36 Steel, No. 4 Standard Heat-Treatment (Aqua regia etch; ×1000.)

The superiority of the bits that are austenitized at the top of the range is probably due to the more complete solution of the carbides contained in the steel. Microsections of these treatments show very little free carbide areas. In contrast to this, the bits that were austenitized at temperatures on the low side of the range or below, revealed very high percentages of free carbides. The carbides are much more effective as abrasive resistors when they are in solution. Consequently, it should be the object of the hardener to get as much solution as possible. There are patented and so-called "secret processes" which utilize this fact as a basis for their treatment. However, they use very high temperatures (2500–2700 F) in the austenitizing cycle and depend solely upon the operator to remove them before damage is done to the tool. It is believed that the same results may be obtained by close temperature control at the top of the austenitizing range.

Photomicrographs reveal a very definite structure is caused by subzero treatment. This structure is decidedly different from that obtained by standard treatments. Further, this in-

vestigator has not been able to produce the de-ired structure or productivity on tools that are treated at —90 F or higher.

Fig. 1 is a photomicrograph of M-36 steel treated with No. 4 treatment, but not subzero-treated. The familiar acicular formation of the marten ite is apparent. Fig. 2 reveals the structure obtained in the same steel with the same treatment only that it has been subzero-treated between the tempers. It may be seen that the martensite is no longer heavy acicular, but rather fine, giving a peppery structure. The same phenomenon is present in Figs. 3 and 4. The microsections were taken of M-2 steel using No. 3 heat-treatment. Fig. 3 is standard-treated, and Fig. 4 is subzero-treated. The apparent absence of the familiar carbides in Figs. 1 and 2 is the result of the extreme austenitizing temperature. This temperature has caused almost all of the carbides to go into solution.

The formation of the fine martensitic structure on the refrigerated material is believed by the author to be caused by the intense internal strains and pressures caused by the extreme low temperature. It is suggested that these pressures also caused the transformation of austenite to martensite to go to completion. Fig. 5 is a microsection of M-2 steel which was treated ac-

cording to No. 2 treatment, and refrigerated at —85 F, between the tempers. The heavy acicular martensitic structure is still present and blocky austenite may be seen. It may also be noted that the results obtained on cutting tests were very much the same as on an unrefrigerated tool. Consequently, it is believed that the pressures set up at —85 F are not sufficient to affect the structure of a material that has high alloy content, and the sluggish transformation properties that are present in high-speed steels.

Conclusions

The following general conclusions have been arrived at by a study of the results of this research:

1 High austenitizing temperatures should be used to produce the best structure for metal removal. However, the control of these temperatures and the austenitizing time must be accurate.

2 Refrigeration treatment of high-speed steel at —100 F or lower between the tempers will produce a superior tool.

3 Low austenitizing temperatures leave too many undissolved carbides, thus producing an inferior tool. Therefore, they should be avoided.

4 For cutting operations on hard alloy material, where intense heat is generated at the cutting edge, cobalt-bearing high-speed steel will generally prove superior.

Acknowledgment

Acknowledgment is given to Mr. Ray P. Kells of the Latrobe Electric Steel Company for furnishing the high-speed steel used in this research and the many suggestions that he made to the investigator.

Machinability of Plain-Carbon, Alloy, and Austenitic (Nonmagnetic) Steels, and Its Relation to Yield-Stress Ratios When Tensile Strengths Are Similar

By E. J. JANITZKY,[1] CHICAGO, ILL.

It is possible by the use of yield-stress ratios of plain-carbon, alloy, and austenitic (nonmagnetic) steels of the same tensile strength to obtain an index of machinability for rough-turning. The relation between Taylor speed and yield-stress ratios of the same tensile strength is expressed mathematically in the paper. A graphical presentation is also given. The yield-stress ratios of steels of the same tensile strength allow co-ordination of machinability of the types of steel listed by the same method, a distinct advantage over the use of any one of the four components of the tensile test alone, or a combination of stress and strain.

THE quest for an index of machinability began with Taylor's[2] establishment of the conception that the measure of machinability may be expressed by the cutting speed at which a standard tool will last for periods of 20 min, 1 hr, or more.

Taylor also found that the change of life of a high-speed steel tool, resulting from a change in the cutting speed, could be represented approximately by an empirical equation

$$VT^n = C \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

in which

V = cutting speed, fpm
T = tool life, min
n = an exponent
C = constant which is dependent for its numerical value upon exact cutting conditions (other than speed). It will vary with the form and size of tools, the material cut, the steel and treatment of the steel from which the tools are prepared, the feed and depth of cut

Curves from which V is deduced are generally called TV curves.

Taylor also developed an empirical relation for carbon steels between cutting speed and the tensile properties of the steel tested by using the tensile strength and elongation. The equation gives some indication regarding machinability but, with the advent of alloy steels, it lost its usefulness. Taylor, however, was not satisfied with the evaluations by this equation.

The present tendency to judge machinability by tensile strength, yield stress, Brinell hardness number or reduction of area, separately, is not satisfactory. Two steels with equal tensile strength or equal yield stress may have different machining properties depending upon the ratio of yield stress to the tensile strength. Likewise two equal Brinell hardness numbers do not necessarily signify equal machinability.

Relationship of Stress and Strain

Before going into the discussion of machinability of steel and its relation to yield-stress ratios when the tensile strengths are similar, it is advisable to consider the relation of stress and strain as they manifest themselves in the tensile test.

A statistical analysis of the relation of the yield-stress ratio to the deformation ratio may be helpful in arriving at a better understanding of the subject.

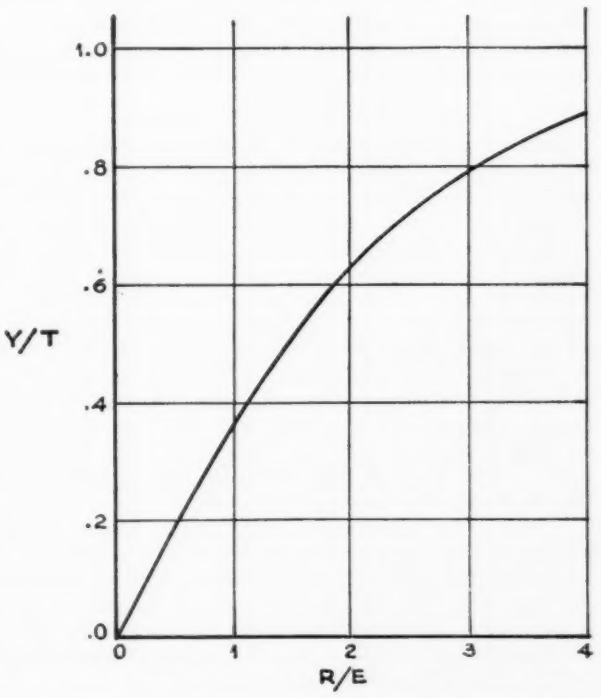

Fig. 1 Illustrating Relation of Deformation Ratio to Yield-Stress Ratio

Yield-stress ratio is defined as the ratio of yield stress to tensile strength, and deformation ratio, the ratio of reduction of area to elongation.

By plotting yield-stress ratios (Y:T) against deformation ratios (R:E), one obtains a curve as shown in Fig. 1.

The curve may be expressed by the equation

[1] Consulting Metallurgical Engineer, Carnegie-Illinois Steel Corporation, South Works.

[2] "On the Art of Cutting Metals," by F. W. Taylor, Trans. A.S.M.E., vol. 28, 1906, pp. 31–279.

Contributed by the Research Committee on Metal Cutting Data and Bibliography and presented at the Semi-Annual Meeting, Pittsburgh, Pa., June 19–22, 1944, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

$$\frac{Y}{T} = 1 - e^{-0.446}\left(\frac{R}{E}\right)^{1.133} \quad \ldots\ldots\ldots\ldots [2]$$

where

T = tensile strength, psi $\times 10^{-3}$
Y = yield stress, psi $\times 10^{-3}$
R = reduction of area, per cent
E = elongation, per cent, in a gage length 4 times diameter
e = base of natural logarithm

The equation was developed by using yield stress at a set of 0.2 per cent gage length and a pulling speed of 0.11 ipm.

From Equation [2], we perceive that, for a given deformation ratio, there is a corresponding yield-stress ratio. We also perceive that at constant tensile strength with increasing deformation ratio, the yield-stress ratio increases and, consequently the yield stress and vice versa.

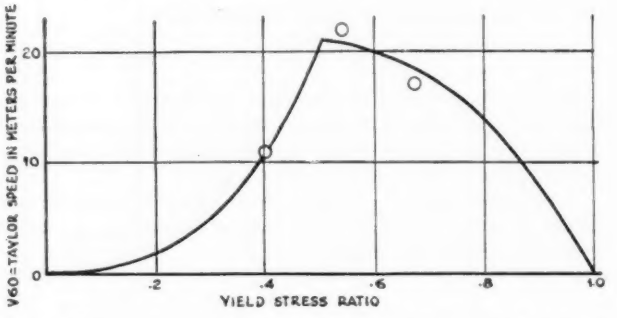

FIG. 2 REPRESENTING AN ISOROTIC CYCLE FOR A TENSILE STRENGTH OF 64.5 KG PER SQ MM OR 91.5 PSI $\times 10^{-3}$ AND DIFFERENT YIELD-STRESS RATIO

From the foregoing observations, it is also evident that co-ordination of machinability with any of the four properties reported in making the tensile test is impossible and leads to erroneous conclusions. The use of indentation hardness for co-ordination of machinability properties may also result in misleading conclusions. An austenitic steel (nonmagnetic) may possess the same Brinell hardness numeral as a quenched and tempered or annealed plain-carbon or alloyed steel and have different tensile properties and, therefore, different machinability properties.

As already mentioned, steels of the same tensile strength may possess different yield-stress ratios and, consequently, different machinability properties. Thus a plot of different yield-stress ratios, but of the same tensile strength, against Taylor speed appears to be the clue to the present enigma.

However, some steels of the same tensile strength but different yield-stress ratio may possess the same Taylor speed. This coincidence manifests itself in nonmagnetic steels of austenitic structure or very low-carbon steels of ferritic structure; that is, in steels of a yield-stress ratio lower than 0.5. Thus the coincidence suggests a family of reversing cycles of the same tensile strength but different yield-stress ratios.

When Taylor speeds are plotted on the ordinate and yield-stress ratios of the same tensile strength on the abscissa, a reversing cycle is obtained.

The cycle, as illustrated in Fig. 2, starts at a yield-stress ratio of 0 and ascends up to a yield-stress ratio of 0.5. From this point the cycle descends to the X axis and terminates at a yield-stress ratio of 1.0.

In Fig. 2, the cycle represents steels of a tensile strength of 64.5 kg per sq mm or 91.5 psi $\times 10^{-3}$, including a nonmagnetic stainless steel of the S-18-8 grade with a yield-stress ratio of 0.4 (own datum).

NOTE: N = normalized, A = annealed, O = oil-quenched, W = water-quenched, T = tempered.

The cycle may be identified as reversing parabolic cycle with the ascending branch of the paraboła (a cubic parabola) having its vertex at 0 yield-stress ratio and the descending branch (an ordinary parabola) having its verfex at the maximum V_{60}, corresponding to a yield-stress ratio of 0.5.

Thus we may express the ascending part of the cycle

$$V_{60} = c_1\left(\frac{Y}{T}\right)^3 \quad \ldots\ldots\ldots\ldots [3]$$

and the descending part of the cycle

$$V_{60} = c_2\left[0.25 - \left(\frac{Y}{T} - 0.5\right)^2\right] \quad \ldots\ldots\ldots [3a]$$

where

$\frac{Y}{T}$ = yield-stress ratio (Y = yield stress, T = tensile strength)
V_{60} = Taylor speed in meters or feet per minute
c_1 and c_2 = factors

Calculating the factor c_2 from data of Langenbach,[3] given in

[3] "Die Zerspannbarkeit-Kennziffer V_{60} in ihrer Beziehung zur Zugfestigkeit und Streckgrenze beim Schrupp-Dreh Vorgang von legierten und unlegierten Staehlen," by F. Langenbach, Technische Hochschule, Aachen, 1932.

Table 1, and plotting it against the corresponding tensile strength, we obtain a hyperbolic relation that is

$$c_2 = \frac{12{,}500}{T^{1.2}}$$

By interpolating the data from the stainless steel

$$c_1 = \frac{25{,}000}{T^{1.2}}$$

Thus Equation [3] will read

$$V_{60} = \frac{25{,}000}{T^{1.2}} \left(\frac{Y}{T}\right)^3$$

and Equation [3*a*]

$$V_{60} = \frac{12{,}500}{T^{1.2}} \left[0.25 - \left(\frac{Y}{T} - 0.5\right)^2\right]$$

In order to transfer the equation into feet per minute when T is expressed in psi $\times 10^{-3}$, $c_1 = 116{,}642$ and $c_2 = 58{,}464$. The factors c_1 and c_2 in this special case are for the dimension of the tool, for its heat-treatment and chemical composition, the depth of cut, and feed.

Credence to these equations is given in Table 1. Data of observed values are in column 6 and the approximated values are in column 7. A family of cycles in steps of 10 kg per sq mm or 14.2 psi $\times 10^{-3}$ is also given in Fig. 3, for comparing relative machinability.

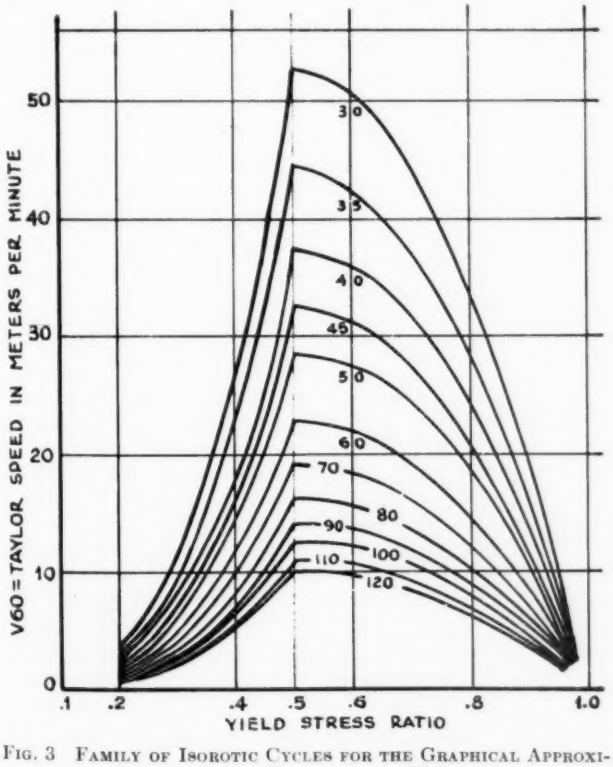

FIG. 3 FAMILY OF ISOROTIC CYCLES FOR THE GRAPHICAL APPROXIMATION OF TAYLOR SPEED (V_{60})
(Numerals at each cycle are kg per sq mm.)

It will be noted by comparison of calculated and actual Taylor speed, that variation in chemical composition does not influence machinability, provided that the steels can be heat-treated to have the same tensile properties. In other words, if two steels are heat-treated to have the same tensile properties (tensile strength, yield stress, elongation, and reduction of area), assuming such heat-treatment is possible, they will be equal in regard to machinability. Leaded, sulphurized, or phosphorized steels, or steels containing other elements as selenium, etc., are exceptions and must be co-ordinated as such. Another method of co-ordination may be applied by including tool angles, that is, the most efficient tool angle for yield-stress ratios of the same tensile strength.

Co-ordination of cold-worked steels of the same tensile strength but different yield-stress ratios may also be accomplished. It is known that cold-drawn or cold-rolled bars machine easier than bars in their natural conditions. It is also known that by cold deformation the yield-stress ratio and also the tensile strength are raised above those in their prior condition. Thus, the machinability of cold-work-processed steels may be also co-ordinated.

When using the same tool and the same feed and depth of cut for steels cold-work-processed to the same tensile strength but different yield-stress ratios, machinability will increase with increasing yield-stress ratio. However, the higher the yield-stress ratio of the steel before cold-processing, the less increase in machinability is to be expected, and cold-work-processing becomes impracticable or technically impossible.

In order not to confuse the conception of machinability, one has to consider that it is a different matter when speed of machining is the primary object and surface finish secondary. In the first case it is desirable to have a lower yield-stress ratio than in the second case, when the material is of the same tensile strength.

Cutting-speed variations also influence the surface finish, that is, the higher the permissible speed the better the surface appearance.

DETAILS OF MACHINABILITY TEST

Following are the details of the machinability test on which the development is based. The data were taken from F. Langen-

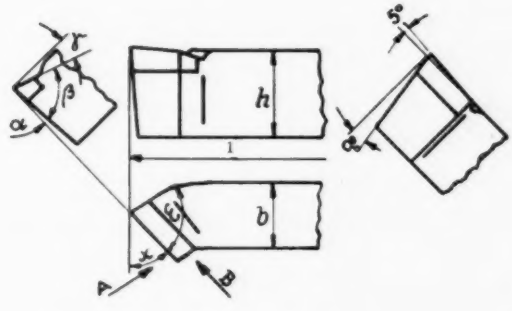

FIG. 4 DIMENSIONS OF TOOL
(Arrows *A* and *B* direction of view. $h = 1.574$ in.; $b = 1.18$ in.; $1 = 13.$ in.; $\alpha = 6$ deg; $\beta = 65$ deg; $\gamma = 19$ deg; $\varepsilon = 45$ deg; $\epsilon = 80$ deg.)

bach's machinability test and selected not only because of the wide range of analyses represented, but also because of precautions used in making the tests, and the fact that only a limited zone was used for making both the machinability tests and the tests for physical properties. As the material under test (bars from 6 to 8 in. diam, and from 60 to 120 in. long) was in the heat-treated condition, it is very important how deep the ma-

chining was performed in regard to the diameter or the location of the tests taken for tensile strength. Fortunately, the machining depth was limited to 2 inches maximum in order to avoid discrepancies on account of hardness gradients, and the tensile-test specimens were taken longitudinally, close to the surface at the ends of the rounds (gage length, 5 times the diameter); yield stress at 0.2 per cent of gage length.

The machining was of the roughing type and dry. The tools were of 18-4-1 composition and the dimensions are given in Fig. 4. The recorded data on machinability represent a depth of cut of 0.236 in. and a feed of 0.039 in. per revolution. The Taylor speed, V_{60}, was obtained by Taylor's method from the TV curves. Each of the TV curves was duplicated and the data so obtained were averaged. If the duplicate tests were not in agreement a triplicate test was run.

The motive of Langenbach's work was to investigate the influence of yield stress on the machinability of steels, as he was aware of the fact that machinability of steels of the same tensile strength decreased with increasing yield stress, however, a co-ordination was not attempted. The present paper deals with the co-ordination. It is perhaps not out of place to mention that the second object of these tests was to establish whether there was a difference between tipped tools when compared with standard tools. Therefore, the machinability of each steel was determined with tipped tools and with standard tools and was found to be independent of the type of tool used.

The Influence of Through-Metal on the Heat Loss From Insulated Walls

By VICTOR PASCHKIS[1] and M. P. HEISLER,[2] NEW YORK, N. Y.

The heat flow through insulation containing "through-metal," or "thermal short-circuits" has been investigated. The heat flow through such a structure (occurring, for example, in the insulation of ship hulls) can be considerably larger than would be found from adding to the heat flow through the insulation that contributed by the "through-metal," as if the two were independent. Thus the apparent effectiveness of an insulation can be very much smaller than would be calculated from the thermal conductivity alone. From the many different forms of thermal short-circuits, one specific type has been selected for investigation, i.e., that of metal strips or fins extending through insulation which is covered on its surfaces by sheet metal. General curves are developed and their application explained, from which an "increase factor" for any condition (conductivity and thickness of the insulation, conductivity and thickness of the strips, outside film conductance) can be read. The "increase factor" is defined as the ratio of the heat flow through an actual structure, compared with the flow that would occur if the insulation and heat flow through metal strips were independent of each other. The method of developing these general curves and the basis of the experimental technique used are explained in two Appendixes.

Statement of Problem

FREQUENTLY, in the practical application of thermal insulation "through-metal" has to be used. The term "through-metal" is here used for any metal extending from the hot surface to the cold one. Because metal has a very much higher conductivity than any insulating material, such through-metal acts like a thermal short-circuit, and therefore greatly influences the flow of heat through a structure. The present paper deals with some problems in connection with the heat losses caused by "through-metal."

Out of the great variety of possible shapes and sizes of such through-metal, one arrangement has been selected as the object of the investigations; the case of a strip of metal connecting the hot surface with the cold surface. Fig. 1 is an isometric sketch of this arrangement. It shows an insulation (of thickness L) covered by sheet metal a and b (thickness W_M). The insulation is assumed to extend infinitely in the x- and y-directions, but in the x-direction it is interrupted by infinitely long strips c (thickness $2\,W_M$) which are spaced at regular intervals W_I. (In case of block insulation W_I represents the width of an individual block.) Arrangements as shown in Fig. 1 are frequently used. Typical examples are the insulated hulls of ships, walls of stratochambers, and industrial ovens with metallic walls. Similar problems occur in almost all insulating practice. By way of example, the following cases may be mentioned: Metal-enclosed bricks such as are used in electric furnaces and in open-hearth furnaces; pipe flanges extending through the pipe insulation; anchor bolts and pipes used in boiler insulation; and mortar joints in brick walls.

It is obvious that such through-metal influences the heat loss of the structure, and also that, at any appreciable distance from the surface, the metal will influence the temperatures in the adjacent insulation.

In determining the heat loss from a structure incorporating through-metal, the oldest and empirical way is to estimate the increase of heat loss due to the metal and account for this increase by an additive, or by a multiplication correction factor, found from experience with similar arrangements.

A distinct step forward is the separate calculation of the heat flowing through the insulation and through the metal, and adding both heat flows. This method is based upon the assumption that the metal does not influence the temperatures in the surrounding insulation. This assumption, however, is in many cases not tenable, as will be evident from this paper. The correct approach must take the lateral flow into consideration.

A general solution for this problem, covering any thickness L of the structure, any spacing W_I of the strips, any thickness W_M of the metal, as well as any conductivity of insulation k_I and metal k_M, is the main object of this report. Only three assumptions have been made which limit the generality:

1 The film conductance on the hot surface is considered to be infinite (this means that the hot surface has the same temperature as the adjacent air (ambient).

2 The thickness of the metallic strips is twice that of the sheet metal covering the surfaces.

3 The thermal properties (conductivities and cold-side film conductance) do not change with temperature.

Lateral Heat Flow

Assume a wall of thickness L (Fig. 2). The hot side is maintained constantly at a temperature t_h, the cold side at a temperature t_{cs}. Now if the wall is homogeneous, then independent of the thermal conductivity of the material of the wall, the temperature at any given distance l from the hot surface always has the same value as given by

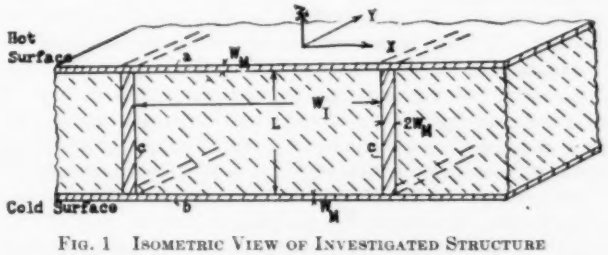

Fig. 1 Isometric View of Investigated Structure

$$t = t_{cs} + \frac{L - l}{L}(t_h - t_{cs}) \qquad [1]$$

If (Fig. 3) two materials with thermal conductivities k_1 and k_2

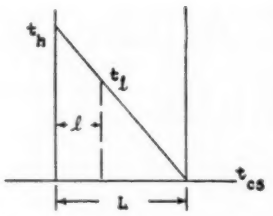

FIG. 2 TEMPERATURE DROP THROUGH HOMOGENEOUS WALL

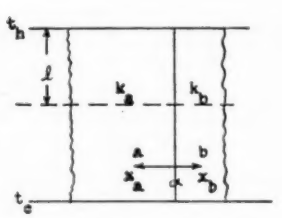

FIG. 3 INTERFACE BETWEEN TWO MATERIALS

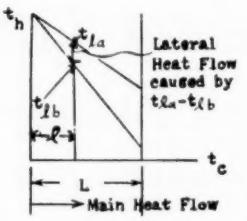

FIG. 4 TEMPERATURE DROP CAUSING LATERAL FLOW

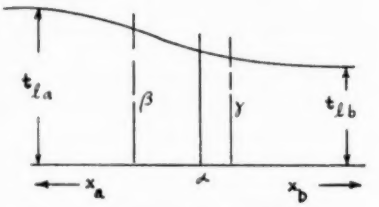

FIG. 5 TEMPERATURE DISTRIBUTION NEAR INTERFACE

are subjected in parallel to the same temperature difference, then their temperatures at a distance l from the hot surface are the same. Between points of equal temperature, no heat transfer can of course occur.

Matters are different however if the cold surface, instead of being held at a constant value, is (Fig. 4) facing an ambient of constant temperature t_c. Now the temperature at point l is not only a function of the quantities appearing in Equation [1] but also of the conductivity k of the material and the film conductance h at the cold surface. The temperature at l can now be found from

$$t_l = t_c + (t_h - t_c)\left(1 - \frac{l}{1 + \frac{k}{h}}\right) \quad \ldots\ldots\ldots [2]$$

Considering again the arrangement in Fig. 3, it is obvious that, since the two materials have different thermal conductivities, there will result different temperatures at each and any level l. Fig. 4 contains two such temperature lines for materials of different conductivities. At distance l from the hot surface, material a will have temperature t_{la} and material b temperature t_{lb}. Of course heat will flow from the point of higher temperature to that of lower temperature. This flow of heat is perpendicular to the main flow, which goes from the hot to the cold surface. It is called hereafter the "lateral" heat flow. The lateral heat flow is proportional to the difference of temperatures $(t_{la} - t_{lb})$. This difference in turn depends upon the relative magnitude of the values k_a/h and k_b/h, as becomes obvious from Equation [2]. If h approaches infinity ($h = \infty$ is the mathematical expression for the surface having the same temperature as the ambient), Equation [2] becomes identical with Equation [1]. No lateral heat flow occurs. If h approaches zero (which is the mathematical expression for a wall covered on the cold side by an absolute insulator), t_l becomes t_h and the entire wall is at uniform temperature equal to the hot-surface temperature.

The lateral heat flow does not leave the temperature field unchanged. If there is no contact resistance between the two materials (Fig. 3), the interface will show a temperature drop line, which lies between that for material a and material b. Adjacent strata will have almost the same temperatures, and only at some distance from α will the influence of the other material be no longer noticeable. Fig. 5 shows schematically the temperatures at level l. The distances x are plotted as abscissas on both sides of position α; temperatures are plotted as ordinates. If in either material the temperatures are taken close to α, say at β and γ, then different temperatures are obtained from those which would be expected if no lateral heat flow occurred; namely, different from t_a and t_b.

Referring to Fig. 1, let $W_I = 2.5$ in., $L = 9$ in., and the thickness $2\,W_M$ of the metal strips c be $^1/_8$ in. Let the conductivity of the insulation be 0.25 Btu/ft, hr, F, the conductivity of the metal strips and sheets be 25 Btu/ft, hr, F, and the film conductance h be 2 Btu/sq ft, hr, F.

In Fig. 6 the thickness L is plotted as abscissa, and temperature as ordinate. The two dotted lines show the temperatures that would exist if no lateral flow occurred. Because of the lateral flow, however, the temperatures approach each other. Near the metal, the line s prevails and in the center of the brick, the line c.

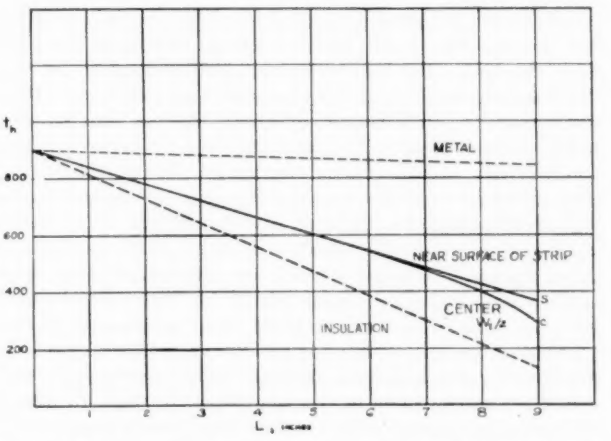

FIG. 6 TEMPERATURE DISTRIBUTION WITH "THROUGH-METAL"

LIST OF VARIABLES

In order to obtain a general solution, a survey of the variables which influence the heat flow was made. The heat flow Q for a structure, as shown in Fig. 1, is governed by the following:

1 The temperature difference between the hot surface and the cold ambient.
2 The net spacing W_I of the strips.
3 The thickness L of the insulation.
4 The thickness W_M of the strips.
5 The conductivities k_I of the insulation and k_M of the strip.
6 The surface-film conductance h.

Instead of plotting a great number of values of Q for many different combinations of the properties involved, it appeared simpler to compare the actual heat loss with a standard value. Although different possibilities for this value are available, it was decided to compare Q with the value that would be obtained if no lateral heat flow occurred. The ratio thus observed

$$\frac{\text{Actual heat loss with lateral heat flow}}{\text{Heat loss with no lateral heat flow}}$$

is called the "increase factor," and is abbreviated hereafter by I.

In order to determine the heat loss for any actual structure, such as Fig. 1, proceed as follows:

1 Determine the heat loss Q_s, i.e., the heat loss assuming no lateral heat flow.
2 Determine the value of I (see "Presentation of Results").
3 Multiply Q_s by I; this gives the actual heat loss Q with lateral heat flow.

4 Q_s can be found from Equation [3], which represents the basic law of steady-state heat flow

$$Q_s = (t_h - t_c)\left(\frac{W_I}{\frac{L}{k_I} + \frac{1}{h}} + \frac{W_M}{\frac{L}{k_M} + \frac{1}{h}}\right) \quad \ldots\ldots\ldots [3]$$

In this equation, as in the entire paper, it is assumed that the strips repeat at equal distances, so that it is sufficient to consider one space W_I and one strip c.

Method of Experiments

All experiments described in this paper were carried out by the "electric analogy method" on the "heat and mass flow analyzer" at Columbia University. This method is based on the identity of laws governing the flow of electricity and of heat in a body. Appendix 1 contains a more detailed discussion and description of the method. Here it may suffice to say that in the analogy:

Electric conductivity represents thermal conductivity.
Voltage represents temperature difference.
Current represents heat flow.

The application of the method consists of building an electrical circuit which is analogous to the structure, measuring the current through the structure for applied voltage (which corresponds to the temperature difference across the structure), and translating the measured current into heat units.

Influence of Individual Variables

It is of interest to study the influence of the different variables just mentioned on the increase factor I.

The temperature difference $t_h - t_c$ has no influence on I. Q_s as well as Q is proportional to the temperature difference, and therefore, I, which by definition is $I = \frac{Q}{Q_s}$, is independent of temperature.

If W_I becomes very small and approaches zero, the influence of the insulating material as compared with the metal strips vanishes. Consequently, for $W_I = 0$, I becomes unity. On the other hand, if W_I becomes very large, the influence of the strips vanishes, and the structure behaves as if it consisted only of insulating material. For $W_I = \infty$, therefore, I again approaches unity. Between $W_I = 0$ and $W_I = \infty$, however, I must have values larger than 1. At some value a maximum will occur.

If L is very small, the thermal resistance of the insulation as well as of the strip becomes very small; the major part of the resistance then lies in the surface film. There will be almost no temperature differences within the structure; therefore very little lateral heat flow occurs, and, as a limit, I becomes unity (for $L = 0$). If, on the other hand, L becomes extremely large, the resistance in the film becomes insignificant; and all points at the same distance l from the hot surface have the same temperature, independent of the material involved. Again no lateral heat flow can develop, and I becomes unity when L equals infinity. The character of the curve is the same as that shown in Fig. 7, for W_I.

It is obvious that a change of W_M will result in a similar curve. If W_M approaches zero, almost all heat flow is limited to the insulation. If on the other hand W_M becomes exceedingly large the influence of the heat flow through the insulation can be entirely neglected, making I equal to unity.

If either of the two conductivities (k_I or k_M) becomes zero or infinite, the importance of the part of the structure having the other conductivity becomes either alone dominant or entirely insignificant, e.g., let $k_I = 0$. Then only the heat flow through

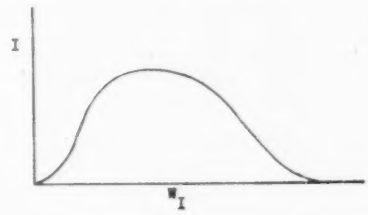

Fig. 7 Characteristic Shape of I—W_I Function

c, the metal strips, with the width W_M remains. If $k_I = \infty$, the heat flow through c becomes entirely insignificant. (If k_M changes, the situation is correspondingly reversed.) Consequently, either of the two conductivities will yield a curve for I of the same character as that shown in Fig. 7 for W_I.

It has been mentioned that for $h = 0$ and for $h = \infty$, the value of I becomes unity, while for other values of h, I is larger than unity.

Summarizing, it can be stated that the curve for I plotted against any single variable (the other variables held constant) yields curves of the same general character: For the two limiting cases, the variable being zero or infinity, I is unity; for all values of the variable in between, I is larger than unity.

Presentation of Results

The presentation of I as a function of six different variables would call for a vast number of charts, which would take long to plot, and then would still be unwieldy to use. Fortunately, however, the six variables can be grouped in four parameters, which will be mentioned. Thus plotting is greatly simplified. The deduction of these parameters, and the proof of their validity, is given in Appendix 2.

The four parameters are as follows

$$f_1 = \frac{W_M}{W_I}, \quad f_2 = \frac{W_I}{L}, \quad f_3 = \frac{k_I \cdot L}{k_M \cdot W_M}, \quad f_4 = \frac{k_I}{h \cdot W_I} \quad \ldots [4]$$

The values of the parameters to be used in the charts were so selected that at least the following limits for the individual variables are covered by the graphs:

W_I = $^1/_{12}$ to $1^1/_4$ ft
W_M = $^1/_{192}$ to $^1/_{24}$ ft (= $^1/_{16}$ to $^1/_2$ in.)
L = $^1/_6$ to $1^1/_2$ ft
k_I = 0.025 to 1.5 Btu/ft, hr, F
k_M = 2.5 to 200 Btu/ft, hr, F
h = 1 to 8 Btu/sq ft, hr, F

For practical purposes, a greater range is covered, since any two of the variables will seldom approach their limit at the same time. Because of the relationship in Equation [4] any one of the values can become larger, if at the same time the other values change accordingly. The values are so selected that f_1 to f_4 can be obtained even if the individual magnitudes are as unfavorable as possible. For example f_1 has been investigated within the limits 0.004 to 0.5 $\left(\text{i.e., } \frac{1}{192 \times 1.25} \text{ to } \frac{12}{24}\right)$.

The results are presented in Table 1 and in charts. In all charts, values of I are plotted as ordinates and values of f_4 as abscissas. Each chart contains several curves, each curve holding for a different but constant value of f_3.

In order to enable proper interpolation, charts are presented for four different values of f_1 and four different values of f_2. Inasmuch as f_1 and f_2 can vary independently, sixteen different combinations are necessary.

The four values of f_1 are 0.004, 0.020, 0.100, 0.500.

The four values of f_2 are 0.25, 0.5, 0.5, 1.5, 7.5.

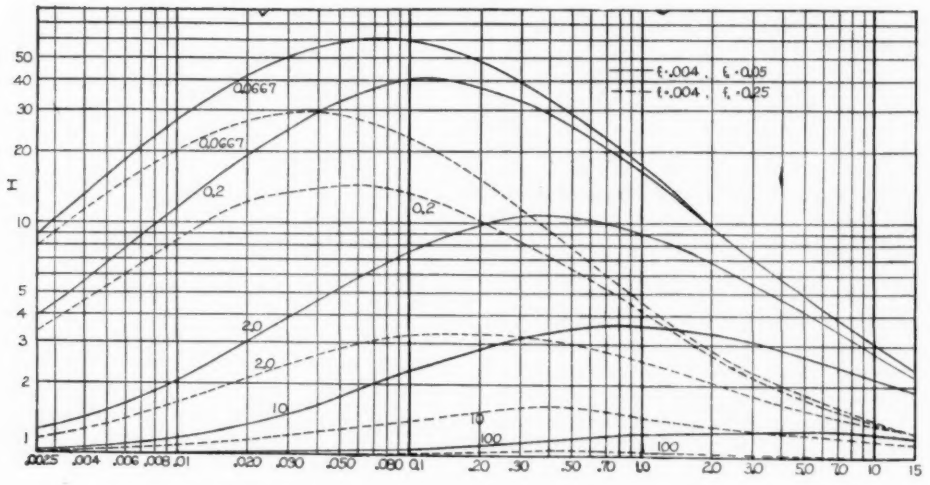

FIG. 8 INCREASE FACTOR I PLOTTED AGAINST f_4 FOR VARIOUS VALUES OF f_3

As explained, each value of f_1 can combine with any of the four values of f_2.

A first survey of the results may be obtained from Table 1, which contains the maximum values of I for different combinations of the values for f_1, f_2, f_3.

The results are shown in Figs. 8 to 14, inclusive. Table 2 shows the combinations of the different parameters to be found in the various figures.

TABLE 1 MAXIMUM VALUES OF "INCREASE FACTOR" I

f_1	f_2	0.05	0.25	1.5	7.5
0.004	f_3 = 0.0667	60.0	29.3	8.90	2.30
	0.2	41.0	14.2	3.40	1.56
	2.0	10.8	3.32	1.36	1.09
	10	3.62	1.64	1.05	1
	100	1.30	1.06	1	1

0.500	Fig. 14	Fig. 14	Fig. 13	

Wherever Table 1 shows amaximum (for I) of 1.0, no curve appears in the graphs, because I has the value 1 over the entire range of f_4.

DISCUSSION OF EXPERIMENTAL RESULTS AND APPLICATION OF CHARTS

Discussion. High values of I occur with low values of f_1 and f_3. The meaning of f_1 and f_2 is so simple (from Equation [4]) that no comment appears to be necessary. The parameter f_3, however, is a complex expression

$$f_1 \cdot f_2 \cdot f_3 = \frac{k_I}{k_M}$$

A low f_3, with other f's unchanged means therefore a very high-grade insulating material with steel, or a medium insulating material with copper for the strips, etc. At high values of f_3, I becomes appreciable only under extreme conditions for the other f values (f_1 low, f_2 medium).

The parameter f_4 definitely shows a critical range in the neighborhood of 0.5. It determines the spacing of the strips and indicates that the spacing exerts its influence not directly but in combination with the thickness of the insulation. If I becomes smaller with decreasing f_2 (i.e., if the spacing of the strips becomes smaller), the heat losses do not necessarily decrease also. The heat losses are the product of the value $Q_s \cdot I$. This is important to keep in mind, because a drop in I might lead to the erroneous assumption that the heat loss drops.

Application of Curves. The curves shown in Figs. 8 to 14, inclusive, enable the determination of the actual heat loss for any condition covered by the general program outlined under "Statement of Problem." The use of the dimensionless parameters f_1 to f_4 makes the trends less easily recognized. Their use, however, is the only means of presenting the results in a practicable way. The use of the curves is best demonstrated in three examples which will cover two different insulating materials. The examples will also show how to use the curves to detect the influence of change in design.

Example 1: An insulation, L = 8 in. (0.667 ft) thick, is reinforced by steel strips $2W_M$ = 1/8 in. (0.0104 ft) thick. The insulation is covered on both sides by steel sheets of the thickness W_M = 1/16 in. (0.0052 ft). The temperature of the hot side of the structure is 570 F; the ambient facing the cold side is 70 F. The film conductance on the cold side is 2 Btu/sq ft, hr, F. The thermal conductivity of the insulating material is 0.08 Btu/ft, hr, F; that of the steel is 26 Btu/ft, hr, F.

(*A*) What is the heat loss if the strips are spaced W_I = 8 in. (0.667 ft) apart?

(*B*) How is the heat loss changed if the spacing changes to W_I = 4 in., 6 in., 12 in., 16 in.?

In order to answer these two questions, the values of the f's must be determined. The parameter f_3 is not influenced by W_I, and therefore has a constant value, f_3 = 0.394. The values of f_1, f_2, f_4 change with W_I, as shown in Table 3.

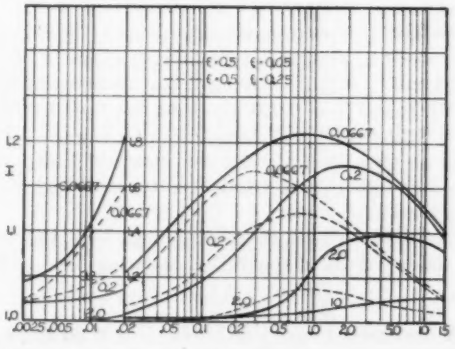

FIG. 14 INCREASE FACTOR I PLOTTED AGAINST f_4 FOR VARIOUS VALUES OF f_3

TABLE 3 VALUES OF PARAMETERS f_1, f_2, AND f_4

W_1	f_1	f_2	f_4
4	0.0156	0.5	0.12
6	0.0104	0.75	0.08
8	0.0078	1.0	0.06
12	0.0052	1.5	0.04
16	0.0039	2	0.03

The values for f_4 can be read directly on the abscissa of the charts; the values of the other f's, however, cannot be read directly. Therefore, the I values for these f's have to be found by interpolation. This interpolation is shown here for $W_I = 8$ in. The values of I for $f_3 = 0.394$ are not directly available in the charts. In order to interpolate, cross-curves have to be drawn (see Fig. 15). Values of f_3 are plotted as abscissas, and I as ordinates. Three curves (full lines) are drawn, each for a

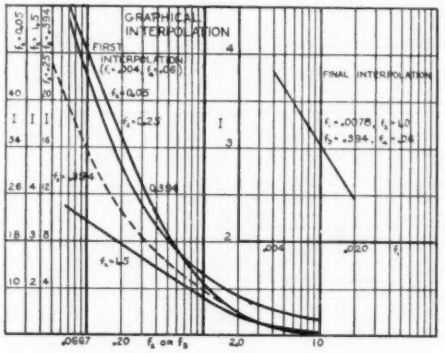

FIG. 15 GRAPHICAL INTERPOLATION

different value of f_2. (Each of the three curves has a different ordinate scale; for curve f_2 use the scale marked $f_2 = 0.05$, etc.) All curves are for $f_1 = 0.004$.

The values of I for $f_3 = 0.394$ (abscissa) are now read as follows:

	I for $f_3 = 0.394$
Curve $f_2 = 0.05$	22.7
Curve $f_2 = 0.25$	8.6
Curve $f_2 = 1.5$	2.45

The value of f_2 in the example ($W_I = 8$ in.) is $f_2 = 1$. For this value interpolation is again necessary. Because $f_2 = 0.25$ and $f_2 = 1.5$ are too far apart for accurate interpolation, a curve with all three values is drawn (dashed curve); f_2 is plotted on the abscissa, I on the ordinate. At $f_2 = 1$, the value of $I = 3.8$ is read on the ordinate. This is the increase factor I for $f_1 = 0.004$ $f_2 = 1.0$, $f_3 = 0.394$, and $f_4 = 0.06$.

A similar chart (not included in this paper) may now be drawn for $f_1 = 0.02$. From this chart, the value of I for $f_1 = 0.02$, $f_2 = 1$, $f_3 = 0.394$, $f_4 = 0.06$ is found to be 2.45.

Now the final interpolation is made (see insert in Fig. 15); f_1 is plotted as abscissa, while the ordinates give values of I for $f_2 = 1$, $f_3 = 0.394$ and $f_4 = 0.06$. By interpolating between the values for $f_1 = 0.004$ and $f_1 = 0.020$, the value for $f_1 = 0.0078$ can be read; $I = 3.22$.

This means that due to lateral heat flow, the heat loss for the structure described in case (A) is 3.22 times as high as if there were no lateral flow.

In order to determine the actual heat loss, the heat flow through the metal and through the insulation have to be calculated

$$\text{Metal heat flow } \frac{(570 - 70)^1/_8 \times {}^1/_{12}}{\frac{8}{12 \times 26} + \frac{1}{2}} = 9.90 \text{ Btu per hr}$$

$$\text{Insulation } \frac{(570 - 70) \times 8 \times {}^1/_{12}}{\frac{8}{12 \times 0.08} + {}^1/_2} = 37.6 \text{ Btu per hr}$$

Total $9.9 + 37.6 = 47.5$ Btu per hr

The actual heat loss is $47.5 \times 3.08 = 146$ Btu per hr

The influence of the spacing (case B) has been studied by similar interpolations. In order to compare the results, it seemed advisable to reduce all of them to a width of 1 ft; inasmuch as the length (of the infinite structure) under consideration is also 1 ft, the results then apply to 1 sq ft. The reduction is carried out by dividing the heat loss by $(W_I + 2W_M)$, where W_I and W_M are expressed in feet.

The results are shown in Fig. 16, in which spacing W_I is plotted as abscissa. Two ordinate scales are used; one for heat flow in Btu/sq ft, hr, the other (dimensionless) for I. Three curves are shown: the full line is for I; the dotted line is for the heat loss without lateral flow (sum of flow through metal and through insulation); the broken line is the actual heat loss with lateral heat flow.

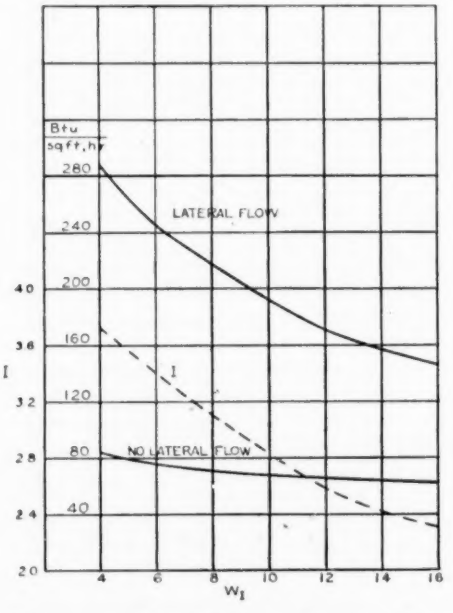

FIG. 16 VARIATION OF HEAT LOSS AND INCREASE FACTOR WITH SPACING OF STRIPS; $h = 2$

Example 2: What is the influence of the cold-side film conductance for the wall described in Example 1? How do the heat losses change if $h_0 = 1.5$, 2.5, or 3.5 instead of 2 as in Example 1?

Changing the film conductance influences only f_4; nevertheless all the interpolations have to be repeated. The results are given in Fig. 17, which shows the actual heat loss and the increase factor, both plotted as ordinates against the spacing W_I of the strips. Each curve is for a different value of h indicated on the curve. Changing the film conductance within the range of the example has relatively small influence on either the heat loss or the increase factor; more than doubling the value of h (3.5 instead of 1.5) increases the heat loss only something like 20 to 35 per cent. Of course conditions may be different for a different value of k_I or L.

Example 3: What is the influence of the thickness of insulation on increase factor and heat loss? What is the influence of the thermal conductivity of the insulation?

The results for this example are shown in Fig. 18. The ex-

ample has been carried through for a spacing of the strips, $W_I = 8$ in.; thickness of the metal, $W_M = {}^1/_{32}$ in.; conductivity of the metal, 26 Btu/ft, hr, F; film conductance, $h = 2$ Btu/sq ft, hr, F.

Thickness L of the insulation is plotted as abscissa. The ordinates have two scales, i.e., one for the heat losses per square foot (Btu/sq ft, hr), one dimensionless for I. The broken lines show the heat loss without lateral heat flow, the full lines the heat loss with lateral heat flow, and the dashed lines the increase factor. There are two curves of each type, i.e., one for a conductivity of the insulation $k_I = 0.08$, the other for $k_I = 0.05$. The values of the conductivities are noted on the curves. The increase factor for $k_I = 0.05$ goes through a maximum, while the corresponding curve of total heat loss does not show a maximum.

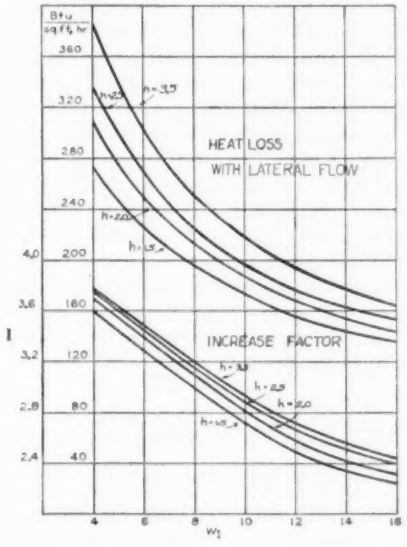

FIG. 17 VARIATION OF HEAT LOSS AND INCREASE FACTOR WITH SPACING OF STRIPS W_I FOR VARIOUS VALUES OF BOUNDARY CONDUCTANCE h

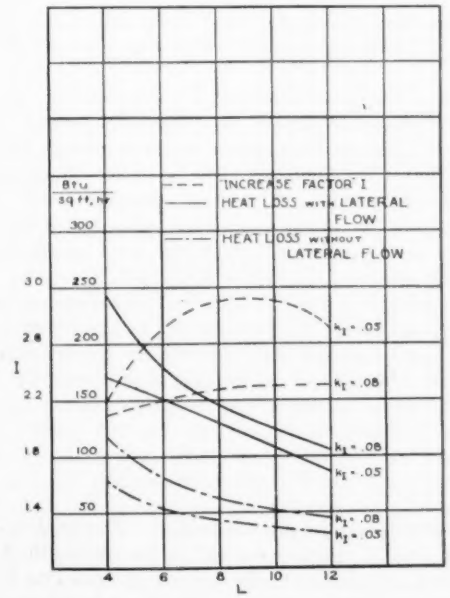

FIG. 18 VARIATION OF HEAT LOSS AND INCREASE FACTOR WITH THICKNESS L, OF INSULATION FOR DIFFERENT THERMAL CONDUCTIVITIES k_I OF THE INSULATION

Conclusions and Verifications. The extremely high values of the increase factor look alarming. Some preliminary tests indicate that the larger part of the additional heat loss can be attributed to the influence of the steel enclosure on both surfaces of the insulators. This should be further investigated, and (in further tests) if it should prove to be true, important design factors may result, e.g., insulation inserted between the strips and the covering sheets would do much to decrease the loss. From these considerations it also follows that a contact resistance between insulation and through-metal, or insulation and covering sheets, would not affect the results materially. Further investigations to verify this point would be desirable.

By way of a general confirmation as to the order of magnitude of the increase factor, reference is made to an article by J. G. Bergdoll (1),[3] in which the author states that in insulating a strato chamber it has been found that, due to thermal short circuits, the actual heat loss was 4 times as high as expected for the conductivity and thickness of the insulation.

SUMMARY

1 The heat flow through a structure composed of an insulation covered by sheet metal and interspersed with metal strips (through-metal) is discussed.

2 The cause of "lateral heat flow" occurring at any plane or level parallel to the surface of the structure, is explained and related to the cold-side film conductance.

3 An "increase factor" is defined as the ratio of the actual heat loss, including lateral heat flow, to the heat flow that would occur if no lateral heat flow existed.

4 The factors influencing the increase factor are discussed.

5 General curves giving the increase factor for various conditions are presented.

6 The use of these general curves is explained by means of examples. The examples show in a readily understandable way the influence of the thermal conductivity of the insulation, its thickness, the spacing of the metal strips, and the film conductance in specific cases.

7 In two Appendixes which follow the experimental technique and the mathematical deductions for the paper are presented.

Appendix I

ELECTRIC ANALOGY METHOD

Ohm's law for the flow of electricity through a conductor is expressed by

$$e = ir \qquad [5]$$

where

e designates voltage
i designates current
r designates resistance

Similarly, Fourier's law for steady-state heat flow through a body can be written

$$t = Q \cdot R \qquad [6]$$

where

t designates temperature difference
Q designates rate of heat flow
R designates thermal resistance

Both the electrical resistance and the thermal resistance are

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

proportional to the length L of the path traveled by the medium (current or heat) and inversely proportional to the area S of flow; both are proportional to the resistivity (ρe and ρt) of the material involved (in case of heat flow, it is more common to use the reciprocal value of the resistivity, namely, the thermal conductivity, $k = \frac{1}{\rho t}$). Therefore, r and R can be expressed by

$$r = \rho e \cdot \frac{L}{A} \quad \ldots\ldots\ldots\ldots\ldots\ldots [7a]$$

$$R = \frac{1}{k} \cdot \frac{L}{A} \quad \ldots\ldots\ldots\ldots\ldots\ldots [7b]$$

From the mathematical identity of Equations [5] and [6] and that of Equations [7a] and [7b], it follows that thermal phenomena can be studied by carrying out certain electrical measurements. (Incidentally, the method is widely inclusive and can be used to analyze the transient state as well as the steady state.)

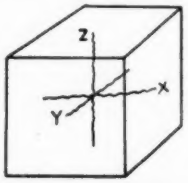

FIG. 19 VIEW OF LUMP WITH RESISTORS REPRESENTING THREE-DIMENSIONAL FLOW

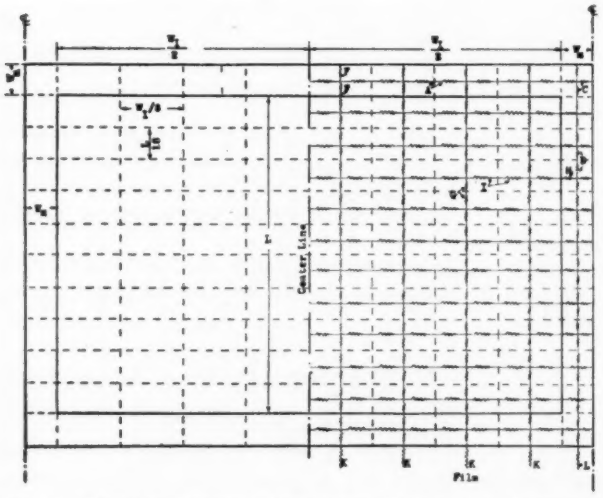

FIG. 20 DIAGRAM SHOWING SECTIONING LAYOUT AND RESISTORS

The equipment at Columbia University, known as the "heat and mass flow analyzer," has been especially devised to handle complex problems of the transient state. The method and the laboratory have been described elsewhere (2). As is evident from this paper, it can be usefully employed for analyzing complicated steady-state problems.

One method of studying steady-heat flow by electric analogy consists in setting up a body which is geometrically identical to the body subjected to heat flow and filling this body with a semiconductor. Electrical measurements then disclose the heat flow, even in odd shapes. Langmuir (3) probably was the first to use this method.

For the present experiments, the analyzer, primarily designed for transient flow, has been used. In this method the body which is to be analyzed is thought of as cut into a number of sections or lumps. The resistance in each of the three directions is considered concentrated in the three axes, as indicated by the isometric sketch, Fig. 19.

The structure being of infinite length in the Y direction, there can be no heat flow in the Y direction, and the problem reduces to one involving only two dimensions.

Thus a network is built up having "horizontal" resistors for flow in the direction X, and "vertical" resistors for flow in the direction Z. Fig. 20 shows the wiring diagram. Because of symmetry, it is sufficient to build up a circuit representing $W_I/2$ and W_M. L has been divided into 10 sections, and $W_I/2$ into four sections. Fig. 20 shows the geometrical meaning of the sections. It is a cross section, showing the same view as the isometric sketch, Fig. 1, with the limits of the sections noted. The film conductance on the cold surface is represented by additional resistors. The letters at each resistor refer to Appendix 2, where the deduction of the dimensionless units is discussed.

A word of comparison with the other electrical method (with geometrical similarity) may not be amiss. The "lumping" method used here is probably more complicated than the "similarity" method. With only 115 sections available, the "lumping" is rather crude. (Previous experiments (4) have shown, however, that this does not affect the accuracy to any appreciable extent.) One great advantage, on the other hand, may be claimed for the "lumping" method; it is easily possible to study separately the influence of the thermal conductivities of the various materials involved.

Appendix 2

DERIVATION OF DIMENSIONLESS UNITS

If two different thermal arrangements lead to the same circuit, they have the same value I. If, once a network is established, all resistors are changed in the same ratio, e.g., all resistors are doubled or halved, the outcome of the experiments is not changed; merely the "scale factor" between Ohm's law and Joule's law is different.

The first step then in deriving the dimensionless units consists in writing the equations for all resistors, Equations [9] to [17]. Resistors having the same letter always have the same value and are changed in value only after the individual test is over.

The next step consists in forming resistor ratios. Here all resistors were compared with R_I as "standard." Any of the other resistors (R_A, R_B, etc.) would have done just as well; all resistors, however, must be compared with the same "standard" (R_I), Equations [18] to [25]. If in these equations certain variables always appear in the same grouping, then this group may be taken as one parameter. Thus the four parameters were empirically evolved. In writing Equations [9] to [18], a value z has been used; z is the "scale factor" transforming heat units into electrical units. The scale factor z in (megohms $\times$ Btu/hr, F) ties in each individual resistor with the thermal resistance it represents. For example, in the case of resistance R_G; the thermal resistance R_{Gt} for this section is expressed by

$$R_{Gt} = \frac{8}{10} \frac{L}{k_I \cdot W_I \cdot 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots [8]$$

This equation is easy enough to find. The total thickness L is divided into 10 sections; one section has for length of the heat path only $L/10$; similarly, the width is divided into 8 sections. Hence, the area is proportional to $W_I/8$. A length in the direction Y of 1 ft is considered. If L and W_I are expressed in feet, k_B in Btu/ft, hr, F, then R_{Gt} is expressed in F, hr/Btu. In

order to obtain the resistance R_G in megohms, R_{Gt} has to be multiplied by z

$$R_G = \frac{8 \cdot z \cdot L}{10 \cdot k_I \cdot W_I} \quad [9]$$

Similarly the other Equations [10] to [17], for the resistors have been found.

$$R_I = \frac{10 \cdot z \cdot W_I}{8 \cdot k_I \cdot L} \quad [10]$$

$$R_A = \frac{1 \cdot z \cdot W_I}{8 \cdot k_M \cdot W_M} \quad [11]$$

$$R_D = \frac{1 \cdot z \cdot L}{10 \cdot k_M \cdot W_M} \quad [12]$$

$$R_L = \frac{z}{h \cdot W_M} \quad [13]$$

$$R_K = \frac{8 \cdot z}{h \cdot W_I} \quad [14]$$

$$R_C = \frac{z \cdot W_M \cdot 1}{k_M \cdot 2 \cdot W_M} = \frac{z}{2k_M} \quad [15]$$

$$R_H = \frac{z \cdot W_M \cdot 10}{k_M \cdot 2 \cdot L} \quad [16]$$

$$R_F = \frac{z \cdot W_M \cdot 8}{k_M \cdot 2 \cdot W_I} \quad [17]$$

Now by comparing each of these resistors with R_I it can readily be found that the variables always appear in given ratios, and only in these ratios. They therefore are selected as parameters. They were given in Equations [4], which, for convenience, are repeated here

$$f_1 = \frac{W_M}{W_I};\ f_2 = \frac{W_I}{L};\ f_3 = \frac{k_I \cdot L}{k_M \cdot W_M};\ f_4 = \frac{k_I}{h \cdot W_I} \quad [4]$$

With these parameters, equations for various resistors read

$$R_G = 0.64 \cdot \frac{R_I}{f_2^2} \quad [18]$$

$$R_A = 0.1 \cdot f_3 \cdot R_I \quad [19]$$

$$R_D = 0.08 \frac{f_3}{f_2} \cdot R_I \quad [20]$$

$$R_L = 0.8 \frac{f_4}{f_1 \cdot f_2} \cdot R_I \quad [21]$$

$$R_C = 0.4 \cdot f_1 \cdot f_3 \cdot R_I \quad [22]$$

$$R_H = 4 \cdot f_1^2 \cdot f_2 \cdot f_3 \cdot R_I \quad [23]$$

$$R_F = 3.2 \cdot f_1^2 \cdot f_3 \cdot R_I \quad [24]$$

$$R_k = \frac{6.4 f_4}{f_2} \cdot R_I \quad [25]$$

The four parameters used are by no means the only ones possible. There are certainly other combinations available. The validity of the parameters chosen was checked twice; once by "dimensional analysis" (5), which shows possible selections of parameters. A second practical test was made by setting up one set of conditions. Then one value, say W_I, was changed. Following Equations [4] this means a change of W_M and L if f_1 to f_4 are to remain unchanged, which in turn calls for other changes. By systematically changing the conditions and corresponding circuits, one must return to the original circuit if the parameters are to be correct. The method of finding the parameters, as just described, is generally applicable in working with the heat and mass flow analyzer, and is in many cases very promising. For specific cases, it yields answers avoiding lengthy and extended mathematical analysis. In other cases of course it would be easier to determine the (dimensionless) parameters mathematically and arrange the experiments accordingly.

Discussion

C. E. Ernst.[4] The influence of through-metal in limiting the effectiveness of insulation has long been realized, but this paper presents what is apparently the first concrete information on the extent of this influence. A true appreciation of the importance of such information can be gained from a consideration of the economics involved.

Thermal insulation for any specific condition should be applied in a thickness consistent with its cost and efficiency and the cost of heat-energy loss. In other words, the economic thickness is that thickness at which the sum of the cost of insulation per year and the cost of heat-energy loss is a minimum.

Through-metal, however, has the effect of reducing the efficiency of insulation, and the greater the amount of through-metal the less the thickness of insulation that can be justified. In other words, if the amount of through-metal is sufficient to nullify the effect of the insulation, the elimination of the insulation can be economically justified.

While, for the present, construction methods apparently do not allow complete elimination of thermal short-circuiting paths through insulation, common sense tells us that it is certainly of economic advantage to reduce them to a minimum.

Herein lies the importance of the present work which is a good start in the right direction. Further work along these lines should lead to better design and construction methods for the incorporation of thermal insulation into all kinds of heated and refrigerated equipment with the efficiency of the insulation in place approaching that of the material alone, while maintaining the required mechanical strength of the structure.

G. M. Dusinberre.[5] The practical use of the authors' curves is considerably restricted by the lack of generality in the basic assumptions. For example, one of the metal walls will generally be designed for structural strength and will be rela-

[4] Johns-Manville Corporation, New York, N. Y.

[5] Department of Mechanical Engineering, Virginia Polytechnic Institute, Blacksburg, Va. Now on duty at U. S. Naval Academy, Annapolis, Md. Mem. A.S.M.E.

tively thick, while the other wall will merely serve as a retainer for the insulation and will be relatively thin. The through-metal will often, as in ship construction, serve a structural purpose in stiffening the strength bulkhead, and the web thickness will be related to the thickness of this bulkhead.

Another serious lack of generality lies in the assumption that the surface resistance can be neglected on one side. There are a great many practical cases where this cannot be done.

Fortunately, the engineer who has to grind out an answer for this type of problem has at his disposal the greater flexibility, generality, speed, and lucidity of the numerical method outlined by Emmons.[6]

The writer worked the authors' Example 1A by this method, using the same assumptions except that the temperature gradient in the thin direction of the metal was neglected.[7] The time required was 2 hr for a 4-in. and a 2-in. network spacing. Additional solutions on the 2-in. spacing would take about $^1/_2$ hr each. This is probably more rapid than the authors' method, considering the intricate interpolation procedure which they describe.

In the numerical method, we work directly in temperatures, and trends are readily recognized. The authors note that the opposite is true when working with parameters. In the numerical method we acquire, incidentally, some other information of value, such as the maximum cold-surface temperature. This is a matter which insulation engineers are sometimes called upon to guarantee.

The temperature-distribution pattern was found to be as indicated in Fig. 21. This pattern is reversed on either side, by symmetry.

The heat flow can be calculated from the various layers. For example, from the cold surface to ambient, we have a mean temperature difference of 123 F. The width of a unit panel is $^2/_3$ ft and the surface coefficient is 2. Then $123 \times {}^2/_3 \times 2 = 164$ Btu per hr. Checking with the second layer in Fig. 21, we have

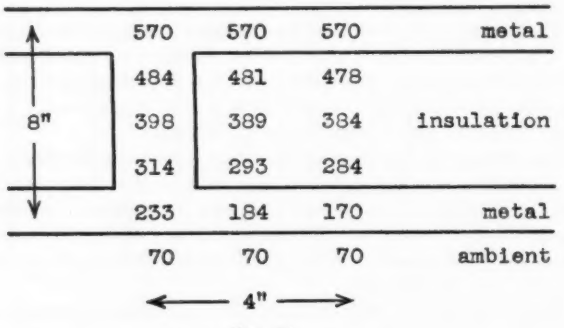

FIG. 21

a temperature difference of 84 F in the metal, and a mean temperature difference of 94 F in the insulation. Then $84 \times 26 \times 6 \times {}^1/_{96} = 137$ Btu per hr for the steel, and $94 \times 0.08 \times 6 \times {}^2/_3 = 30$ Btu per hr for the insulation, a total of 167 Btu per hr. The hot-side layer figures 169 Btu per hr, which is close enough to give the answer as 167 ± 3 Btu per hr.

This does not agree with the authors' figure of 146 Btu per hr. If the authors would publish a temperature-distribution diagram for this example, it might indicate where the discrepancy lies.

H. G. ELROD, JR.[8] For the conditions outlined by the authors, the heat flow per section may be obtained from the following formula

$$Q = \frac{t_h - t_c}{\frac{L}{k_I} + \frac{1}{h}} \left[W_I + \frac{k_M}{k_I}(2W_M) - \left\{ \frac{(2W_M)}{L\,W'_M} \left(1 - \frac{k_I}{k_M}\right) \frac{\tanh \alpha \frac{W_I}{2} + \frac{k_M}{k_I}(W_M)}{\alpha \tanh \alpha \frac{W_I}{2} + \beta W_M} \right\} \right]$$

where

$$\alpha^2 = \frac{\frac{k_I}{L} + h}{k_M W_M'}$$

and

$$\beta = \frac{\frac{k_M}{L} + h}{k_M W_M'}$$

W_M' the thickness of the metal walls need not be one half of the thickness of the through-metal strips.

The foregoing formula was derived by neglecting the temperature drop in the thin direction of the metal, and the lateral heat flow in the insulation. The first assumption is obviously allowable; the second assumption, because it arbitrarily restricts the heat flow, should cause the formula to yield values of heat flow smaller than actually found. Nevertheless, the formula values consistently exceed those shown by the authors in Fig. 17. On the other hand, the formula agrees well with the numerical method. The following is a comparison between formula and numerical method for the authors' example (1*a*):

	Formula	Numerical method	Authors' value
Over-all heat flow, Btu per hr	165	167 ± 3	146
Cold-surface temperatures,[a] deg F	168	170	
	184	184	
	238	233	

[a] Obtained using a temperature-distribution formula based upon precisely the same assumptions as used for the formula given in this discussion.

The writer's formula can be applied to the case where the metal-wall thicknesses and film coefficients are the same on both sides of the insulation. For this case, L should stand for one-half of the thickness of the insulation, and $t_h - t_c$ should be replaced by one half the total temperature difference.

The solution for cylindrical through-metal (bolts and pipes) has already been illustrated.[9]

AUTHORS' CLOSURE

Mr. Ernst stresses the fact that through-metal greatly increases the heat losses of insulated structures, and that the value of insulation is therefore decreased. Examination of this problem shows that the economic thickness of insulation is greater for structures with thermal short circuits than for those without. Quite apart from any numerical examination, pure reasoning can prove that this must be so. With increasing thickness, the influence of the thermal short circuit decreases; therefore, greater thickness results in a smaller increase factor. However,

[6] "The Numerical Solution of Heat-Conduction Problems," by H. W. Emmons, Trans. A.S.M.E., vol. 65, 1943, p. 607–615.

[7] This gradient works out to be on the order of 0.01 deg F in the present example. It seems surprising that the authors used two resistances in series to subdivide such a relatively small quantity.

no increase in thickness within practical limits can offset the increased losses due to through-metal. Therefore, every care should be taken in design of equipment to avoid through-metal as far as possible. After the limit has been reached, the economic thickness of the insulation should be determined, and this can best be done by using curves such as are contained in this paper.

With regard to the example checked by Messrs. Dusinberre and Elrod, it should be noted that in the paper an increase factor of 3.08 was inadvertently introduced in place of the actual value 3.22 found from the graphical interpolations. If 3.22 is used, as should have been done, the heat loss becomes $3.22 \times 4.75 = 153$ Btu per hr. This is about 7 per cent less than the loss calculated by the discussers, and the difference must be attributed to the many steps in the interpolation. This was verified by setting up the network for this specific case and measuring the heat loss, which was found to be approximately 165 Btu per hr.

In specific reply to Mr. Dusinberre's comments it can be agreed that the present curves do not cover all cases which he mentions as important. If only one case at a time has to be solved, the use of the numerical method may be helpful, if no network or analyzer is quickly available. If, however, a larger number of such cases have to be solved, the development of curves would be desirable, because the practicing engineer will rarely find the time for the calculations entailed by the numerical method.

Mr. Dusinberre's statement that in the numerical method trends are more readily recognized than when working with parameters is misleading. The statement that trends are not readily seen when working with parameters refers to the trends due to the individual variables, as conductivity, spacing, etc. Such trends cannot be found by solving only one problem, either by the numerical method or on the analyzer. They can be detected only by solving a number of problems sufficient to cover the range it is desired to investigate. The best presentation of a large number of tests is by dimensionless parameter as used in this paper.

The maximum cold-surface temperatures can be found on the analyzer without additional work. They could be presented in graphs similar to those shown in the paper.

Network spacings of 2 in. and 4 in., as used by Mr. Dusinberre, are sufficient in the present example. In many instances, they will not yield accurate results, in which case the work involved by the numerical method increases considerably.

In his footnote,[7] Mr. Dusinberre overlooks the fact that the network, as shown in Fig. 20, refers not only to the example discussed by him but also to broader cases in which the subdivision as shown is necessary because the temperature gradient in the thin direction of the metal cannot be neglected.

Mr. Elrod's formula is interesting, and it would be desirable that he publish proof. The assumptions made are rather broad for certain conditions, and the value of the equation would be enhanced if Mr. Elrod would determine the limits (perhaps expressed in f_1, f_2, f_3, and f_4) within which his formula can be safely used.

Formulas for Calculating the Temperature Distribution in Electrical Coils of General Rectangular Cross Section

By T. J. HIGGINS,[1] CHICAGO, ILL.

In a recent paper (1)[2] Prof. Max Jakob outlined a procedure for calculating the temperature at any point T, the maximum temperature T_m, and the average temperature T_a in an electrical coil maintained at uniform surface temperature. Mr. Jakob derived explicit formulas for certain simple coils, i.e., the circular cylindrical coil, the infinite-plate coil, the spherical coil. The present paper is devoted to effecting formulas for T, T_m, and T_a for the very important case of the toroidal coil of general rectangular cross section. Following Jakob, the procedure is to pose determination of T as a boundary-value problem in the mathematical theory of heat; effect the formal solution for T; and obtain the corresponding formulas for T_m and T_a by use of their known relationship with T. Illustrative of application of the general formulas derived in the present paper, the maximum and average temperatures in a coil of given dimensions are calculated and are found to be in excellent agreement with the known measured values.

1 General Remarks

A current-carrying toroidal coil of rectangular cross section, composed of many turns of insulated wire of circular or of rectangular cross section, is an important component of many electrical devices. Commonly, the coil is either exposed to the atmosphere, e.g., the field coils of a dynamo, or is submerged in a liquid, e.g., the coils of a transformer. Usually, conditions are such that the temperature distribution in the coil is substantially independent of the angular co-ordinate of a system of cylindrical co-ordinates, the axis of which is the axis of the coil. If so, the temperature distribution is two-dimensional, i.e., it is the same over any cross section of the coil. Only this case will be considered.

In use, the heat generated in the coil results in a general temperature rise throughout the coil. In consequence, a point of maximum temperature is to be found in the cross section of the coil. By virtue of the assumed angular symmetry, this maximum temperature is the maximum temperature in the coil. Because the permissible maximum coil current is that which produces a specified maximum temperature in the coil, and because the "hot" or "operating" resistance of the coil depends upon, and can be calculated from, the average (mean) temperature of the coil, formulas for predetermining the temperature distribution, maximum temperature, and average temperature are of considerable interest to the designer of toroidal coils. Unfortunately, but few such formulas are available to him in the literature.

Undoubtedly, this paucity of formulas stems from the analytical difficulties posed by the various factors which affect the temperature distribution in the coil. In the main, the temperature at an arbitrary point in the coil is determined by (*a*) the geometry of the coil, (*b*) the surface conditions, (*c*) the current density in the metal, (*d*) the temperature variations of the thermal conductivities of the insulation and of the metal, and (*e*) the temperature variation of the electrical resistivity of the metal. If each of these quantities is specified analytically, determination of the temperature distribution can be set as a problem in the mathematical theory of heat. Theoretically, a rigorous solution of this problem is possible. Practically, such a solution is mathematically intractable.

Thus for specification of even the simplest conditions for items (*b*) to (*e*), i.e., uniform surface temperature and uniform current density, thermal conductivities and electrical resistivity independent of the temperature, the writer is unacquainted with any analysis, rigorous or approximate, wherein the actual toroidal geometry of the coil is taken into account. The mathematical analysis prerequisite to such a solution is so severe that, perforce, those who have worked on the problem have limited themselves to analyzing coils of simple geometry in which the temperature distribution approximates (so it is thought) that in certain special shapes of toroidal coils.

For example, a rectangular cylinder (i.e., an infinite cylinder of rectangular cross section) can be considered as a torus of the same cross section and of infinite inner radius. If, then, a toroidal coil of rectangular cross section is such that the inner radius is large compared with either dimension of its cross section, the temperature distribution in it tends to that in a rectangular cylindrical coil of the same cross section.

If, further, the length of the radial side (width) of the rectangular cross section of the toroidal coil is small, compared with that of the axial side (height), the temperature distribution in both the toroidal and the cylindrical coils tends to that in the geometrically simpler plate coil (i.e., a cylindrical coil with cross section an infinite strip of definite width). Accordingly, if the toroidal coil tends to either of these two limiting shapes, it can be conjectured that an approximate formula for the temperature distribution in the toroidal coil is afforded by the formula for the corresponding rectangular cylindrical or plate coil.

However, for these simpler coils, as for the more complex toroidal coil, the author is unacquainted with any rigorous solution for the temperature distribution. Neither is it to be expected that any exists. For even if temperature variations in the thermal conductivities and electrical resistivity be neglected, in a rigorous solution (as a problem in the mathematical theory of heat), account must yet be taken (*a*) of the discrete distribution of current density over the cross section, zero in the insulation, practically uniform in the metal, and (*b*) of the boundary conditions at the interfaces between the insulation and the metal, continuity of the temperature and of the normal component of heat-flux density. While it is not difficult to take the first factor into account, the second renders a rigorous solution mathematically intractable.

---

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Heat Transfer Division and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

Aware, explicitly or intuitively, of this intractableness, yet desirous of obtaining some approximation to the rigorous formulas for temperature distribution in these simpler coils, those who have worked at this problem have resorted, perforce, to various artifices. These latter comprise two categories, as follows:

1 Physical considerations serve as bases for the deduction of empirical formulas for the maximum and the average temperatures.

2 Formulas for the temperature distribution, maximum temperature, and average temperature in a homogeneous infinite plate or a homogeneous rectangular cylinder, subject to certain conditions of surface temperature and internally generated heat, are affected rigorously by application of the mathematical theory of heat. It is then implied that these formulas can be utilized either directly, in conjunction with certain measurements, or in combination with empirically calculated physical "constants," to calculate the corresponding temperatures in plate or in rectangular cylindrical coils.

In one or the other of these fashions formulas have been effected by Binder (2), Humburg (3), Jakob (1, 4), Ott (5), Punga (6), Rogowski (7), and Vidmar (8). The most recent, most inclusive, and most applicable work is that of Jakob (1). His analysis encompasses an important factor neglected by the others, i.e., the temperature variation of the resistivity of the conducting metal.[3] This factor has a decided effect upon the temperature distribution in the coil.

We epitomize Jakob's analysis:[4] If a toroidal coil is of such inner radius that it can be approximated by a cylindrical coil of the same cross section, and if the toroidal coil is composed of many turns of light wire, then:

1 We identify the temperature distribution T, the maximum temperature T_m, and the average temperature T_a for the coil with the corresponding quantities in a homogeneous cylinder of the following characteristics:

(*a*) Of the same cross section as the coil.

(*b*) Of "equivalent" thermal conductivity k (calculated as outlined in Section 4).

(*c*) Maintained at the same surface conditions as the coil.

(*d*) And wherein q, the heat generated per unit volume per unit time, is $q_0[1 + \alpha_0 T]$; T_s is the surface temperature; α_0 the temperature coefficient of resistivity of the conducting metal at 0 deg C; and $q_0 = I^2R_0/V$, I being the coil current, V the volume of the coil, and R_0 the coil resistance when the entire coil is at temperature 0 deg C.

2 And proceed to determine T, T_m, and T_a for the homogeneous cylinder as a problem in the mathematical theory of heat.

For the boundary condition of uniform surface temperature, Jakob obtains formulas for T, T_m, and T_a for the one-dimensional problems of the circular cylinder, and the infinite plate of definite thickness (and also the sphere). These formulas obtained, Jakob suggests that the formulas for T, T_m, and T_a for the circular cylinder can be used to approximate the corresponding quantities in the toroidal coil of square cross section, and that those for the infinite plate can be used similarly for toroidal coils of quite elongated rectangular cross section. In support of this suggestion and illustrative of his analysis in general, the formulas for T_m and T_a for the circular cylinder are used to calculate T_m and T_a in the toroidal coil of square cross section utilized in the experiments of Rogowski and Vieweg (11). The values thus calculated are found to be in substantial agreement with the known measured values.

Now most rectangular toroidal coils are neither of square nor of quite elongated rectangular cross section. In consequence, it is most desirable to have formulas for T, T_m, and T_a that are applicable for the general rectangular cross section. Such formulas are derived in Sections 2 to 4. Illustrative of their use and substantiative of their correctness, the formulas for T_m and T_a are then utilized to calculate these temperatures in the same coil as that used by Jakob in his numerical example. Seemingly, no other experimental data are available. Excellent agreement is obtained between the calculated and the measured values.

2 Solution of the Associated Heat Problem

The axis of a homogeneous infinite rectangular cylinder of thermal conductivity k watts cm^{-1} deg C^{-1} is coincident with the z axis of a Cartesian system of co-ordinates, the sides of the right cross section are parallel to the x and y axes (Fig. 1). The surface of the cylinder is maintained at uniform temperature T_s deg C. Heat per unit volume per unit time is developed in the cylinder at the rate of $q_0(1 + \alpha_0 T)$ watts cm^{-3}, q_0 and α_0 being constant and T a function of x and y alone. Required: The expressions for the temperature $T(x, y)$ at any point in the cylinder, the maximum temperature T_m, and the average temperature T_a.

From the mathematical theory of heat, the expression for T is that solution of the partial-differential equation

$$\partial^2 T/\partial x^2 + \partial^2 T/\partial y^2 = -q_0(1 + \alpha_0 T)/k \quad [1]$$

which satisfies the given boundary condition

$$T = T_s \quad [2]$$

at $$x = \pm a, \quad y = \pm b$$

and the condition stemming from the symmetry of the problem

$$T(x, y) = T(\pm x, \pm y) \quad [3]$$

By virtue of Equation [3], the temperature T is an even function of x and of y. Accordingly, T can be expressed by the double Fourier cosine series

$$T = A_0 + \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} A_{ij} \cos M_i x \cos N_j y \quad [4]$$

in which A_0, A_{ij}, M_i, and N_j are constants to be determined from Equations [1] and [2]. Substituting Equation [4] in Equation [2], we find Equation [4] satisfies Equation [2] providing

$$M_i = \pi(2i - 1)/2a \qquad i = 1, 2, 3 \quad [5]$$

$$N_j = \pi(2j - 1)/2b \qquad j = 1, 2, 3 \quad [6]$$

and

$$A_0 = T_s \quad [7]$$

We determine A_{ij} from Equation [1] in the usual fashion. Substituting Equation [4] in [1]

[3] Jakob (1) remarks, and it is also so mentioned in the discussions of Davis and Tramontini appended to his paper, that his analysis encompasses the effects of the temperature variation of the thermal conductivity. In the opinion of the author, this is not so. For if the thermal conductivity k were a function of the temperature θ, then the correct form of Equation [5] of Jakob's paper would be $\partial(k\ \partial\theta/\partial x)/\partial x = -q'''$, whence assumption of some analytical expression of k as a function of θ gives rise to a more or less complicated differential equation. The correct interpretation of the constants in Equations [5] and [6] of Jakob's paper is that k is constant and q''' is a linear function of temperature $q_s(1 + \epsilon_s\theta)$, q_s a constant, and ϵ_s a temperature coefficient of resistivity at s deg C. Hence Equation [6] becomes $q'''/k = m(1 + \epsilon\theta) = (q_s/k)(1 + \epsilon_s\theta)$. Note that in his numerical example Jakob himself identifies ϵ with the temperature coefficient of electrical resistivity. For further discussion of the temperature variation of thermal conductivity see Section 4 of the present paper.

[4] This is the writer's interpretation as deduced from study of the numerical example in Jakob's paper. For a qualitative discussion of the correctness of this procedure see Section 4 of the present paper.

$$\sum_{i=1}^{\infty}\sum_{j=1}^{\infty} A_{ij}(M_i^2 + N_j^2 - C^2)\cos M_i x \cos N_j y = C' \quad [8]$$

in which

$$C^2 = q_0\alpha_0/k;\ C' = q_0(1 + \alpha_0 T_s)/k;\ C'/C^2 = T_s + \alpha_0^{-1} \quad [9]$$

multiplying each member of Equation [8] by $\cos M_p x \cos N_q y$, p, and q arbitrary positive integers; integrating over a quadrant of the cross section shown in Fig. 1

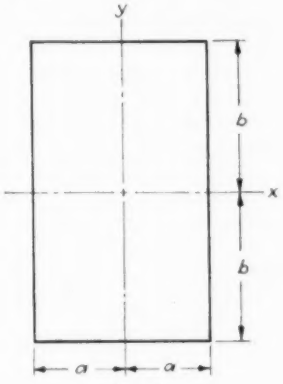

FIG. 1

$$\sum_{i=1}^{\infty}\sum_{j=1}^{\infty} A_{ij}(M_i^2 + N_j^2 - C^2)\int_0^a\int_0^b \cos M_i x \cos M_p x \cos N_j y \cos N_q y\, dy\, dx = 4C'\int_0^a\int_0^b \cos M_p x \cos N_q y\, dy\, dx \quad [10]$$

evaluating the double integrals (all integrals on the left-hand side vanish except those for which $p = i$, $q = j$); simplifying by use of Equations [5] and [6]; and solving for A_{ij} yields

$$A_{ij} = (4C'/ab)(-1)^{i+j}/M_i N_j(M_i^2 + N_j^2 - C^2) \quad [11]$$

Substituting Equations [7] and [11] in Equation [4], we have

$$T = T_s + (4C'/ab)\sum_{i=1}^{\infty}\sum_{j=1}^{\infty}(-1)^{i+j}\cos M_i x \cos N_j y/M_i N_j(M_i^2 + N_j^2 - C^2) \quad [12]$$

We can transform Equation [12] into forms more convenient for numerical computation by use of the identities[5]

$$(2/b)\sum_{j=1}^{\infty}(-1)^{j-1}\cos N_j y/N_j(N_j^2 + K_i^2) = (1/K_i^2)(1 - \cosh K_i y \operatorname{sech} K_i b) \quad [13]$$

in which $K_i^2 = M_i^2 - C^2$ and K_i is the positive root; and

$$(2/a)\sum_{i=1}^{\infty}(-1)^{i-1}\cos M_i x/M_i K_i^2 = \begin{cases} (1/C^2)(1 - \cosh Cx \operatorname{sech} Ca),\ C^2 < 0 \\ (-1/C^2)(1 - \cos Cx \sec Ca),\ C^2 > 0 \end{cases} \quad [14]$$

[5] "Sur une méthode de sommation de certaines series de Fourier," by E. Roth and G. Kouskoff, *Revue Gènèrale de l'Electricité*, vol. 23, 1928, pp. 1061–1073.

Substituting Equation [13] in Equation [12] yields

$$T = T_s + (2C'/a)\sum_{i=1}^{\infty}(-1)^{i-1}\cos M_i x(1 - \cosh K_i y \operatorname{sech} K_i b)/K_i^2 M_i \quad [15]$$

Simplifying Equation [15] by use of the second form of Equation [14], we have

$$T = T_s - (C'/C^2)(1 - \cos Cx \sec Ca) - (2C'/a)\sum_{i=1}^{\infty}(-1)^{i-1}\cos M_i x \cosh K_i y/K_i^2 M_i \cosh K_i b \quad [16]$$

in which $C^2 > 0$.

By virtue of the symmetry of Equation [12], an alternative form of Equation [16] can be obtained by interchanging a and b, x and y, M_i and N_j, K_i and $K_j (= N_j^2 - C^2)$. As this is easily done, we shall not write down this alternative form.

The maximum temperature T_m occurs at the center of the cross section. Substituting $x = 0$, $y = 0$ in Equation [16], we have

$$T_m = T_s - (C'/C^2)(1 - \sec Ca) - (2C'/a)\sum_{i=1}^{\infty}(-1)^{i-1}/K_i^3 M_i \cosh K_i b \quad [17]$$

The average temperature T_a over the cross section is given by

$$T_a = (1/4ab)\int_{-a}^{a}\int_{-b}^{b} T\,dy\,dx \quad [18]$$

Substituting Equation [16] in Equation [18], and integrating, yields

$$T_a = T_s - (C'/C^2)(1 - \tan Ca/Ca) - (2C'/a^2 b)\sum_{i=1}^{\infty}(-1)^{i-1}\sin M_i a \tanh K_i b/K_i^2 M_i^2 \quad [19]$$

3 Special Cases of the General Heat Problem

Certain special cases of the general problem are of particular interest.

Rectangular Cylinder and Uniform Heat Density. If $\alpha_0 = 0$, whence $C^2 = 0$, q is uniform throughout the cylinder. Taking the limit as $C^2 \to 0$ of the right-hand members of Equations [16], [17], and [19] (the details are contained in the Appendix), yields

$$T = T_s + C'(a^2 - x^2)/2 - (2C'/a)\sum_{i=1}^{\infty}(-1)^{i-1}\cos M_i x \cosh M_i y/M_i^3 \cosh M_i b \quad [20]$$

$$T_m = T_s + C'a^2/2 - (2C'/a)\sum_{i=1}^{\infty}(-1)^{i-1}/M_i^3 \cosh M_i b \quad [21]$$

$$T_a = T_s + C'a^2/3 - (2C'/a^2 b)\sum_{i=1}^{\infty}(-1)^{i-1}\sin M_i a \tanh M_i b/M_i^4 \quad [22]$$

This case was studied by Humburg (3), and later by Jakob (4). The latter's formulas for T, T_m, and T_a are less compact than the author's; they are expressed in terms of double-infinite

series whereas the present ones are expressed in terms of single-infinite series. The two forms are equivalent, however, in that Equations [20], [21], and [22] can be transformed into the corresponding Equations [17], [19], and [21] of Jakob's paper (1).

Infinite Plate and Nonuniform Heat Density. As $b \to \infty$, the rectangular cross section tends to an infinite strip of thickness $2a$, whence the rectangular cylinder tends to an infinite plate of thickness $2a$. Substituting $b = \infty$ in the right-hand members of Equations [16], [17], and [19], yields

$$T = T_s - (C'/C^2)(1 - \cos Cx \sec Ca) \quad [23]$$

$$T_m = T_s - (C'/C^2)(1 - \sec Ca) \quad [24]$$

$$T_a = T_s - (C'/C^2)(1 - \tan Ca/Ca) \quad [25]$$

Jakob (1) has recently considered this case in detail. Corroborative of the present analysis, Equations [23], [24], and [25] are identical (aside from notation) with the corresponding Equations [14], [15], and [16] of Jakob's paper (1).

Infinite Plate and Uniform Heat Density. Substituting $b = \infty$ in Equations [20], [21], and [22], yields

$$T = T_s + C'(a^2 - x^2)/2 \quad [26]$$

$$T_m = T_s + C'a^2/2 \quad [27]$$

$$T_a = T_s + C'a^2/3 \quad [28]$$

This case was studied first by Rogowski (7). The present equations for T, T_m, and T_a are identical with his.

4 Application of the Heat Problem to Electrical Coils

The formulas of Sections 2 and 3 can be utilized to calculate temperatures in electrical coils, provided we interpret q_0, α_0, and k as deduced in this section.

Inasmuch as the wire comprising an electrical coil is insulated, the same current I flows through any cross section of the wire. If R_0 is the resistance of the coil when its temperature is uniform at 0 deg C, the Joulean power developed in the coil at this temperature is I^2R_0; whence the average power per unit volume is I^2R_0/V. Now if the coil were composed of wire of zero thickness of insulation, I^2R_0/V would be identical with $q_0 (= i^2\rho_0)$ (i being the current density, and ρ_0 the resistivity at 0 deg C of the metal), the power per unit volume developed at any point in the coil. If the coil were composed of thinly insulated wire, the average of q_0 over the sectioned metal and insulation of a cross section of the wire would closely approximate I^2R_0/V. Accordingly, if we restrict ourselves to coils composed of thinly insulated wire (and commonly the wire is thus insulated), it is rational to identify q_0 in the equations of Sections 2 and 3 with I^2R_0/V.

In use, both the temperature T and the power density q vary from point to point in the coil. If, in addition, we assume that the coil is composed of wire of cross section small in comparison with that of the coil,[6] which is the case if (as is usual) the coil is composed of many turns of light wire, the current density i over any cross section of the (metal of the) wire is substantially uniform; whence variation in $q (= i^2\rho)$ from point to point in the coil must be attributed to variation in the resistivity of the metal from point to point. As a function of temperature $\rho = \rho_0(1 + \alpha_0 T)$; from which we derive $q = q_0(1 + \alpha_0 T)$. Accordingly, we identify α_0 in the equations of Sections 2 and 3 with the temperature coefficient of resistivity at 0 deg C of the metal of the coil.

The thermal conductivities k_m and k_i of the metal and of the insulation of a coil are quite different. Commonly, k_m is several thousand times greater than k_i. Accordingly, k in the formulas of Sections 2 and 3 is to be identified with the "equivalent thermal conductivity" of the coil.[7] The equivalent thermal conductivity of an array of parallel circular cylindrical metallic conductors embedded in a homogeneous insulation can be determined from curves due to Richter (9). These curves are reproduced in a text on electrical design by Moore (10).

If, as is frequently the case, the wire is of square or of not too elongated rectangular cross section, Richter's curves can yet be used through the device of replacing the rectangular cross section by an "equivalent" circular cross section of the same area. Alternatively, the areas of sectioned metal and insulation, comprising the cross section of a coil, can be taken as comprising a network of thermal conductances; these conductances are combined into a single equivalent thermal conductance in the same fashion as a series-parallel network of electrical conductances is reduced to a single equivalent conductance; and the equivalent conductivity k determined therefrom. This method of calculating k is made use of in Jakob's paper (1).

In general, despite the large ratio of k_m/k_i, k is only several times larger than k_i. Accordingly, if we were to attempt to take the variation of the thermal conductivities of k_i and k_m into account, it would be rational to do so by identifying the variation in k with that in k_i. Few quantitative data are available, however, on the temperature variations of the thermal conductivities of insulating materials. Nor, for that matter, are the k_i values known accurately at any particular temperature. In consequence although it is possible to effect a solution for the heat problem of Section 2, in which k as well as q is taken as a linear function of the temperature (in fact, the writer has done so), such a refinement as applied to calculation of the temperature in electrical coils would be meaningless.

In the light of the discussion to this point, we may expect that if a coil comprises many turns of thinly insulated wire of comparatively small cross section, and if the constants q_0, α_0, and k are interpreted as outlined in this section, the formulas of Sections 2 and 3 will yield fairly accurate values of temperature. Comparatively few experimental data are available for affording, through comparison of known test values with calculated values, either confirmation or disproval of this statement. Seemingly, the only available published data suitable to this purpose are those of Rogowski and Vieweg (11). Certain of their data were used by Jakob (1) to illustrate use of the formulas and procedure advanced in his paper. The author utilizes these same data in the numerical example of Section 5.

5 Numerical Example

We consider the following problem: To calculate the maximum temperature attained in the rectangular toroidal coil during Run 2 of the experiments of Rogowski and Vieweg (11). This particular run is selected in the thought that the surface condition apposite to the formulas derived in this paper, i.e., uniform surface tem-

[6] If the cross section of the wire is large, the current density will be nonuniform over the cross section. For, since the resistivity of different filaments of the wire will vary with the temperature variation over the cross section, and since all filaments are connected in parallel, whence the voltage gradient ϵ along each filament must be the same, the current density $i = \epsilon/\rho$ will necessarily vary over the cross section. Thus in the case of a single heavy circular cylindrical conductor, the current density is a minimum at the center of the cross section, at which point the temperature is greatest.

[7] Our reason for doing so is as follows: In various problems having to do with the flow of heat in materials which are not homogeneous from point to point but which are homogeneous in a "fine-grained" sense (a nonhomogeneous pattern of small area is regularly ranked to form a comparatively large area, thus the cross section of the coil is composed of a regular array of identical nonhomogeneous cross sections of the wire), experience is to the effect that utilization of such an equivalent thermal conductivity permits satisfactory analytical formulation of an otherwise intractable problem. Thus, heat-flow problems in cellular materials are handled in precisely this fashion.

perature, is more closely approximated in Run 2 than in the other runs. In Run 2 the coil is cooled on all sides by an air blast.

Given Data: Toroidal coil with square cross section; inner radius 4 cm; winding composed of 1416 turns of 0.1-cm-diam copper wire insulated with lacquer-soaked silk; these turns are arranged in coaxial layers, each layer composed of 40 turns; surface temperature 76.1 C; maximum temperature 122.4 C; mean temperature calculated from the "hot" or operating resistance 96.7 C; cold resistance ≈ 11 ohms; coil current 3 amp.

Derived Data: Using the given data, we find the volume V of the coil to be 754 cu cm. The percentage conductivity of the copper wire is not stated. Taking it to be 100 per cent, we find (as can be found in any electrical handbook) that $\alpha_0 \approx 0.00423$ deg C^{-1} and $\alpha_{20} = 0.00393$ deg C^{-1}. The temperature at which the "cold" resistance ≈ 11 ohms was measured is not stated. We assume 20 deg C (68 F). Then $R_0 = 11[1 - 0.00393 \times 20]$ 10.13 ohms; whence $q_0 = I^2R_0/V = 0.1207$ cm^{-3}. Jakob (1) has calculated the equivalent conductivity of the coil to be $k = 0.00531$ watt cm^{-1} deg C^{-1}.

Using these derived values of α_0, q_0, and k, we find by direct computation

$$C^2 = 0.0963;\ C' = 29.9;\ C'/C^2 = 310.6;\ Ca = 0.683$$
$$M_1 = 0.714;\ M_1^2 = 0.5098;\ K_1^2 = 0.4135;\ K_1 = 0.643;\ K_1b = 1.415$$
$$M_2 = 2.142;\ M_2^2 = 4.588;\ K_2^2 = 4.492;\ K_2 = 2.119;\ K_2b = 4.651$$

These values were calculated on a 20-in. slide rule. Substituting appropriately in Equations [17] and [19], we have

$$T_m = 76.1 + 89.8 - (42.2 - 0.11) = 123.8 \text{ deg C}$$

$$T_a = 76.1 + 58.8 - (136.7 - 0.13) = 98.3 \text{ deg C}$$

The terms within the parentheses are those contributed by the infinite series in Equations [17] and [19]. We note that these series converge so rapidly that generally it is necessary to compute only the first term; the second term is certainly much smaller than the error inherent in the general procedure.

Comparing these calculated values with the corresponding measured values,[8] $T_m = 122.4$ deg C and $T_a = 96.7$ deg C, we find differences of 1.4 deg C and 1.6 deg C. These differences are 1.15 per cent and 1.65 per cent, respectively, of T_m and T_a.

Considering the various assumptions made in Section 4, and the uncertainties in the given data, this substantial agreement between calculated and measured values is most gratifying. For, although success in this one numerical example hardly constitutes a general validification of the formulas given in this paper and although it is most desirable to obtain additional and more precise experimental data for use in effecting similar comparisons, it is substantiative of the author's opinion that the formulas of this paper will yield satisfactory numerical values of the temperature in rectangular toroidal coils, providing the coil geometry and surface conditions are such that application of these formulas is justifiable.

ACKNOWLEDGMENT

The author is indebted to Prof. M. Jakob for calling attention to the subject of this paper, and for personal discussion of certain points of his previous paper (1).

Appendix

To obtain the limit as $C^2 \to 0$ of the right-hand member of Equation [16], we note that

$$\lim_{C^2 \to 0} K_i = M_i$$

and that

$$\lim_{C^2 \to 0} (C'/C^2)(1 - \cos Cx \sec Ca)$$
$$= \lim_{C^2 \to 0} (C'/C^2)[1 - (1 - C^2x^2/2! + C^4x^4/4! - \ldots)(1 - C^2a^2/2! + C^4a^4/4! - \ldots)^{-1}]$$
$$= \lim_{C^2 \to 0} (C'/C^2)[1 - 1 + C^2(x^2 + a^2)/2! - C^4(a^4/4! + x^4/4! + a^2x^2/2 \cdot 2!) + \ldots]$$
$$= C'(x^2 + a^2)/2!$$

Taking the limit as $C^2 \to 0$ of the right-hand member of Equation [16] and making use of the foregoing evaluations yields Equation [20].

In similar fashion, Equation [22] follows from Equation [19] by making use of the identity

$$\lim_{C^2 \to 0} (C'/C^2)(1 - \tan Ca/Ca)$$
$$= \lim_{C^2 \to 0} (C'/C^2)[1 - (Ca + C^3a^3/3 + 2C^5a^5/15 + \ldots)/Ca]$$
$$= C'a^2/3$$

Discussion

VICTOR PASCHKIS.[9] Electrical coils are usually operated at constant voltage. Thus, if for reasons of poor design the temperature and therewith the electrical resistance would increase considerably, the current would drop.

It would be of considerable interest if the author's investigation could be extended to include the case of constant voltage, and a current initially not known but dependent upon the resulting temperatures.

In discussing the paper orally, Prof. L. M. Boelter mentioned some desirable refinements which may make the problem mathematically unsolvable. If this should be the case, investigation on

[8] Jakob (1) states that the measured value was 100 deg C (= 76.1 + 23.9), but Rogowski and Vieweg definitely state 96.7 deg C for T_a.

[9] Research Associate, Department of Mechanical Engineering, Research Laboratories, Columbia University, New York, N. Y.

the "heat and mass-flow analyzer" might offer a solution. The desirability was mentioned of determining the apparent thermal conductivity of laminated materials, such as cores of transformers, etc. Such determination would also be highly desirable in connection with heat flow in strip coils and staples of metal sheets. For this purpose a temperature range up to 1600 F or 1800 F should be investigated.

Knowledge of the thermal conductivity under these conditions would make possible a rational analysis of uniformity in heat-treating practice.

Friction Factors for Pipe Flow

By LEWIS F. MOODY,[1] PRINCETON, N. J.

The object of this paper is to furnish the engineer with a simple means of estimating the friction factors to be used in computing the loss of head in clean new pipes and in closed conduits running full with steady flow. The modern developments in the application of theoretical hydrodynamics to the fluid-friction problem are impressive and scattered through an extensive literature. This paper is not intended as a critical survey of this wide field. For a concise review, Professor Bakhmeteff's (1)[2] small book on the mechanics of fluid flow is an excellent reference. Prandtl and Tietjens (2) and Rouse (3) have also made notable contributions to the subject. The author does not claim to offer anything particularly new or original, his aim merely being to embody the now accepted conclusions in convenient form for engineering use.

IN the present pipe-flow study, the friction factor, denoted by f in the accompanying charts, is the coefficient in the Darcy formula

$$h_f = f \frac{L}{D} \frac{V^2}{2g}$$

in which h_f is the loss of head in friction, in feet of fluid column of the fluid flowing; L and D the length and internal diameter of the pipe in feet; V the mean velocity of flow in feet per second; and g the acceleration of gravity in feet per second per second (mean value taken as 32.16). The factor f is a dimensionless quantity, and at ordinary velocities is a function of two, and only two, other dimensionless quantities, the relative roughness of the surface, $\frac{\epsilon}{D}$ (ϵ being a linear quantity in feet representative of the absolute roughness), and the Reynolds number $\mathbf{R} = \frac{VD}{\nu}$ (ν being the coefficient of kinematic viscosity of the fluid in square feet per second). Fig. 1 gives numerical values of f as a function of $\frac{\epsilon}{D}$ and $\mathbf{R}$.

Ten years ago R. J. S. Pigott (4) published a chart for the same friction factor, using the same co-ordinates as in Fig. 1 of this paper. His chart has proved to be most useful and practical and has been reproduced in a number of texts (5). The Pigott chart was based upon an analysis of some 10,000 experiments from various sources (6), but did not have the benefit, in plotting or fairing the curves, of later developments in functional forms of the curves.

In the same year Nikuradse (7) published his experiments on artificially roughened pipes. Based upon the tests of Nikuradse and others, von Kármán (8) and Prandtl (9) developed their theoretical analyses of pipe flow and gave us suitable formulas with numerical constants for the case of perfectly smooth pipes or those in which the irregularities are small compared to the thickness of the laminar boundary layer, and for the case of rough pipes where the roughnesses protrude sufficiently to break up the laminar layer, and the flow becomes completely turbulent.

The analysis did not, however, cover the entire field but left a gap, namely, the transition zone between smooth and rough pipes, the region of incomplete turbulence. Attempts to fill this gap by the use of Nikuradse's results for artificial roughness produced by closely packed sand grains, were not adequate, since the results were clearly at variance from actual experience for ordinary surfaces encountered in practice. Nikuradse's curves showed a sharp drop followed by a peculiar reverse curve,[3] not observed with commercial surfaces, and nowhere suggested by the Pigott chart based on many tests.

Recently Colebrook (11), in collaboration with C. M. White, developed a function which gives a practical form of transition curve to bridge the gap. This function agrees with the two extremes of roughness and gives values in very satisfactory agreement with actual measurements on most forms of commercial piping and usual pipe surfaces. Rouse (12) has shown that it is a reasonable and practically adequate solution and has plotted a chart based upon it. In order to simplify the plotting, Rouse adopted co-ordinates inconvenient for ordinary engineering use, since f is implicit in both co-ordinates, and $\mathbf{R}$ values are represented by curved co-ordinates, so that interpolation is troublesome.

The author has drawn up a new chart, Fig. 1, in the more conventional form used by Pigott, taking advantage of the functional relationships established in recent years. Curves of f versus $\mathbf{R}$ are plotted to logarithmic scales for various constant values of relative roughness $\frac{\epsilon}{D}$; and to permit easy selection of $\frac{\epsilon}{D}$, an accompanying chart, Fig. 2, is given from which $\frac{\epsilon}{D}$ can be read for any size of pipe of a given type of surface.

In order to find the friction loss in a pipe, the procedure is as follows: Find the appropriate $\frac{\epsilon}{D}$ from Fig. 2, then follow the corresponding line, thus identified, in Fig. 1, to the value of the Reynolds number $\mathbf{R}$ corresponding to the velocity of flow. The factor f is thus found, for use in the Darcy formula

$$h_f = f \frac{L}{D} \frac{V^2}{2g}$$

In Fig. 2, the scales at the top and bottom give values of the diameter in both feet and inches. Fig. 1 involves only dimensionless quantities and is applicable in any system of units.

To facilitate the calculation of $\mathbf{R}$, auxiliary scales are shown at the top of Fig. 1, giving values of the product (VD') for two fluids, i.e., water and atmospheric air, at 60 F. (D' is the inside diameter in inches.) As a further auxiliary, Fig. 3 is given, from which $\mathbf{R}$ can be quickly found for water at ordinary temperatures, for any size of pipe and mean velocity V. Dashed lines on this chart have been added giving values of the discharge or quantity of fluid flowing, $Q = AV$, expressed in both cubic feet per second and in U. S. gallons per minute.

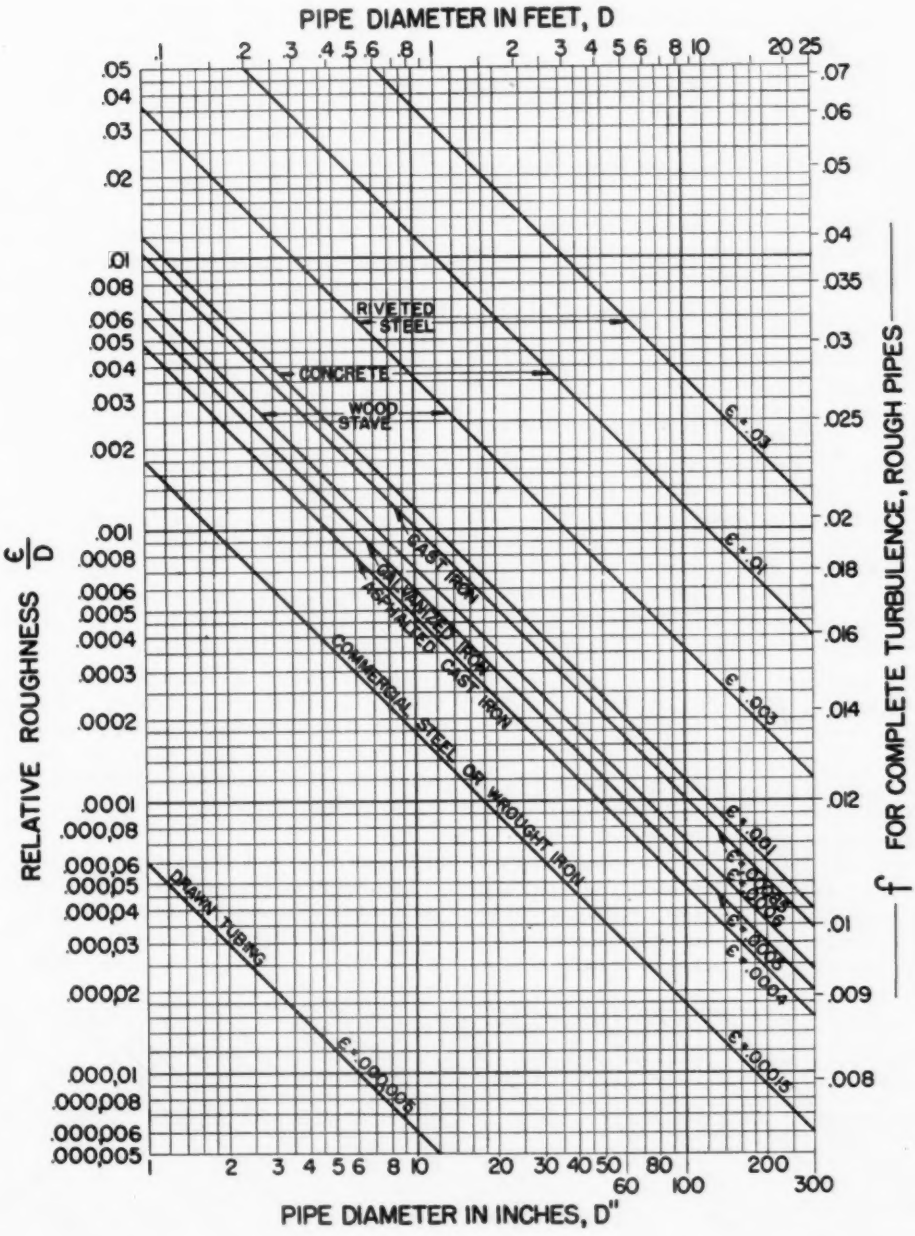

FIG. 2

For other fluids, the kinematic viscosity ν may be found from Fig. 4, which with Prof. R. L. Daugherty's kind permission has been reproduced.[4] To enable **R** to be quickly found for various fluids, Fig. 4 includes an auxiliary diagram constructed by Dr. G. F. Wislicenus, which gives **R** for various values of the product VD'' shown by the diagonal lines. For any value of ν in the left-hand diagram, by following a horizontal line to the appropriate diagonal at the right, the corresponding **R** may be read at the top of the auxiliary graph.

Over a large part of Fig. 1, an approximate figure for **R** is sufficient, since f varies only slowly with changes in **R**; and in the rough-pipe zone f is independent of **R**. From the last consideration, it becomes possible to show, in the right-hand margin of Fig. 2, values of f for rough pipes and complete turbulence. If it is seen that the conditions of any problem clearly fall in the zone of complete turbulence above and to the right of the dashed line in Fig. 1, then Fig. 2 will give the value of f directly without further reference to the other charts.

ILLUSTRATION OF USE OF CHARTS

Example 1: To estimate the loss of head in 200 ft of 6-in. asphalted cast-iron pipe carrying water with a mean velocity of 6 fps: In Fig. 2, for 6 in. diam (bottom scale), the diagonal for "asphalted cast iron" gives $\frac{\epsilon}{D} = 0.0008$ (left-hand margin). In Fig. 3, for 6 in. diam (left-hand margin), the diagonal for $V = 6$ fps gives $\mathbf{R} = 2.5\ (10^5)$ (bottom scale) (or, instead of using Fig. 3, compute $VD'' = 6 \times 6 = 36$). In Fig. 1, locate from the right-

hand margin the curve for $\frac{\epsilon}{D} = 0.0008$ and follow this curve to a point above $\mathbf{R} = 2.5\ (10^5)$ on the bottom scale (or below $VD'' = 36$ on the top scale). This point gives $f = 0.02$ (left-hand margin); then

$$h_f = f\frac{L}{D}\frac{V^2}{2g} = 0.02\,\frac{(200)}{(0.5)}\,\frac{(6)^2}{64.3} = 4.5 \text{ ft friction loss}$$

Example 2: To estimate the loss of head per 100 ft in a 15-in. new cast-iron pipe, carrying water with a mean velocity of 20 fps: In Fig. 2, for 15 in. diam (bottom scale), the diagonal for "cast iron" gives $\frac{\epsilon}{D} = 0.0007$ (left-hand margin). In Fig. 3, for 15 in. diam (left-hand margin), the diagonal for $V = 20$ fps gives $\mathbf{R} = 2\ (10^6)$ (or, instead of using Fig. 3, compute $VD'' = 20 \times 15 = 300$). In Fig. 1, the curve for $\frac{\epsilon}{D} = 0.0007$ (interpolating between 0.0006 and 0.0008, right-hand margin), at a point above $\mathbf{R} = 2\ (10^6)$ (bottom scale) (or below $VD'' = 300$, top scale) gives $f = 0.018$ (left-hand margin). In this case the point on Fig. 1 falls just on the boundary of the region of "complete turbulence, rough pipes." Here $\mathbf{R}$ or VD'' need only be approximated sufficiently to see that the point falls in the complete turbulence region, and f can then be found directly from the right-hand margin in Fig. 2 without further reference to Fig. 1; then

$$h_f = f\frac{L}{D}\frac{V^2}{2g} = 0.018\,\frac{(100)}{(1.25)}\,\frac{(20)^2}{64.3}$$

$$= 8.95 \text{ or, say, 9 ft friction loss}$$

It must be recognized that any high degree of accuracy in determining f is not to be expected. With smooth tubing, it is true, good degrees of accuracy are obtainable; a probable variation in f within about ±5 per cent (14), and for commercial steel and wrought-iron piping, a variation within about ±10 per cent. But, in the transition and rough-pipe regions, we lack the primary and obvious essential, a technique for measuring the roughness of a pipe mechanically. Until such a technique is developed, we have to get along with descriptive terms to specify the roughness; and naturally this leaves much latitude. The lines in Fig. 2 might be more graphically represented by broad bands rather than single lines, but this is not practical due to overlapping.

Even with this handicap, however, fairly reasonable estimates of friction loss can be made, and, fortunately, engineering problems rarely require more than this. It will be noted from the charts that a wide variation in estimating the roughness affects f to a much smaller degree. In the rough-pipe region, for the reasons just explained, the values of f cannot be relied upon within a range of the order of at least 10 per cent.

The charts apply only to new and clean piping, since the rapidity of deterioration with age, dependent upon the quality of the water or fluid and that of the pipe material, can only be guessed in most cases; and in addition to the variation in roughness there may be, in old piping, an appreciable reduction in effective diameter, making an estimate of performance speculative.

Although we have no accepted method of direct measurement of the roughness, in any case where we have a sample of pipe of the same surface texture available for test in the laboratory or in the field, then from a test of such a pipe in any size we can, by aid of the charts, find the absolute roughness corresponding to its performance. Thus we have a means for measuring the roughness hydraulically. The scale of the absolute roughness ϵ used in plotting the charts is arbitrary, based upon the sand-grain diameters of Nikuradse's experiments.

The field covered by Fig. 1 divides itself into four areas representing distinct flow characteristics. The first is the region of laminar flow, up to the critical Reynolds number of 2000. Here the flow is fully stabilized under the control of viscous forces which damp out turbulence, permitting a completely rational solution. The values of f are here given by a single curve, $f = \frac{64}{\mathbf{R}'}$, independent of roughness, representing the Hagen-Poiseuille law.

Between Reynolds numbers of 2000 and 3000 or 4000, the conditions depend upon the initial turbulence due to such extraneous factors as sudden changes in section, obstructions, or a sharp-edged entrance corner prior to the reach of pipe considered;

and the conditions are probably also affected by pressure waves initiating instability. This region has been called a critical zone, and the indefiniteness of behavior in this region has been indicated by a hatched area without definite f lines. The minimum limit for f values is the dotted continuation of the laminar-flow line, corresponding to very smooth and steady initial flow. When there is distinct turbulence in the entering fluid, the flow in the critical zone is likely to be pulsating (2) rather than steady. The effects of strong initial turbulence may even extend into the laminar-flow zone, raising the f values somewhat, as far as to a Reynolds number of about 1200.

Above a Reynolds number of 3000 or 4000, conditions again become reasonably determinate. Here we find two regions, namely, the transition zone and the rough-pipe zone. The transition zone extends upward from the line for perfectly smooth pipes, for which the equation is

$$1/\sqrt{f} = 2\log_{10}\frac{\mathbf{R}\sqrt{f}}{2.51};\ \text{or}\ 1/\sqrt{f} = 2\log \mathbf{R}\sqrt{f} - 0.8$$

(Kármán, Prandtl, Nikuradse) to the dashed line indicating its upper limit, plotted from the relation

$$\frac{1}{\sqrt{f}} = \frac{\mathbf{R}}{200}\frac{\epsilon}{D}$$

(following the corresponding line in Rouse's chart, reference 12). In the transition zone the curves follow the Colebrook function

$$1/\sqrt{f} = -2\log\left(\frac{\epsilon/D}{3.7} + \frac{2.51}{\mathbf{R}\sqrt{f}}\right)$$

These curves are asymptotic at one end to the smooth pipe line and at the other to the horizontal lines of the rough-pipe zone. Actually, the curves converge rapidly to these limits, merging with the smooth pipe line at the left, and at the right, beyond the dashed line, becoming indistinguishable from the constant f lines for rough pipe.

The Colebrook Function

The basis of the Colebrook function may be briefly outlined. Von Kármán had shown that, for completely turbulent flow in rough pipes, the expression $1/\sqrt{f} - 2\log(D/2\epsilon)$ is equal to a constant (1.74), or, as expressed by Colebrook, $2\log\frac{3.7D}{\epsilon} - 1/\sqrt{f}$ is equal to zero. In the transition region of incomplete turbulence von Kármán's expression is not equal to a constant but to some function of the ratio of the size of the roughnesses to the thickness of the laminar boundary layer. Accordingly, Nikuradse had represented his experimental results on artificially roughened pipes by plotting $1/\sqrt{f} - 2\log(D/2\epsilon)$ versus ϵ/δ, in which δ is the laminar layer thickness. By this method of plotting, the results for all types of flow and degrees of roughness were shown to fall on a single curve. Using logarithmic scales, the smooth-pipe curve becomes an inclined straight line, and the rough-pipe curves merge in a single horizontal line.

Colebrook (11), using equivalent co-ordinates,[5] plotted in his Fig. 1, here reproduced as Fig. 5, the results of many groups of tests on various types of commercial pipe surfaces. He found that each class of commercial pipe gave a curve of the same form, and while these curves are quite different from Nikuradse's sand-grain results, they agree closely with each other and with a curve representing his transition function.

[5] ϵ/δ may be expressed in alternative forms as proportional to $\frac{\mathbf{R}\sqrt{f}}{r/k}$ in which $r = D/2$, $k = \epsilon$; or to $\rho\frac{V_*k}{\mu}$ in which $V_* = \sqrt{\frac{\tau_0}{\rho}}$. τ_0 being the shearing stress at the pipe wall, ρ the mass density of the fluid and μ its absolute or dynamic viscosity.

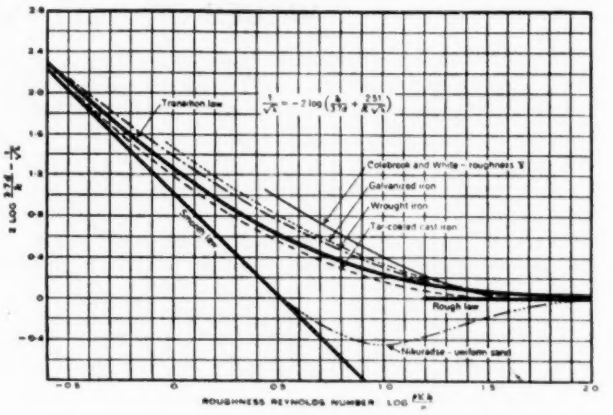

FIG. 5

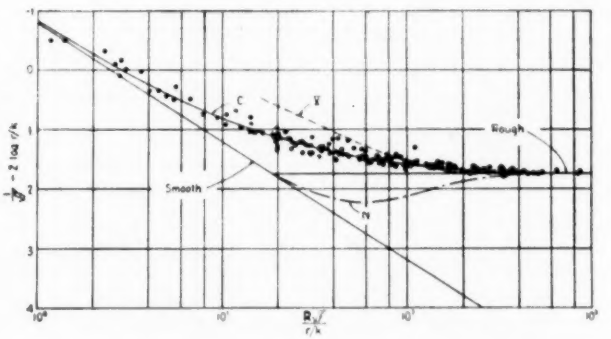

FIG. 6

Rouse (12), also using equivalent co-ordinates, has plotted in his Fig. 6, here reproduced as Fig. 6, a large number of points each of which represents a series of tests on a given size of commercial pipe, together with the Colebrook curve. As he points out, the deviation of the points from the Colebrook curve "is evidently not much greater than the experimental scatter of the individual measurements in any one series."

When the thickness of the laminar layer, which decreases with increasing Reynolds number, becomes so small, compared to the surface irregularities, that the laminar flow is broken up into turbulence, the flow conditions pass over into the zone of "rough pipes," with complete turbulence established practically throughout the flow. Viscous forces then become negligible compared to inertia forces, and f ceases to be a function of the Reynolds number and depends only upon the relative roughness, giving horizontal lines of constant f in the chart. These lines agree with the von Kármán rough-pipe formula

$$1/\sqrt{f} = 2\log\left(\frac{3.7}{\epsilon/D}\right),\quad \text{or}\quad 1/\sqrt{f} = 1.74 - 2\log\left(\frac{2\epsilon}{D}\right)$$

Since f depends upon the relative roughness, the ratio of the absolute roughness to the pipe diameter, even a fairly rough surface in a very large pipe gives a small relative roughness. Thus Colebrook plots the results obtained on the penstocks of the Ontario Power Company, where metal forms and specially laid concrete produced a very smooth example of concrete surface. This in combination with the large diameter gave a relative roughness comparable to drawn brass tubing, with f values falling practically on the "smooth pipe" line of Fig. 1. Such specially fabricated welded-steel pipe lines as those of the Colorado aqueduct system would probably give values along the same curve.

On the other hand, at very high velocities in drawn tubing of

small diameter, even the small absolute roughness is sufficient to break up the laminar boundary layer, and the tubing becomes in effect a "rough pipe." Very few experiments have carried the velocities and Reynolds numbers high enough to permit a close estimate of ϵ for drawn brass, copper, or similar tubing; but by applying the Colebrook function to the available data (14, 15), for the smoothest surfaces reported upon, ϵ was estimated as of the order of 0.000005; and a line corresponding to this value has been drawn in Fig. 2, serving as a minimum limit for surfaces likely to be encountered in practice.

Pipe Friction Factors Applied to Open-Channel Flow

Pipe friction factors have sometimes been applied to open-channel flow, and more commonly the friction losses in large pipes and other closed conduits have been computed from open-channel formulas. The Chezy formula for open channels is $V = C\sqrt{mS}$ in which V is the mean velocity; m the hydraulic mean depth or "hydraulic radius," the sectional area divided by the wetted perimeter; S the slope, the loss of head divided by length of channel, and C a coefficient. The Chezy formula is equivalent to the Darcy formula for pipes, the Chezy coefficient C being convertible into f by the relation $f = \frac{8g}{C^2}$. It should be considered, however, that the Chezy coefficients have been derived principally from observations on relatively wide and shallow channels of large area and rough bottoms, far from circular in shape, and that they involve a free water surface not present in closed conduits, so that, even when the flow is uniform, the problem is highly complex. Consequently, such formulas as Manning's are recommended for open channels in preference to the use of values of C derived from the pipe friction factors.

Open channels dealt with in engineering practice are usually rough-surfaced and of large cross section, corresponding to large Reynolds numbers and falling in the zone of complete turbulence, so that the friction factors are practically independent of Reynolds number. The presence of a free surface, however, with surface waves or disturbances, introduces a consideration not involved in closed-conduit flow. It is therefore the author's view that while, for open channels, we can drop the Reynolds number as an index of performance, we should replace it by a new criterion, the Froude number relating the velocity head and depth, which can be expressed as $\frac{V^2}{2gm}$ or $\frac{V}{\sqrt{gm}}$; or more strictly $\frac{V}{\sqrt{g\mathfrak{d}}}$, in which $\mathfrak{d}$ denotes the average depth or sectional area divided by the surface breadth; the latter form representing the ratio of mean velocity to the gravitational critical velocity or velocity of propagation of surface waves.

This proposed criterion defines whether the flow falls in the "tranquil," "shooting," or critical state. The neglect of this factor may at least partially account for inconsistencies between various open-channel formulas, and between open-channel and pipe-friction formulas, and casts particular doubt on accepted formulas for open-channel friction in the critical or shooting-flow regions. These considerations suggest the plotting of open-channel friction factors as a function of the relative roughness and the Froude number, in similar manner to the plotting of f as a function of the relative roughness and the Reynolds number for closed conduits.

For the foregoing reasons, Fig. 1 is not recommended with much confidence for general application to open channels, for which a formula such as Manning's better represents the available information. The charts can however be applied, at least as an approximation, to noncircular closed conduits of not too eccentric a form or not too different from a circular section, by using an equivalent diameter

$$D = 4m = 4\left(\frac{\text{Sectional area}}{\text{Length of perimeter}}\right)$$

Since civil engineers usually classify surface roughness by the Kutter and Manning roughness factor n, it would be helpful in selecting a value of ϵ for such variable surfaces as concrete, if we could correlate ϵ and n. P. Panagos[6] has applied the Colebrook function to the test data collected by Scobey (16) and finds the following values of ϵ corresponding to the Kutter n ratings given by Scobey, which may be at least tentatively utilized:

Kutter n.....	0.0105	0.011	0.012	0.013	0.014	0.015	0.016
Absolute roughness ϵ.....	0.00015	0.0005	0.002	0.005	0.011	0.02	0.03

Accordingly, on the basis of Scobey's data the lines given in Fig. 2 for concrete may be somewhat more definitely described as follows:

ϵ	n	
0.001	0.0115	Highest practical grade of concrete. Surface and joints smooth
0.003	0.0125	
0.01	0.014	Concrete surface with slight form marks, fairly smooth joints or roughly troweled
0.03	0.016	Prominent form marks or deposits of stones on bottom

Although the curves in Fig. 1 are plotted from definite functional forms which can be accepted with some confidence within the degree of accuracy required in engineering use, further information will be welcomed which would improve the location and definition of the lines in Fig. 2, or which would add new lines for other materials. Any tests of friction head in pipe of any material can be applied to Fig. 1, and corresponding points can be readily located in Fig. 2. A 45-deg line through a point so located can then be added to Fig. 2, to represent a particular kind of pipe surface.

Acknowledgment

For helpful suggestions and assistance, the author is particularly indebted to Prof. B. A. Bakhmeteff, Mr. Ralph Watson, Dr. G. F. Wislicenus, Dr. A. T. Ippen; and to Mr. P. Panagos for collecting data and numerical checking.

Discussion

R. L. DAUGHERTY.[7] The writer has nothing but commendation for this excellent paper. The author has presented the latest theory combined with the available experimental data in a manner which makes it more convenient for use than has been the case heretofore. His evaluation of relative roughness for different types and sizes of pipes is a step forward.

While this paper deals primarily with pipe friction it is interesting to note the suggestions made concerning the treatment of the flow in open channels. The latter has not been given the attention from the standpoint of rational analysis that has been devoted in the past to pipes. It is to be hoped that developments in this field may be made along the lines suggested by the author.

The author calls attention to the well-known fact that in the transition zone the Nikuradse curves for his artificial sand-grain roughness are quite different from those obtained with commercial pipes. The writer would like to know if the author has any explanation to offer for this marked difference.

C. W. HUBBARD.[8] This paper is of interest to engineers who must estimate fluid-friction loss closely for certain types of problems. Ordinarily the Manning type of formula is preferred, since the roughness value may be determined from the type of surface of the wall as contrasted to the Darcy formula where the roughness coefficient varies with the size of pipe and is difficult to estimate. The author's Fig. 2 allows a quantitative wall roughness estimated from the type of wall to be used.

During some recent tests made to select a protective paint for steel which would also have a low friction loss, it was found that several coatings, particularly those consisting of certain bitumastic constituents which required them to be applied thickly to the wall, gave low flow-resistance values. The tests, made in 3-in. pipes, which were split longitudinally to allow proper application of the coating, showed roughness values of the order of those obtained with drawn-brass tubing. However, the appearance of the coating was not as smooth as drawn tubing. The writer had previously experienced this effect with similar coatings. There seems to be little published material on the friction loss produced by various protective paints and coatings on pipe walls, particularly on small pipes when the flow is likely to occur in the transition range where the friction loss is dependent upon Reynolds number. Apparently the roughness of such surfaces is of the wavy type which cannot be evaluated on the same basis as the same magnitude of roughness which is of the granular type.

A. T. IPPEN.[9] The author has ably satisfied the object of his paper stated in the beginning with an extremely timely and practical summary of the latest information available on pipe friction. Academic research in this field over the last 30 years conducted on a fundamental basis has finally yielded a satisfactory explanation of the nature of the laws of pipe friction and has cleared up the concepts of energy dissipation in conduits and channels.

The evidence for the adoption of the methods for determining the pipe friction factor as presented by Colebrook is rather astonishing. Some experiences in this connection may be contributed here. The writer has computed two comprehensive sets of data on pipe friction, one by John R. Freeman and another by L. H. Kessler. The former completed his experiments during the years 1889 to 1893 and his data were published by this Society in a special volume (15)[10] in 1941. The second set of data was obtained from pipe-friction experiments at the Wisconsin Experimental Station, the results of which were published in 1935. Both experimenters performed tests on $^1/_4$ in- to 8 in-diam wrought-iron pipes in new condition covering the maximum range in Reynolds numbers possible under their experimental conditions. After plotting these results every one of their runs shows essentially the f versus $\mathbf{R}$ curve indicated by Colebrook and ϵ values calculated for all the various sizes come out very close to the average value stated for wrought-iron pipe in the present paper. It must be remembered that Kessler's data were obtained 40 years after those of Freeman and that it can hardly be assumed that manufacturing processes remained identical during that period.

Another fact of importance to the practical engineer from this analysis of Freeman's and Kessler's data is worth mentioning. Rouse and Moody in their f versus $\mathbf{R}$ curves terminate the transition range from smooth- to rough-pipe flow along a line corresponding to a ratio of absolute roughness ϵ to the laminar boundary-layer thickness δ of 6.08. Kessler's and Freeman's data do not give a single value that high in all their runs; their highest values obtained were about $\frac{\epsilon}{\delta} = 2.5$. Under practical conditions of use therefore the flow of water in pipes occurs well in the transition range from smooth- to rough-pipe flow.

This fact easily explains why a final solution of the pipe-friction problem was possible only after the concepts of "smooth-pipe" and "rough-pipe" flow had been established separately. While Nikuradse's results on uniformly sand-coated pipe were helpful in this respect, they also resulted in more complicated transition curves than are obtained from tests with the statistical roughness patterns encountered on most commercial pipe surfaces. The Colebrook universal function seems to fit the better in this transition range; the more the roughness irregularities are statistically distributed as far as size and shape are concerned and vice versa, the more regular the size and pattern of the irregularities the closer Nikuradse's transition curves are approached, where finally the critical velocity for all roughness bodies is the same in the ideal case of completely uniform size.

The familiar functions for the pipe friction factor f may be written in the following form

$$\frac{1}{\sqrt{f}} = 1.74 - 2 \log \frac{18.6}{\mathbf{R}\sqrt{f}} \quad \ldots\ldots [1]$$

for smooth-pipe flow

$$\frac{1}{\sqrt{f}} = 1.74 - 2 \log \frac{\epsilon}{r} \quad \ldots\ldots [2]$$

for rough-pipe flow

$$\frac{18.6}{\mathbf{R}\sqrt{f}} = 0.282 \frac{\delta}{r} \quad \ldots\ldots [3]$$

for laminar boundary-layer thickness.

[9] Assistant Professor, Hydraulic Laboratory, Lehigh University, Bethlehem, Pa.

[10] Numbers in parentheses throughout the discussion refer to the Bibliography at the end of the author's paper.

According to Colebrook, Equations, [1] and [2] are combined into the following universal function

$$\frac{1}{\sqrt{f}} = 1.74 - 2 \log \left(\frac{18.6}{\mathbf{R}\sqrt{f}} + \frac{\epsilon}{r} \right) \quad [4]$$

This function reverts to either Equation [1] or Equation [2], if either the influence of the relative roughness disappears or when the viscous influence becomes insignificant. By use of Equation [3], the Colebrook function may be written in the alternative form

$$\frac{1}{\sqrt{f}} = 1.74 - 2 \log \frac{\epsilon}{r} \left(1 + 0.282 \frac{\delta}{\epsilon} \right) \quad [5]$$

This equation clearly brings out the dependence of the pipe friction phenomena upon the thickness of the laminar boundary layer, i.e., on the viscosity of the fluid. It will be found in practical calculations that this influence is very seldom absent. The proposed ultimate value of $\frac{\mathbf{R}\sqrt{f}}{r/\epsilon} = 400$ is equivalent to a value of $\frac{\epsilon}{\delta}$ of 6.08.

It is evident that aging of pipes under varying conditions of use will result in new values of absolute roughness which at present are not easily predicted. From experiments on galvanized steel pipe of 4 in. diam at the Hydraulic Laboratory of Lehigh University, an initial average value of $\epsilon = 0.00045$ ft was obtained. This value of ϵ was doubled within 3 years as a result of the change in surface conditions with aging under moderate conditions of use. It must be remembered here that this change in ϵ represents only about a 20 per cent increase in the Darcy-Weisbach factor f, since the ϵ value is a much more sensitive indicator of pipe roughness than the factor f.

In conclusion, it may be hoped that this paper will bring the general adoption of this relatively easy and reliable method of determining pipe friction and thereby establish a standard procedure in practice which is based upon sound analytical and experimental evidence.

W. S. Pardoe.[11] In the following tests on pipes of various diameters and materials, the exponent n in the exponential formula

$$V = Kd^m S^n$$

varied from 0.535 to 0.546, thus checking Williams' and Hazen's formula

$$V = 1.318\, C_w r^{0.63} S^{0.54}$$

very closely. The maximum value of **R** was about 1,250,000 for 8-in. Neoprene dock-loading hose (very smooth) which is much below the "complete turbulence zone." The tests included:

6-in. Italite cement-asbestos pipe (predecessor of Transite)
4-in. Ruberoid cement-asbestos extruded pipe
4-in. fiber conduit
6-in. and 8-in. Neoprene dock-loading hose for E. I. du Pont de Nemours
2-in. to 12-in. steel pipe
8-in. rubber dock-loading hose with 1-in. × 1/8-in. helical metal band on inside

In no case except the last did the exponent n show even a tendency of decreasing, let alone approaching a value of 0.5 or complete turbulence. This must be due to the smoothness of the materials and the low value of Reynolds number. In the last case, the values of f did show a tendency to become constant, the value of ϵ/D being quite large.

The writer has not conducted a sufficient number of tests on pipes and is far from a pundit on this subject. At some time in the future, he will attempt to work into the "complete turbulence zone," if such there is, even if he must use a bit of 4-in. turberculated cast-iron pipe.

Mr. Pigott in his discussion has mentioned my insistence on the fact that the coefficients of Venturi meters become constant. This coefficient may be approximated by the formula

$$C = \sqrt{\frac{1 - \beta^4}{1 - \beta^4 + K}}$$

in which β is the diameter ratio d_2/d_1 and K is the coefficient of loss in

$$h_f = K \frac{V_2^2}{2g}$$

The value of K on the flat part of tests of 85 cast-iron Venturi meters approximates

$$K = \frac{0.0435}{(d_2'')^{0.25}}$$

As the absolute roughness is constant, the proportional roughness varies inversely as the diameter or the coefficient increases with the diameter. The tests ran to quite high values of Reynolds number in terms of $\frac{V_2 d_2 \rho}{\mu}$, thus indicating there is such a thing as complete turbulence. Solving the foregoing expression

$$K = \frac{1 - \beta^4}{c^2} - (1 - \beta^4)$$

Hence a constant value of c gives a constant K, or h_f varies as V^2.

This is of course arguing from the writer's experience with Venturi meters to make up for his lack of adequate experimental knowledge of the subject under discussion.

Professor Moody says f is a function of "two and only two" dimensionless quantities ϵ/D and $\frac{VD\rho}{\mu}$. The writer has found in his work on Venturi meters a variation of over 1/2 per cent, due to the effect of the ambient temperature.[12]

As a variation of 1/2 per cent in c requires a variation of 25 per cent in k it seems to the writer the effect of a difference of temperature of 20 deg F on f at low value of **R** might be considerable. This effect is brought about by a change in the boundary shear; thus

$$\tau_0 = \frac{f\rho V^2}{8} = \mu \frac{dv}{dy}$$

If Q is kept constant dv/dy will also be constant, and μ corresponds to the temperature of the inside wall of the pipe, which will lie between the ambient temperature and that of the water. It will decrease as the velocity increases as a result of the heat being conducted away more rapidly. This the writer will check in future experiments; it may throw some light on the upper limit of the critical or unstable zone. The effect is a function of Reynolds and Prandtl's or Nusselt's numbers, and the writer is not certain "what the price of cheese in Denmark does to effect f."

[12] "Effect of High Temperatures and Pressures on Cast-Steel Venturi Tubes," by W. S. Pardoe, Trans. A.S.M.E., vol. 61, 1939, p. 247.

Professor Moody is to be congratulated on producing a very usable plot of friction factors which in due time may replace the Pigott and Kemler curves which have to date been extensively quoted and used by engineers. Thus do we progress.

R. J. S. PIGOTT.[13] This study of friction factor in pipes is particularly interesting to the writer, as it is a valuable further rationalization of a situation which has been unsatisfactorily empirical.

At the time the writer's own correlation (4) was presented (1933) there was almost complete lack of uniformity between various formulations in general use, wandering all the way from Kutter, Hazen, and Williams tables, to Aisenstein's averaged values.

There was great need to prepare a formulation that would work satisfactorily for all kinds of conduit, from brass tubing to brick ducts, and for all fluids.

Dr. Kemler, then on the writer's staff, did the laborious part of the job, in correlating the results of all the experiments published up to that time, culling all those with incomplete data (6). The writer summarized this work, in form for direct application generally, introducing the roughness effect by rather strong-arm empirics, but at any rate the resulting chart worked well and has been growing in use.

The great value of the author's study is that it puts the roughness effect, at last, on a much better justified basis. For example, Buckingham (Fig. 1, reference 5) drew the lines for different sizes of steel pipe curved as they approached the viscous region, the same as the author now shows them; Stodola (Fig. 1, ref. 5) shows them straight and intercepting.

The later material used by the author shows that they are curved. Another important point settled by the author is that the lines for all roughnesses finally reach a constant value. The point at which this condition obtains is plainly shown to be a function of relative roughness, and so solves a difficulty Dr. Kemler and the writer had, in correlating some of the test material. Some of the experimental results showed rather flat coefficients that were unexpected in regions of moderate roughness. But this constant value of f is confirmed by Professor Pardoe's findings on Venturi discharge coefficients. He has been pointing out for years that the coefficient reaches a constant value at some Reynolds number that increases with size. Since most Venturis above rather small sizes are made with cast approach cones and the losses are substantially represented by pipe friction, this situation corresponds to flat final value of f at complete turbulence, and a decrease of the value of f with decrease of roughness.

Some engineers may be interested in the flow of queer materials like greases, muds, cement slurries, etc., that have thixotropic properties (quoted from the rheologists), that is, they have plasticity mixed in with viscosity. All these materials have apparent viscosities which decrease with increase of shear rate, but, when they finally reach turbulent flow, behave like true liquids of rather low viscosity. Such activities as oil-well drilling, cement-gun and grouting operations, automotive greasing equipment, and ball bearings involve such materials. In food industries, one gets tomato ketchup and pea soup; glue and soap solutions, paint and varnish operations, and various queer materials in the rayon and plastics industries. For those interested, a paper[14] by the writer presents more or less a rational solution that has been quite satisfactorily supported by tests.

In Fig. 1, the author has drawn his dotted line of complete turbulence somewhat in advance of the Reynolds number values at which the friction factor becomes a constant quantity. The writer finds that the expression

$$\frac{3500}{\frac{\epsilon}{D}} = \mathbf{R}_t$$

represents, as closely as can be determined from the small-scale diagram, the point at which the friction factor becomes absolutely constant. It is curious and probably only accidental that the value 3500 corresponds about to the upper limit of the critical zone.

HUNTER ROUSE.[15] Important results of laboratory research frequently do not reach the hands of practicing engineers until many years after the original papers have been published. A salient case in point is the discovery by Blasius in 1913 of the dependence of the Darcy-Weisbach resistance coefficient f upon the Reynolds number $\mathbf{R}$, which did not come into general engineering use until perhaps a decade ago. It often happens, however, that once engineers have accepted a new idea they are loath to modify it in any way. The paper under discussion is a very commendable endeavor to make recent experimental findings immediately useful to the engineer, but the writer feels that it still caters to a regrettable degree to the engineer's innate conservatism.

If the writer's belief is correct, this paper is intended to fulfill the same purpose as that which prompted the writer to present a somewhat similar paper (12) and resistance chart at the Second Hydraulics Conference in 1942. The author claims that in this chart, which is reproduced herewith in slightly modified form,[16] the writer adopted co-ordinates inconvenient for ordinary engineering use. Such criticism resulted from the writer's deliberate advancement beyond the now familiar Blasius f-versus-$\mathbf{R}$ notation in the belief that both greater convenience and greater significance would be attained thereby. Since these two papers of identical purpose thus differ in their basic method of approach, a criticism of the one point of view must necessarily involve a defense of the other.

Although Blasius' original dimensional analysis of the variables involved led to his adoption of the form VD/ν as the most significant grouping of terms upon which f should depend, it must be realized that the following three different combinations of the same variables are all equally valid for the basic case of a smooth pipe:[17]

$$f = \frac{2gh_fD}{LV^2} = \varphi_1\left(\frac{VD}{\nu}\right) = \varphi_1(\mathbf{R})$$

$$f = \frac{2gh_fD}{LV^2} = \varphi_2\left(\frac{2gh_fD^3}{L\nu^2}\right) = \varphi_2'(\mathbf{R}\sqrt{f})$$

$$f = \frac{2gh_fD}{LV^2} = \varphi_3\left(\frac{2gh_fQ^3}{L\nu^5}\right) = \varphi_3'(\mathbf{R}f^{1/3})$$

The combination now most familiar to the engineer, of course, is the first, although it has long since been proved that it will yield a linear plot on logarithmic paper for only the laminar zone. The second, on the other hand, is the basis of the Kármán-Prandtl analysis of the turbulent zone, the general functional relationship simply being written in the specific form

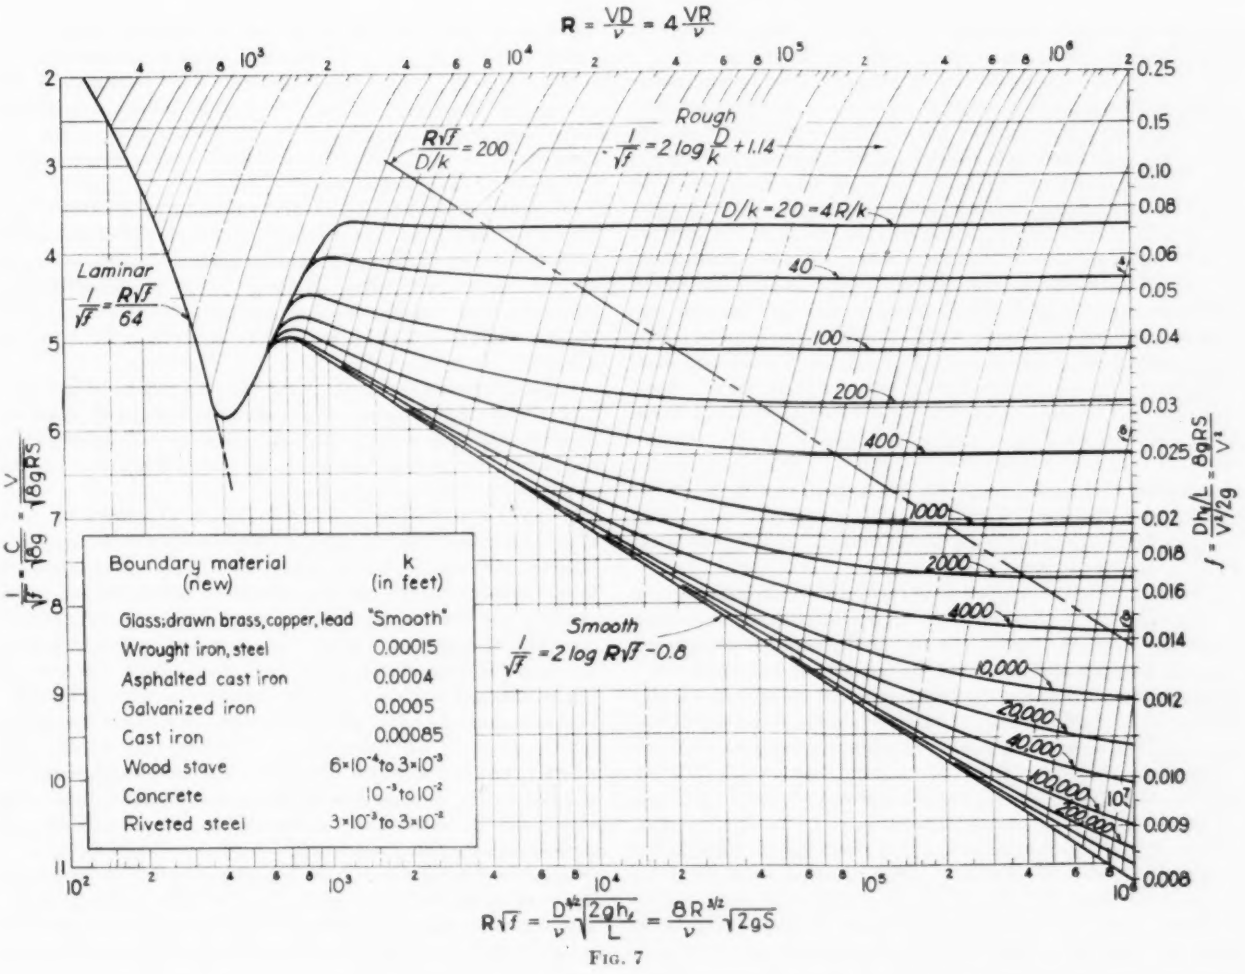

FIG. 7

$$1/\sqrt{f} = A + B \log (\mathbf{R}\sqrt{f})$$

Despite the author's indication to the contrary, f is not inextricably embodied in the second term of this relationship, as may be seen from the identity $\mathbf{R}\sqrt{f} = \sqrt{(2gh_fD^3/L\nu^2)}$. If the Kármán-Prandtl parameters are chosen as the basis of a semilogarithmic chart, as in the accompanying figure, not only will the smooth-pipe relationship plot as a straight line, but all transition curves from the smooth to the rough relationship will be geometrically similar. It would appear to the writer that this combines ease in interpolation (and hence convenience) with greater significance than the Blasius plot will permit. This, therefore, is one of the writer's two reasons for continuing to recommend the newer type of chart in preference to that of the author.

The writer's second reason will be evident after further inspection of the foregoing functional relationships. The first relationship will be directly useful in graph form only if the velocity or rate of flow is known; otherwise the desired coefficient may be evaluated from the graph only through the inconvenient process of trial and error. If the velocity or rate of flow is not known, on the other hand, a graph of the second functional relationship will make the desired coefficient immediately available. In order to provide a single chart which would satisfy both sets of requirements, the writer supplied ordinate scales of both f and $1\sqrt{f}$ (the latter being proportional to the Chezy C) and abscissa scales of both $\mathbf{R} = VD/\nu$ and $\mathbf{R}\sqrt{f} = \sqrt{2g\,h_f/L}\;D^{3/2}/\nu$. Since the parameters $1/\sqrt{f}$ and log $(\mathbf{R}\sqrt{f})$ were selected by the writer for the primary ordinate and abscissa scales, the alternative abscissa parameter log $\mathbf{R}$ is necessarily represented by curved lines over a portion of the writer's chart. Had log f and log $\mathbf{R}$ been chosen as the primary parameters, log $(\mathbf{R}\sqrt{f})$ would still have required sloping lines in the grid; such choice therefore involves no particular advantage over the writer's but rather defeats the writer's purpose owing to the accompanying distortion of the entire system of transition curves. The author's graph, of course, contains no secondary grid system simply because it permits direct solution for only one of the several variables.

Brief mention might be made of the third possible combination of variables, which is evidently applicable to problems in which the diameter is the unknown quantity. So long as the pipe is smooth, such a plot will be of use, but the adoption of a similar function for the case of rough surfaces will still require a trial-and-error solution, unless the graph is made hopelessly complex, owing to the fact that for a given boundary material the pipe diameter must be known before the relative roughness may be evaluated. Solution by trial might therefore proceed just as well from either of the other two functional relationships contained in the writer's diagram.

The writer commends the author's presentation in graph form of the values of absolute roughness given in the writer's paper, but notes with interest that this plot is consistent with the writer's rather than the author's choice of basic parameters. Such a graph would therefore have its greatest value when prepared as

a marginal extension of the writer's resistance chart, for then no relative-roughness computations would have to be made.

So far as the author's discussion of open-channel resistance is concerned, the writer takes exception to two points of fundamental importance: First, the author states that such relationships as the Manning formula should be used in open-channel computations in preference to values derived from pipe tests, implying that the familiar empirical open-channel formulas are inherently more valid. It is known, however, that the Manning formula (not to mention those of Bazin and Kutter) is not in accordance with the logarithmic law of relative roughness upon which the author's paper is based. So far as the writer can ascertain, the only reason pipe tests could not generally be used in evaluating open-channel resistance lies in the fact that few open-channel boundary surfaces are suitable to testing in pipe form. Aside from the moot question of the effect of cross-sectional shape (which the empirical open-channel formulas in no way answer), it would appear to the writer that a general resistance graph for uniform open channels should differ little from that for pipes, except in that the familiar parameters C and S might conveniently be included in the co-ordinate scales; this has been done in the present form of the writer's chart.

The writer's second objection to the author's closing section is in regard to his implication that the Froude number should replace the Reynolds number as the fundamental resistance parameter for open-channel flow. So far as boundary resistance is concerned, the writer can see no possibility of the Froude number playing a comparable role. It is true that viscous shear is of little significance in comparison with boundary roughness in most open-channel problems, but it is also true that the effect of surface waves upon the internal resistance to flow has not yet been ascertained. The open-channel problem is, in fact, quite analogous to that of ship resistance, in which the matter of surface drag is considered wholly independent of the Froude number. If, to be sure, the phenomena of slug flow, atmospheric drag, and air entrainment prove to govern the resistance in the comparatively infrequent case of supercritical flow in open channels, then the Froude number may well become an appropriate resistance criterion, as it already is for cases of channel transition. But to imply that it should replace the Reynolds number as a resistance parameter whenever a free surface exists seems rather untimely to the writer, in that it could lead to serious misinterpretation of those few principles of boundary resistance which have been definitely established.

P. H. Schweitzer.[18] Lest the author's charts, presented in delightfully handy forms, be used indiscriminately, it is perhaps in order to add one note of caution. Most of the statements, formulas, and charts are valid only for "long" pipes. For short pipes, the rules controlling turbulence are different, and Reynolds number is not the sole or deciding criterion for the state of flow.

If the velocity of flow in a long tube is decreased below the "critical" value, a change from turbulent to laminar flow takes place rather abruptly. The author sets the indeterminate region between 2000 and 4000 Reynolds number. Even that represents a rather narrow strip in the total range covered by the flow of such liquids as water or light oil. Outside of this indeterminate region, the flow is either completely laminar or decidedly turbulent, ignoring the rather thin laminar-boundary layer.

While this is true of relatively long tubes, for short tubes or nozzles it is not. In a short tube, as was shown by the writer,[19] the normal state may be described as "semiturbulent flow," which may be visualized as a turbulent core in the center and a laminar envelope near the periphery. The thickness of the laminar envelope may vary between wide limits. The change from turbulent to laminar flow or the reverse takes place in a short tube so gradually that the intermediate stage usually covers the whole practical region.

Of course, in both long and short tubes, turbulent flow is promoted by high flow velocity, large tube size, curvature of the tube, divergence of the tube, rapid changes in direction and cross-sectional area of the tube. Laminar flow is promoted by high liquid viscosity, laminar approach, rounded entrance to the tube, slight convergence of the tube, absence of curvature and disturbances.

Irrespective of the length of the tube an originally turbulent flow will remain turbulent, if its Reynolds number $\mathbf{R} = vd/\nu$ is greater than the critical Reynolds number. Conversely, an originally laminar flow will remain laminar if $\mathbf{R}$ is lower than the number.

If the flow at the entrance is turbulent but its Reynolds number in the tube is lower than the critical, the flow will turn purely laminar if the tube is straight, reasonably smooth, and sufficiently long. If the flow at the entry of the tube is laminar but its Reynolds number is above the critical, it is hard to predict the character of the ensuing flow. If the entry is smooth and rounded and the tube free from disturbances and irregularities, the flow will remain laminar even at Reynolds numbers[20] as high as 15,000.

In a complete absence of all disturbances, a laminar flow probably never turns turbulent, no matter how high its Reynolds number, but the slightest disturbance will ultimately cause turbulence if the Reynolds number is above the critical. The higher the Reynolds number the greater the disturbance, the shorter the tube travel necessary for turbulence to set in.

In a short tube the critical Reynolds number is not the one above which the flow generally or in a particular case is turbulent. The flow is frequently laminar at Reynolds numbers above the critical and it may be turbulent or semiturbulent at Reynolds number below the critical.

The critical Reynolds number is the one below which, in a straight long cylindrical tube, disturbances in the flow will damp out. Above the critical Reynolds number disturbances (approach, entry, etc.) never damp out, no matter how long the tube is. The critical Reynolds number so defined was found by Schiller[21] to be approximately 2320.

In short tubes, or nozzles, the length is not nearly enough for the flow to assume a stable condition. Under the circumstances, a Reynolds number higher than critical will have a tendency toward turbulence and vice versa, but it may take a tube travel of 60 times diameter before a stable velocity distribution is developed. The actual flow in the nozzle will be influenced considerably by the state of flow before the orifice and the disturbances in the approach and within the nozzle. The combination of these factors in addition to the Reynolds number will determine the state of turbulence at the exit of the short tube. For a given short tube or nozzle, the influence of the nozzle factors can be considered the same; therefore the Reynolds number alone will determine the character of the flow.

With decreasing Reynolds number, the thickness of the laminar layer increases and the turbulent inner portion decreases until it finally disappears. It is peculiar to nozzles or short tubes that the change from turbulent to laminar flow (or vice versa)

takes place gradually rather than abruptly. The semiturbulent state extends over a wide range of Reynolds numbers, differing only in the relative thickness of the turbulent core and laminar envelope.

Author's Closure

The paper was intended for application to normal conditions of engineering practice and specifies a number of qualifications limiting the scope of the charts, such as their restriction to round (straight) new and clean pipes, running full, and with steady flow. Under such conditions it was stated, as noted by Professor Pardoe, that the friction factor f "is a dimensionless quantity, and at ordinary velocities is a function of two, and only two, other dimensionless quantities,—the relative roughness of the surface and the Reynolds number."

Under abnormal conditions f could of course be affected by other dimensionless criteria. In closed conduits at very high velocities or with rapidly varying pressures it depends on the Mach or Cauchy number introducing the acoustic velocity. In open channels, as pointed out, free surface phenomena, gravity waves, make it logically dependent on Froude's number. At very low velocities in shallow open troughs it would conceivably be controlled also by the Weber number for surface tension and capillary waves. Capillary forces while important to insects, as to a fly on flypaper, are negligible to us in problems of engineering magnitude. Under usual conditions of pipe flow only the two dimensionless ratios mentioned need be considered, and it is possible to present the relations between the factors in a chart such as Fig. 1.

The discussions have brought out a number of other departures from normal conditions and further limitations to the scope of the charts. Professor Pardoe reminds us that a considerable temperature difference between the fluid and pipe wall may have a measurable effect on the shear stresses, due to ambient currents which would increase the momentum transfer in similar manner to turbulent mixing. This effect would probably be of importance only at the lower Reynolds numbers and with material temperature differences.

Mr. Pigott reminds us that the scope is limited to simple fluids and does not cover "queer materials like greases, muds, cement slurries" and mixtures with suspended solids. Professor (now Commander) Hubbard and Professor Pardoe mention some unusual forms of pipe surfaces. The author thinks that most of these, including paint coatings, will follow the lines of the charts closely enough for practical purposes if the proper roughness figures are determined; but the rubber dock-loading hose with helical internal band will probably follow a curve similar to curve V in Fig. 6, which Colebrook and White obtained for spiral-riveted pipe.

Dr. Ippen mentions the rate of increase of roughness from corrosion and gives some useful test information. Colebrook found that corrosion usually increases the value of ϵ at substantially a uniform rate with respect to time. Professor Schweitzer calls attention to the point that the pipe must be long, with an established regime of flow, and that the charts do not apply to the entrance or "smoothing section" which require separate allowances. Fortunately we are seldom concerned with close estimates of friction loss in short tubes, where friction is a minor element in the total loss of head.

Dr. Ippen's discussion admirably summarizes the basic structure of the charts and gives supporting evidence. His own studies of the problem had, the author believes, led him independently to conclusions similar to Colebrook's.

The Colebrook function has given us a practically satisfactory formulation bridging the previous gap in our theoretic structure, a region in which the majority of engineering problems fall. It has the further useful property of covering in a single formula the whole field of pipe flow above the laminar and critical zones; and throughout the field agrees with observations as closely as can be reasonably demanded within the range of accuracy available in the measurements, particularly in the evaluation of the boundary roughness.

Referring to a question raised by Professor Daugherty, the inconsistency between Nikuradse's tests in the transition zone and those from commercial pipe is usually attributed either to the close spacing of the artificially applied sand grains, such that one particle may lie in the wake behind another, or to the uniformity of Nikuradse's particles in contrast to the usual commercial surface, which is probably a mixture of large and small roughnesses distributed at random. The latter explanation seems particularly plausible, since a few large protuberances mixed with smaller ones could project far enough into the laminar boundary layer to break it up, while a uniform layer of projections of average size would all remain well within the same thickness of layer. Thus Nikuradse's curve clings closely to the smooth pipe line much farther than the curve for commercial surfaces. At any rate the artificial character of Nikuradse's surfaces weighs against the use of his values in the region where the discrepancies appear.

Mr. Pigott reviews the progress in charting friction factors and gives evidence supporting the laws adopted. At the end of his discussion he brings up an interesting question, the form and location of the dashed line in Fig. 1 marking the boundary of the rough pipe zone for complete turbulence, beyond which the friction factors become practically horizontal. With his gift for detecting relationships he arrives at a modified equation for this curve.

Referring to Figs. 5 and 6 it will be noted that Nikuradse's experiments on artificial roughness gave a curve which dropped below the "rough pipe" line and then approached it from below, while ordinary commercial pipes give points which approach the rough pipe line from above, and that both sets of points seem to merge with the rough pipe line at about $\frac{\mathbf{R}\sqrt{f}}{D/2\epsilon} = 400$, which Rouse accordingly adopted as the equation of the boundary of the rough pipe zone, the dashed line shown in Fig. 1. If, however, we adopt the Colebrook function for the transition region to the left of this boundary curve, strictly speaking the Colebrook curves never completely merge with the constant f lines but are asymptotic to them; so that on the basis of the Colebrook function there is no definite boundary to the rough pipe region.

Practically however the Colebrook function converges so rapidly to the horizontal f lines that beyond Rouse's dashed curve the differences are insignificant. Considering the practical difficulties of measurement and consequent scatter of the test points, and the fact that the Colebrook function is partly empirical and merely a satisfactory approximation, it seems hardly justifiable to draw fine distinctions from an extrapolation of this function. If the function could be accepted as completely rational it would be more logical to locate the boundary curve so that it would correspond to some fixed percentage of excess in f over the f for complete turbulence.

Prompted by Mr. Pigott's suggestion, the author has analyzed the Colebrook equation from this point of view. Calling f the value of the friction factor according to Colebrook, and f_k the value for complete turbulence according to von Kármán, the Colebrook equation can be expressed

$$1/\sqrt{f_k} - 1/\sqrt{f} = 2\log\left(1 + \frac{3.7 \times 2.51}{\epsilon/D\,\mathbf{R}\sqrt{f}}\right)$$

Calling $\frac{3.7 \times 2.51}{\epsilon/D\ \mathbf{R}\sqrt{f}} = x$, a small quantity compared to 1 (of the order of 0.05 or less in the region of the boundary curve) then $\log (1 + x)$ can be expanded in a series giving

$0.4343\left(x - \frac{x^2}{2} + \frac{x^3}{3} - \ldots\right)$; and neglecting x^2 and higher powers

$1/\sqrt{f_k} - 1/\sqrt{f} = 0.8686x.$

If now we denote by s the *proportional* change in f, that is $s = \frac{f - f_k}{f_k} = \frac{f}{f_k} - 1$, s being small compared to 1, then

$$1/\sqrt{f_k} - 1/\sqrt{f} = 1/\sqrt{f}\left(\sqrt{f/f_k} - 1\right)$$
$$= 1/\sqrt{f}\left(\sqrt{1+s} - 1\right)$$

which, expanding by the binomial formula, is very nearly

$$1/\sqrt{f}\ (1 + s/2 - 1) = s/2\sqrt{f}$$

Hence

$$s/2\sqrt{f} = 0.8686x = \frac{0.8686 \times 3.7 \times 2.51}{\epsilon/D\ \mathbf{R}\sqrt{f}};\ \text{and}\ s = \frac{16.1}{\epsilon/D\mathbf{R}}$$

is the proportional change in f caused by the Colebrook function.

In plotting Fig. 1, the author, instead of continuing indefinitely with the insignificant effect of the small term, and favoring the view that f should become substantially constant in the rough pipe zone, adopted the compromise of ignoring the variation when it fell below about one half of one per cent; and beyond this point the f lines were drawn horizontally at the Kármán value. That is, the chart applied the Colebrook formula only to the transition zone.

Putting $s = .005 = \frac{16}{\epsilon/D\mathbf{R}}$, we have $\mathbf{R} = \frac{3200}{\epsilon/D}$, practically confirming Mr. Pigott's deduction. If we adopt a one per cent variation of f as a reasonable allowance, the boundary curve could be plotted from $\mathbf{R} = \frac{1600}{\epsilon/D}$. It might be more logical, to be consistent with the Colebrook function, to use this formula for the boundary curve instead of Rouse's form. The two curves differ but little, and the choice seems more a matter of academic preference than practical importance; the scatter of test observations obscures a final answer.

As noted in numerous references in the paper the author has been indebted to Professor Rouse for his contributions to the subject, particularly his valuable paper at the Iowa Hydraulic Conference. Professor Rouse's inclusion in his discussion of his chart, Fig. 7, from the latter paper, is a useful addition to the material here collected. The co-ordinates selected for this chart bring out the functional relationships in a simple manner; and those who prefer to adopt this form of chart now have it at hand.

The author still considers it less convenient for usual engineering problems than his Fig. 1. While the horizontal scale of Fig. 7 can be expressed in terms of the frictional loss of head in place of f, this is of no help where the velocity is given and the friction loss is to be found, nor is it of much help in usual engineering problems where the total head is given and the velocity is to be found. The total head almost always includes not only the friction loss in a pipe system, but also the exit loss, and the losses at entrance and in fittings, bends, and changes in section; and we can seldom assign in advance the value of the friction head or slope of the hydraulic gradient; so that successive approximations or trial-and-error solutions are still required. While Rouse's chart is easier to construct, for the reasons explained the author adopted the form of Fig. 1 as easier to use.

Regarding the author's suggestions as to open channels, the questions raised by Professor Rouse are probably due mainly to the omission of fuller explanation in the paper. It was not the intention to imply that at low velocities in relatively smooth open channels the friction loss would be independent of Reynolds number, and it may well be found that in this region the logarithmic laws may continue to apply, at least in modified form, and that, as Professor Rouse states, "a general resistance graph for uniform open channels should differ little from that for pipes."

The author was speaking of another region, "open channels dealt with in engineering practice...usually rough-surfaced and of large cross section, corresponding to large Reynolds numbers and falling in the zone of complete turbulence." With fairly high velocities, corresponding to large Reynolds numbers, in the presence of a free surface, dimensional considerations require us to include the Froude number as a criterion; and in the region of complete turbulence we can fortunately afford to omit the Reynolds number as a controlling factor so that we do not have too many variables to handle. The author did not intend to imply that the Froude number "should replace the Reynolds number as a resistance factor *whenever a free surface exists*" but only in the region described, which however is within the range of ordinary practice.

Professor Rouse recognizes that free-surface phenomena comprise a factor in the problem; his objection to including the Froude number is merely that "the effect of surface waves upon the internal resistance to flow has not yet been ascertained—" which calls on us to investigate the effect rather than to ignore it. Certainly wave-making resistance is a very real factor both in ship resistance, and in open channel flow in the region of the gravitational critical velocity. Even in tranquil flow it still may have a measurable effect; the location of the maximum velocity point below rather than at the surface suggests an influence of this factor.

The author is confident that Professor Rouse will agree with his belief that further research on open channel friction is much needed; and he commends such a project particularly to the civil engineers. Neither the f versus $\mathbf{R}$ charts nor such formulas as Manning's, Kutter's or Bazin's are believed to take into account all of the major controlling factors, and a statistical analysis of available data along the lines suggested, supplemented by further experiments, may yield working charts or formulas of great value to engineers.

It is regretted that Professor (now Major) Colebrook, who has been serving in the British Army since 1939, was unable to submit a discussion. The author wishes to thank all of the discussers for their useful contributions, and also to thank Mr. Richard B. Willi for his able presentation of the paper at the Pittsburgh meeting on behalf of the author.

Factors Affecting the Thickness of Coal-Ash Slag on Furnace-Wall Tubes[1]

By W. T. REID[2] and P. COHEN,[3] PITTSBURGH, PA.

Modern central-station power plants generating steam in slag-tap pulverized-coal-fired furnaces often report difficulties in operation as the result of excessive accumulations of slag on the heat-absorbing surfaces of the furnace. Such deposits of slag interfere with the expected transfer of heat from the furnace to the tube metal, and not only may cause trouble in maintaining superheat temperatures at proper levels, but also may be responsible for troubles experienced with circulation. Few means have been available in the past to evaluate the tendency of slags to form objectionable deposits. This paper describes methods of predicting the relative thickness of slag deposits on heat-absorbing surfaces and is based upon the application of data obtained in the laboratory on the flow properties of coal-ash slags at high temperatures. Although based on idealized furnace conditions, it should serve as a guide in comparing the behavior of different coal ashes in the same furnace under similar operating conditions, or in predicting the effect of change in these conditions on the action of a given coal ash. Also, it should serve as a guide for field tests of the effect of slag on furnace performance.

As a result of increased interest in the effect of slag on the performance of modern central-station boiler furnaces burning pulverized coal, recent studies in this laboratory have been directed largely toward determining the fundamental properties of coal-ash slags at high temperatures. Such data are useful in studying the accumulation of slag on heat-absorbing surfaces, such as furnace-wall tubes. One of the problems facing both designers and operators of these furnaces is the effect of deposits of slag in decreasing the normal transfer of heat from the furnace cavity to the tube metal, resulting in unpredictable and variable fluctuations in the temperature of the furnace gases. This usually causes difficulty in maintaining a desired superheat temperature, while troubles experienced with circulation often have been attributed to unexpected variations in the rate of heat transfer to certain sections of waterwalls caused by unforeseen slag accumulations.

Design rates of heat transfer based upon previous experience with a certain coal may not be attainable when other coals are burned because of differences in the composition of the ash, which may result in thicker slag deposits and, consequently, greater insulating effects. A proper knowledge of slag characteristics and of the behavior of slag in the furnace should permit the design of furnaces having predictable heat-absorbing characteristics when fired with coal having ash of known composition and would make it possible to select coals upon the basis of slag performance rather than upon the now generally used guide of the cone-softening temperature.

Only recently has that fundamental information been obtained which makes possible a critical analysis of the action of slag on heat-absorbing surfaces. The development in 1940 by the Bureau of Mines of a high-temperature viscometer[4] for measuring the flow properties of coal-ash slag at temperatures where the slag behaved as a true liquid and, in 1943, of a modification,[5] permitting study of the region where the slag behaved as a plastic rather than a viscous material, furnished methods of obtaining the required data. A preliminary discussion of a means of calculating the thickness of slag deposits on heat-absorbing surfaces based on the flow properties of the slag was given in the second report,[5] but its importance seemed to warrant additional explanation. Consequently, the study was carried further

The present paper reviews the information included in a forthcoming Technical Paper of the Bureau of Mines,[6] in which the subject is treated in considerable detail and in which the mathematical derivations of the complex relationships are given. The present paper describes the principal elements included in that publication to show the factors which are of importance in fixing the thickness of slag deposits on heat-absorbing surfaces but does not include specific details as to the means of arriving at the relationships obtained. It is expected that much of the information included will be used in a field study of the action of coal ash in boiler furnaces now being conducted in co-operation with the Special Research Committee on Furnace Performance Factors; thus the present paper may be considered as a preliminary report to that committee. Others interested in the effect of slag on heat transfer in boiler furnaces may find the method advantageous over purely speculative schemes based upon empirical considerations.

The factors involved in this study can be divided into two classes, one fixed by the properties of the slag and the other dependent on furnace conditions; one example of this is the rate of supply of slag to the wall from the flame. Factors depending on the flow properties of the slag will be discussed first.

Properties of Slag Affecting Its Behavior on Furnace Walls

This report refers only to the deposition of slag on the walls of that part of the furnace where the slag surface is molten and a continuous surface flow of slag occurs. On other sections of the furnace, such as on generating tubes, where adherent but nonflowing deposits are formed, or where the deposits break off after reaching considerable thickness, the conditions are less susceptible to analysis and will not be considered here. Because of the

high rate of heat transfer in the slagging zone, an analysis confined to that part of the furnace is most important.

Physical Structure of Slag Deposits. Examination of a section of slag, taken from the wall of a slag-tap furnace in the slagging zone, often gives a visual indication of the flow process. Fig. 1 shows a representation of a typical deposit. Immediately adjacent to the surface of the tube is a thin, semiporous, irregular layer of partly melted ash, through which the slag adheres to the tube. Next, is a dense, crystalline layer of slag, which usually makes up the largest part of the deposit. Finally, there is a layer of glassy slag which extends to the surface, the boundary between it and the crystalline layer usually being sharply defined. The arrangement of these layers results from the temperature gradient through the slag which existed during operation of the furnace, and does not result from events subsequent

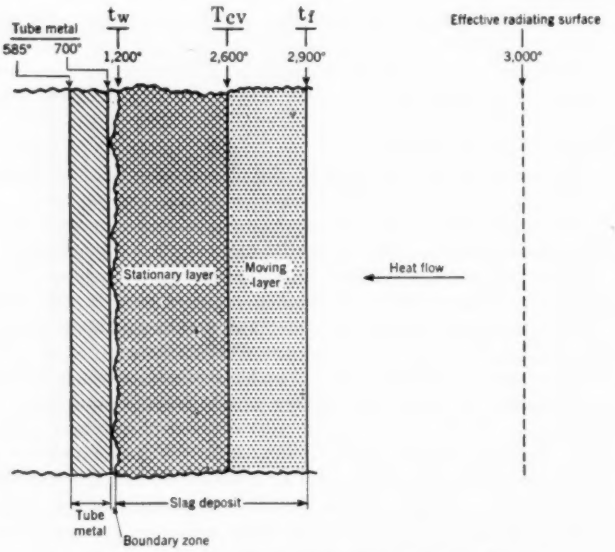

FIG. 1 TEMPERATURE DISTRIBUTION IN SLAG DEPOSIT

to taking the furnace off the line, in which case the glassy layer would have been next to the tube surface, having there been cooled most rapidly. It is evident, then, that when a furnace is operating, the part of the slag deposit nearest the tube is maintained at a sufficiently low temperature for the slag to crystallize, whereas on the furnace side the slag is molten.

Flow Properties of Coal-Ash Slags. Laboratory studies have shown that coal-ash slags are not true liquids over a wide range of temperatures. Most slags on being cooled slowly from high temperatures where they exist as true liquids, at some point, depending upon the composition of the slag and the state of oxidation of its iron content, and somewhat on the thermal history of the melt, begin to separate solid material from the otherwise liquid slag. This solid matter, usually present as very small crystals, causes the slag to become plastic rather than viscous. The essential characteristics of this plastic state are that a definite shear stress (the internal yield stress) is necessary to produce flow and that the rate of flow is proportional to the excess of the applied shear stress over this minimum value. The temperature at which this transition occurs is called the "temperature of critical viscosity," T_{cv}; values of this constant have been determined for a wide range of composition of coal-ash slags, including variation in the state of oxidation of the iron in the slag that is significant. Because both the internal yield stress and the plastic viscosity increase rapidly with decrease in temperature below T_{cv} and, furthermore, at low applied shear stress the effect of even slight internal yield stress is such as to make the apparent viscosity very high, the important assumption is made that the flow of slag at temperatures below T_{cv} is insignificant as compared with flow at higher temperatures. In other words, for all practical purposes where the applied stress is low (as by the action of gravity), the point at which the temperature of critical viscosity occurs in a slag deposit represents an abrupt change in physical properties; slag at a lower temperature behaves as a solid, while hotter slag flows like any liquid; the slightest application of force producing a corresponding flow. Thus it is reasonable to believe that the demarcation between the crystalline stationary layer and the glassy flowing layer of slag on furnace walls occurs at the temperature of critical viscosity.

In the flowing liquid layer of slag, the low-temperature boundary will be at the temperature of critical viscosity, while the high-temperature boundary will be at the furnace temperature; thus usually there will be a temperature difference of several hundred degrees between the two sides of the layer. The viscosity of the liquid slag and its variation with temperature will determine the thickness of the liquid layer required to carry off the slag being supplied. Data obtained from a great many determinations of the viscosity of coal-ash slags in the liquid region, that is, at temperatures higher than T_{cv}, show that the variation of viscosity with temperature can be expressed in the form $\eta^{-z} = At - B$ where η is the viscosity in poises; Z and A are constants for the entire field of composition normally found and are equal numerically to 0.1614 and 0.000452, respectively; t is the temperature in degrees F; and B depends on the composition of the slag. Knowing the viscosity of any slag at a particular temperature, B can be computed from the known values of Z and A.

The flow properties important in fixing the thickness of a slag deposit on a heat-absorbing surface are, therefore, (1) the temperature of critical viscosity, because it fixes the lower temperature of the flowing layer and determines the fraction of the total deposit that effectively will be solid and thus can be considered to be fixed in position; (2) the relationship between temperature and viscosity of the liquid layer, which will control the rate at which the slag can flow to cause a decrease in the over-all thickness. Obviously, as the temperature of critical viscosity increases, the fraction of the total deposit of slag which is stagnant will also increase, and the thickness of the layer will be greater. Likewise, as the viscosity of the liquid layer of slag increases at any fixed temperature, the rate of flow of the slag will be decreased, and the slag thickness will be greater. Thus if these properties of the slag are known from measurements made in the viscometer and correlated with composition, it is possible to predict actions of the slag in the furnace.

EFFECT OF FURNACE CONDITIONS

Factors other than the fundamental flow properties of coal-ash slags are important in fixing the thickness of slag on heat-absorbing surfaces. These include (1) temperatures in the furnace and of the slag deposit; (2) the quantity of slag being supplied to the surface from the furnace gases per unit of time; (3) the height in the furnace at which flow begins; (4) the height at which the thickness of slag is to be considered; (5) the angle of inclination of the flowing slag (essentially that of the furnace wall); and (6) the rate of heat transfer through the layer of slag. Additional factors dependent upon slag properties other than flow include (1) the thermal conductivity of the slag, and (2) the density of the slag.

The importance of temperature is obvious, because the flow properties of any given slag depend principally on that factor. Further, assuming that the temperature gradient through the slag deposit is linear, the thickness of the flowing layer of slag

will depend on the temperature of its boundaries, this layer then being a definite fraction of the total thickness of the deposit. For instance, if the furnace side of the slag deposit is at a temperature of 2900 F, the tube side is at 1200 F, and the temperature of critical viscosity is 2600 F, the flowing layer is $\frac{2900 - 2600}{2900 - 1200} = 0.18$ of the total thickness of the deposit, and the stationary layer is 0.82 of the total thickness. In this case the total thickness of the deposit will be 5.6 times that of the flowing layer.

If the furnace is operating under steady conditions, so that equilibrium occurs and no change takes place in any factor, the volume of slag flowing past a given position in the furnace must equal the total volume of slag deposited on the furnace wall in the slagging zone above that position. Therefore, the quantity of slag being deposited from the flame is important. It is also evident that the height of the slagging zone in the furnace, and the position of the area being considered, will affect the quantity of slag flowing past any given point. Because the quantity of slag reaching the wall is difficult to determine, comparisons in this report are based upon an arbitrary quantity of slag flow, and two different slags are compared by considering the ratio of the thicknesses that would be obtained for the same flow of slag in each case. By taking this ratio for all slags relative to a "standard" slag and fixed furnace conditions, a set of relative thicknesses is obtained.

The angle of the flowing layer of slag will affect its thickness in a simple manner. Although wall tubes are usually vertical, this factor has been included to permit consideration of special cases.

The point of major interest is of course the rate of heat transfer from the furnace through the slag to the tubes. For a given temperature drop through the deposit, the rate of heat transfer is proportional to the reciprocal of the total thickness of slag, the proportionality factor being the thermal conductivity. Lacking any information at present on the thermal conductivity of coal-ash slags, this factor can be assumed to be independent both of composition and temperature, and the relative rates of heat transfer of the deposits can be obtained from their relative thickness. Lack of information on absolute values of rate of slag deposition, thickness of the deposit, or the rate of heat transfer need not detract from the usefulness of this study; when the data are available, the absolute values can be computed by these same methods.

Equation for Computing Thickness of Slag Deposits

The assumptions made in deriving the equation for the thickness of slag on heat-absorbing surfaces are (1) the flow of slag at temperatures below that of the critical viscosity is insignificant; (2) the thermal gradient through the slag deposit is constant; (3) the slag density is independent of composition and temperature; and (4) the slag exists on a plane surface and heat transfer occurs normal to that surface.

The equation, the derivation of which is given in another publication,[6] is long and involved, including, as it does, approximately 10 parameters. Those interested in the mathematical method may wish to follow the derivation step by step; others interested solely in the action of slag in furnaces can better understand its usefulness by referring to the figures given later. The equation is

$$D = \frac{0.00115\ \Delta t \left(\int_h^{h_m} V_s\, dh \right)^{1/3}}{(\rho\ \sin\alpha)^{1/3}\ [\ ]^{1/3}}$$

where

$$[\ ] = \left[\left(\frac{\omega + A'\Delta t}{7.20} \right) \left\{ \frac{(\omega + A'\Delta t)^{8.20} - (\omega + A'\beta\Delta t)^{8.20}}{8.20} - (\omega + A'\beta\Delta t)^{7.20}(1 - \beta)(A'\Delta t) \right\} \right.$$

$$\left. -0.122 \left\{ \frac{(\omega + A'\Delta t)^{9.20} - (\omega + A'\beta\Delta t)^{9.20}}{9.20} - (\omega + A'\beta\Delta t)^{8.20} (1 - \beta)(A'\Delta t) \right\} \right]$$

The nomenclature used is as follows:

- t_f = temperature, deg F, of furnace side of slag deposit
- t_w = temperature, deg F, of wall side of slag deposit
- T_{cv} = temperature of critical viscosity, deg F, below which no flow is assumed to occur
- $\Delta t = t_f - t_w$, temperature drop across slag deposit, deg F
- D = total thickness of slag deposit, in.
- ρ = density of slag, assumed constant, lb mass per cu ft
- h_m = height in furnace at which flow begins, above datum line, ft
- h = height above datum line in furnace, ft
- V_s = volume of slag supplied to wall at height h, ft³ per ft² per sec
- V = volume of slag flow at height h, ft³ per ft² per sec
- α = angle of inclination of wall from horizontal, deg
- $\beta = \frac{T_{cv} - tw}{\Delta t}$ = fraction of deposit which does not flow
- $A' = 1.546A = 0.000699$
- $B' = 1.546B$
- $\omega = A't_w - B'$
- t_g = temperature of gas, deg F
- T_g = temperature of gas, deg R
- t_a = adiabatic combustion temperature, deg F
- T_f = temperature of furnace side of slag deposit, deg R

Application of Equation

Effect of Change in Viscosity and Temperature of Critical Viscosity. The effect on the thickness of slag deposits caused by change in the flow properties of the slag is shown in Fig. 2; the data were calculated by the equation just described. This and

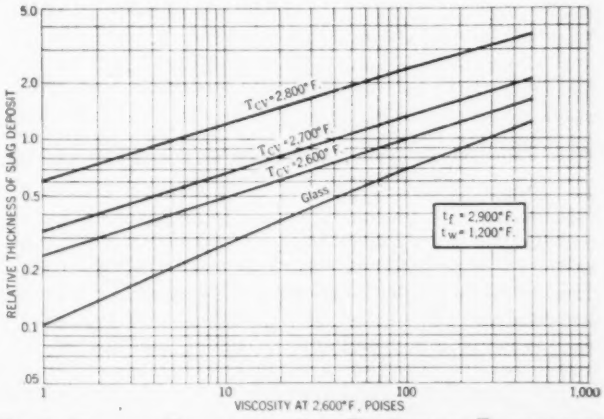

Fig. 2 Relative Thickness of Slag Deposits for Temperature of Furnace Side of Slag Deposit of 2800 F

the succeeding plots express the thickness of slag in terms of the relative thickness compared with a "standard" slag having a viscosity of 100 poises at 2600 F, and a temperature of critical viscosity of 2600 F. They show that the effect of change in viscosity is only slightly greater than change in the temperature of critical viscosity, T_{cv}. For instance, with a slag for which T_{cv} is 2600 F, decreasing the viscosity from 100 to 10 poises, as measured at 2600 F, decreases the slag thickness to 48 per cent of the

original thickness and, if the viscosity were reduced to 1 poise, to 23 per cent. However, if T_{cv} is changed from 2600 F to its minimum value, which would be the case for a slag which acted as a glass, the thickness would be 55 per cent of the original if the viscosity were maintained at 100 poises and 31 per cent if the comparison were made at a viscosity of 1 poise for both slags. It should be noted that as T_{cv} approaches the temperature of the furnace side of the slag deposit, there is a sharp increase in relative thickness at all viscosities, whereas when T_{cv} decreases to approximately 2000 F, the properties approach that of a glass.

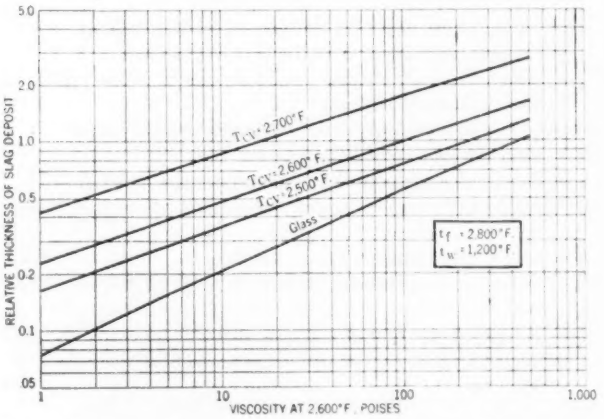

FIG. 3 RELATIVE THICKNESS OF SLAG DEPOSITS FOR TEMPERATURE OF FURNACE SIDE OF SLAG DEPOSIT OF 2900 F

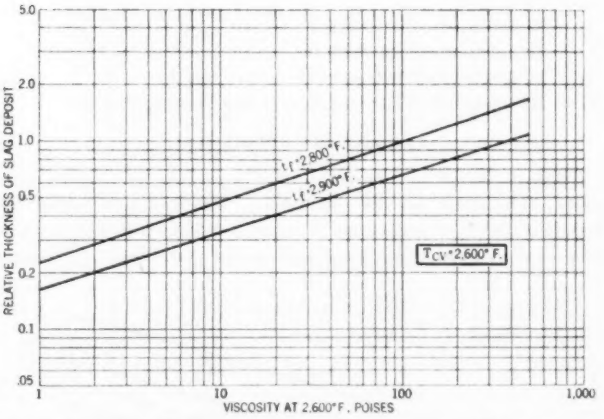

FIG. 4 RELATIVE THICKNESS OF SLAG DEPOSITS FOR TEMPERATURE OF CRITICAL VISCOSITY OF 2600 F

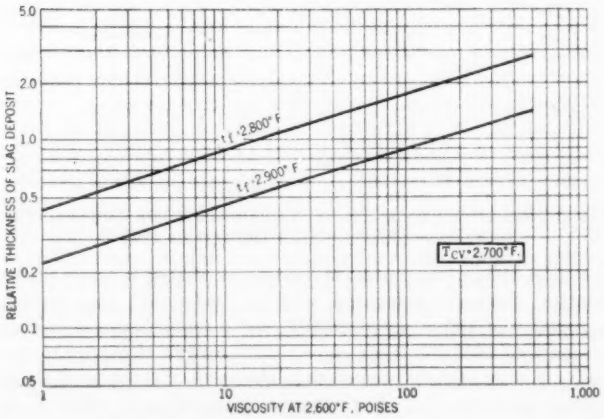

FIG. 5 RELATIVE THICKNESS OF SLAG DEPOSITS FOR TEMPERATURE OF CRITICAL VISCOSITY OF 2700 F

Effect of Change in Furnace Conditions. Changing the rate of heat release in a furnace will affect the temperature of the furnace side of the slag deposit, t_f. Fig. 3 shows the result of increasing t_f to 2900 F, the principal change being a slight decrease in the spacing of the curves. Viscosity and temperature of critical viscosity are again approximately of equal significance in affecting the thickness of the slag deposit.

A different method of expressing the same data is shown in Fig. 4, where the effect of change in furnace temperature on thickness is shown for slags of varying viscosity but with a fixed temperature of critical viscosity of 2600 F. It is apparent that increasing t_f from 2800 to 2900 F decreased the thickness at 100 poises to 66 per cent of the original thickness, and that the percentage decrease of thickness is approximately the same for a given change in t_f independent of the viscosity of the slag. In Fig. 5, where the same type of plot is used, except that T_{cv} is increased to 2700 F, similar effects are observed, except that increasing t_f from 2800 to 2900 F decreased the relative thickness at 100 poises from 1.8 to 0.9, or to 50 per cent of the original thickness. Again, because the isotherms are parallel lines, this percentage change will be constant over the range of viscosities studied.

As noted previously, both the viscosity and the temperature of critical viscosity of coal-ash slags have been determined experimentally for a wide range of compositions. These data have been correlated so that knowledge of the chemical analysis of the slag permits prediction of these properties. Such correlations have been used in Fig. 6, in expressing the relative thickness of slag deposits as a function of composition. Thus knowing the composition of two slags being deposited on the wall tubes of a furnace under identical conditions, a prediction can be made of the relative thickness of the two deposits.

Fig. 6 shows that increase in the equivalent Fe_2O_3 content of the slag results in decreased thickness and that decreasing the ferric percentage, that is, increasing the state of reduction of the iron oxides, decreases the thickness of the deposit. The action of CaO is also to decrease the thickness of the slag as its content increases, the effect being greatest with slags containing less than 20 per cent equivalent Fe_2O_3. For instance, with a slag containing 15 per cent equivalent Fe_2O_3, at a ferric percentage of 20, the thickness with 10 per cent CaO is 44 per cent of that for a slag having 5 per cent CaO, while at 30 per cent equivalent Fe_2O_3 the thickness would be 73 per cent that for a slag containing 5 per cent CaO. Although these relationships may appear complex, by reference to this figure they can be made relatively simple. It is important to note that the use of this figure is limited to slags having a silica : alumina ratio of 2; experimental work now in progress will extend it later to cover a wider range of compositions, including most commonly occurring slags.

Relative Rates of Heat Transfer Through Slag Deposits. The relative rate of transfer of heat through two slags is shown in Fig. 7, as a function of the temperature of the furnace side of the slag deposit; the slags had viscosities of 5 and 100 poises, respectively, and a temperature of critical viscosity of 2600 F. It is obvious that normal change in the viscosity of the slag is more important than change in furnace temperature in affecting the rate of heat transfer. Also, as the furnace temperature approaches the temperature of critical viscosity, the rate of heat transfer will approach zero. This is true of course because under these conditions the thickness of slag increases markedly; because such slag deposits probably would not be physically strong enough to build up indefinitely, this region of the curve has theoretical significance only.

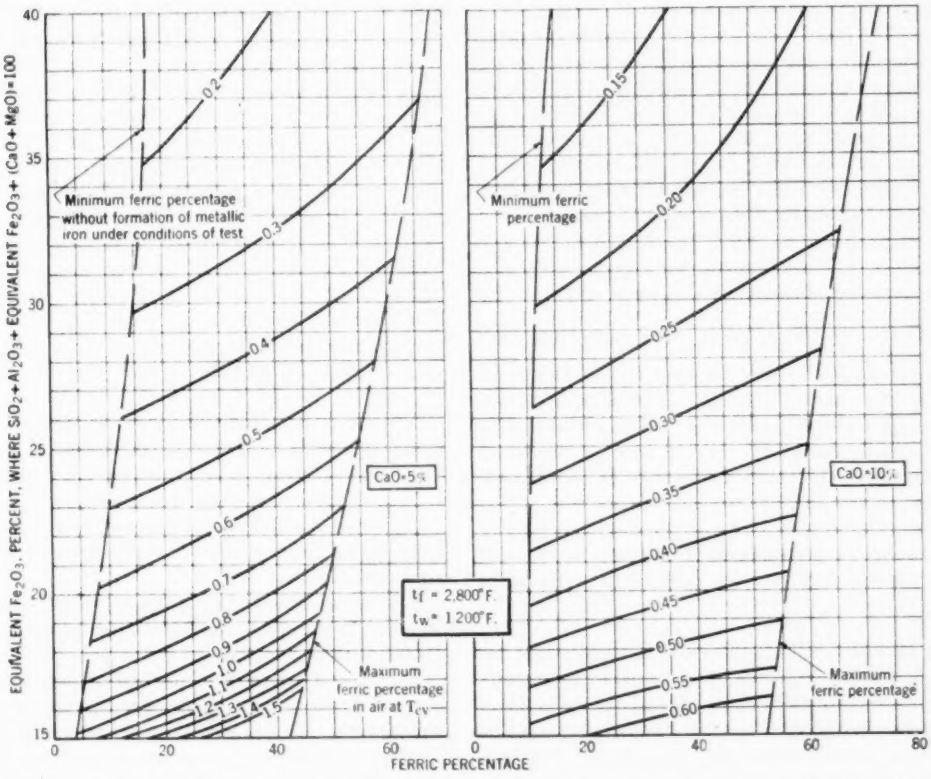

FIG. 6 RELATIVE THICKNESS OF SLAG DEPOSITS AS FUNCTION OF COMPOSITION AND FERRIC PERCENTAGE FOR A SILICA: ALUMINA RATIO OF 2

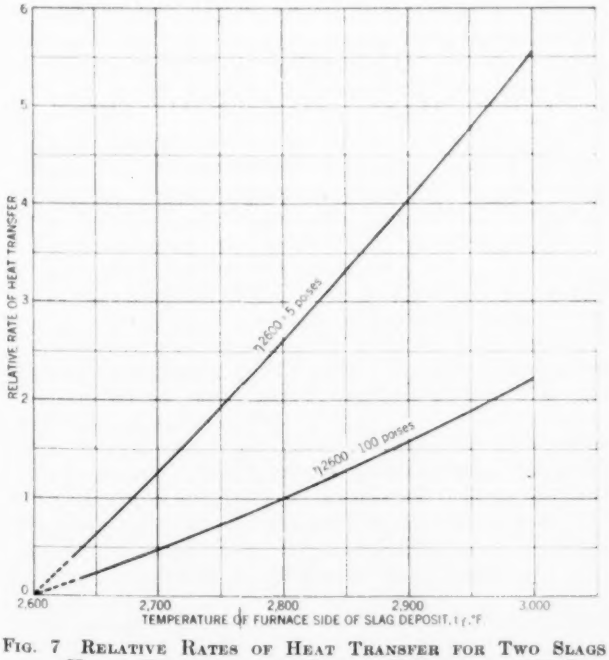

FIG. 7 RELATIVE RATES OF HEAT TRANSFER FOR TWO SLAGS HAVING TEMPERATURE OF CRITICAL VISCOSITY OF 2600 F

EFFECT OF SLAG ON RATE OF HEAT TRANSFER UNDER FURNACE CONDITIONS

The principal interest in the thickness of slag on furnace-wall tubes, of course, is based upon its effect on the rate of transfer of heat. This has already been described briefly, but for a model furnace where conditions are assumed constant over the entire area under study; actually, in an operating furnace they would vary from point to point in an unknown manner. The problem of taking these variations into account would be enormous, even if the distribution of thermal energy were known or if the rate of supply of slag to the walls could be accurately determined. Also, if the conditions in the furnace were uniform throughout, comparison between different slags would be complicated by the fact that any change would result in a different rate of heat transfer, and the temperatures in the furnace would be different unless there had been some accidentally correct change in the rate of firing. However, a means of making the necessary corrections is available and will be described briefly.

A method of determining the heat absorbed by furnace walls has been described by Wohlenberg and others[7] who measured the temperature of furnace-exit gases with high-velocity thermocouples. Mullikin,[8] using the Stefan-Boltzmann law, determined the fraction of the total heat supplied which was absorbed in the furnace and estimated the effects of the slag accumulation. More recently Bailey[9] studied the effect of slag on the heat absorption in steam-generating units, using the cone-fusion temperature as a measure of the flow properties of the slag. He obtained a relationship, called the "gas-ash temperature graph," between the properties of the slag and the temperature measured in several typical furnaces.

[7] "An Experimental Investigation of Heat Absorption in Boiler Furnaces," by W. J. Wohlenberg, H. F. Mullikin, W. H. Armacost, and C. W. Gordon, Trans. A.S.M.E., vol. 57, 1935, paper RP-57-4, pp. 541–553.

[8] "Evaluation of Effective Radiant Heating Surface and Application of the Stefan-Boltzmann Law to Heat Absorption in Boiler Furnaces," by H. F. Mullikin, Trans. A.S.M.E., vol. 57, 1935, paper RP-57-2, pp. 517-529.

[9] "Modern Boiler Furnaces," by E. G. Bailey, Trans. A.S.M.E., vol. 61, 1939, pp. 561–576.

The method used in the present investigation is described in detail in Appendix II of reference 6. Briefly, it may be described as follows: If all the heat transfer in the slagging zone is assumed to occur by radiation, then the sensible-heat loss of the furnace gases between the adiabatic temperature t_a, and the furnace gas temperature t_g, must equal the heat transfer by radiation from the furnace gases at temperature t_g to the furnace wall at temperature t_f. Further, this must equal the heat conducted through the slag layer from the furnace side at temperature t_f to the tube side at temperature t_w. If the sensible-heat loss is proportional to $t_a - t_g$, the heat transfer by radiation to $T_g^4 - T_f^4$, the capitals denoting absolute temperatures, and the heat transfer by conduction to $\frac{t_f - t_w}{D}$, then these three quantities are mutually proportional, and a change in any one factor will result in changes in the others, which can be calculated. Thus in a given furnace, if a change is made in the coal fired so that the thickness of slag deposited on the wall tubes is decreased, other things being equal, the heat transfer through the slag will be increased, and, as a result, the furnace temperature will be lowered. Knowing the expected change in slag thickness resulting from a change in composition of the ash in the coal, therefore, allows prediction of the effect on furnace performance.

Summary

The increasing importance of slag deposits to the designer and operator of slag-tap pulverized-coal boiler furnaces has created a demand for more quantitative knowledge of the behavior of slag under furnace conditions. Recent developments in the study of these slags have furnished data from which the thickness of slag deposits can be calculated for idealized conditions.

An equation is given relating the thickness of the slag deposit to the flow properties of the slag, the temperature of the hot and cold sides of the deposit, and the volume of slag flow. The relative thickness of slag deposits for typical conditions can be calculated from this equation, thus providing a method of comparing the behavior of different coal ashes on furnace walls.

It is shown that for fixed furnace conditions, increase in the temperature of critical viscosity, that is, the temperature at which the slowly cooled slag changes from the liquid to the plastic state, and increase in the viscosity of the slag cause approximately equal increases in the thickness of the slag deposit. As the temperature of critical viscosity approaches the temperature of the furnace side of the slag deposit, there is a large increase in the thickness for all viscosities. It is shown that, for a fixed temperature of critical viscosity, there is an equal percentage decrease in the thickness of the deposit for all viscosities as the temperature of the furnace side of the slag deposit is increased.

The relationship between slag composition and relative thickness of deposit is shown for part of the field of composition of coal-ash slags. Increase in equivalent Fe_2O_3 content and decrease in ferric percentage decrease the thickness of the deposit; CaO also decreases the deposit thickness as its content increases, the effect being greatest with slags containing less than 20 per cent equivalent Fe_2O_3.

Change in viscosity of slag due to change in composition of ash is shown to be more important than normal change in furnace temperature in affecting the rate of heat transfer.

Reference is made to a method of determining the effect on furnace temperatures of changes in the rate of heat transfer through the slag deposit, thus permitting the correlation of all the factors involved. Although the method applies strictly only to a model furnace, its application to operating furnaces should assist in studying the part taken by slag in affecting furnace performance.

Draft-Gear Action in Train Service

By O. R. WIKANDER,[1] PITTSBURGH, PA.

In order to investigate the most desirable characteristics of a draft gear by mathematical analysis, a study has been made of the mechanics of an elastic bar, which is subjected to external forces that correspond to those acting in trains under various service conditions. The results of this study, including the derivation of the various equations governing the behavior of an elastic bar, solid or with free slack, are given in another paper by the author.[2] The present paper contains substantially the same equations but transcribed so as to apply to railway trains. Numerical examples are given showing the applications of these equations to assumed test trains.

Definition of Terms

THE "capacity" of a draft gear is the amount of energy required to close it solid in drop test under a 27,000-lb tup, ft-lb.

The "recoil energy" of a draft gear is the amount of work, expressed in ft-lb or as a fraction or percentage of the draft-gear capacity, which the gear performs when it recoils the full distance of its service travel.

The "free slack" per coupling is the maximum relative movement between two adjacent cars, which can be made without compressing the draft gears.

The "controlled slack" per coupling is the amount of movement between adjacent cars, which is resisted by draft-gear action.

The "residual slack" per coupling is the amount of controlled slack which is released between two adjacent cars when, during a train operation, a previously compressed train is stretched, or a previously stretched train is compressed. (The effect is substantially that of increasing the free slack by the amount of the residual slack.)

The "propagation speed" is the speed at which a force or vehicle speed is transmitted through a train without free slack.

The "rate of progressive force application" is the speed at which a serial force application progresses through a long train.

The "propagation ratio" is the ratio of the propagation speed to the rate of progressive force application.

The "passing point," existing under certain conditions in elastic bars or long trains with free and residual slack, is the point at which the slack take-up passes the force application, and is defined by the number of the car at which it occurs, counted from the end of the bar or the train, at which the progressive external forces were originally applied.

The "critical train slack" is the amount of free plus residual slack per coupling which, in case of emergency-brake application, will place the passing point at the rear end of a train. A decrease below this amount of slack will move the passing point toward the front end of the train, and an increase will move it to an imaginary point beyond the rear end of the train.

Equations Governing Train Dynamics

The following nomenclature will be used:

C = capacity of one draft gear, ft-lb
e = base of natural logarithms
F = retarding force per car, lb
L_1 = length per car between buffing surfaces, ft
M = mass per car, slugs
M_1 = mass of locomotives and tender, slugs
n = number of cars or number of car in train
n_1 = number of car at passing point
n_2 = number of car of maximum coupler pressure in train without free slack
P = drawbar pull of a locomotive, lb
P_1 = tractive effort of a locomotive, lb
p = propagation ratio
q = full travel per draft gear, ft
s_1 = free plus residual slack per coupling, ft
s_2 = critical free plus residual slack per coupling, ft
t_1 = time interval between emergency brake or other force applications on adjacent cars, sec

Starting a Train

It will be assumed for the present that the train is started down a hill of such a grade that the frictional and gravitational forces balance. The entire power of the locomotives is thus applied to acceleration of the masses. Different equations apply, depending upon whether the train is started stretched or with free slack, and also whether the drawbar pull or the tractive effort of the locomotive is assumed to be constant during the starting period.

In any stretched train the drawbar pull P will be transmitted through the train at a constant propagation speed V which may be expressed as

$$V = (L_1/q)\sqrt{(C/M)} \quad [1]$$

Case 1. A locomotive of constant drawbar pull starts a train without free slack:

In this case the pickup speed v of the individual cars is also constant and may be expressed as

$$v = Pq/\sqrt{(CM)} \text{ or } P = (v/q)\sqrt{(MC)} \quad [2]$$

The time t required to set the train of n cars in motion, or the duration of the starting period, is

$$t = nq\sqrt{(M/C)} \quad [3]$$

The distance D traveled by the locomotive during the time t may be expressed as

$$D = nPq^2/C \quad [4]$$

After the time t, the train as a whole would, in this as well as in the following three cases, accelerate at the rate of $P/(M_1 + nM)$ if no external forces were impeding its motion.

Case 2. A locomotive of constant tractive effort starts a train without free slack:

During the starting time t, between the application of the tractive effort P_1 and until the last car begins to move, the speed of the locomotive increases according to the equation

$$v = [P_1q/\sqrt{(MC)}][1 - e^{-t\sqrt{(MC)}/(qM_1)}] \quad [5]$$

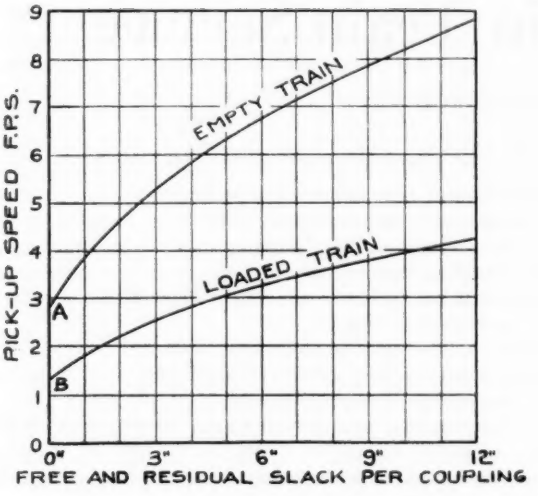

FIG. 1 PICK-UP SPEEDS OF EMPTY AND LOADED TRAINS AT CONSTANT DRAWBAR PULL

The duration t of this starting period is given in Equation [3].

Substituting this value in Equation [5], the latter takes the form

$$v = [P_1q/\sqrt{(MC)}][1 - e^{-nM/M_1}] \quad [5a]$$

This equation expresses the speed of the locomotive at the time when car n begins to move.

The drawbar pull at that time is

$$P = P_1(1 - e^{-nM/M_1}) \quad [6]$$

Case 3. A locomotive of constant drawbar pull starts a train with free slack:

The pick-up speed of the individual cars is constant and can be expressed as

$$v = [P_1q/\{2\sqrt{(CM)}\}][1 + \sqrt{\{1 + 4s_1C/(P_1q^2)\}}] \quad [7]$$

The duration of the starting period or the time t at which car n is set in motion is

$$t = [nq\sqrt{M}/(2\sqrt{c})][1 + \sqrt{\{1 + 4s_1C/(P_1q^2)\}}] \quad [8]$$

The distance D traveled by the locomotive during the starting time t or until the last car is picked up may be expressed as

$$D = n[s_1 + (P_1q^2/\{2c\})(1 + \sqrt{\{1 + 4s_1C/\{P_1q^2\}\}})] \quad [9]$$

Case 4. A locomotive of constant tractive effort starts a train with free slack:

The pickup speeds v of the individual cars increase with the number of the car n counted from the locomotive. The relationship between v and n under the assumption that all bunched cars have a uniform speed is expressed by the equation

$$n = (M_1/M)\{[\sqrt{(s_1C)}/\sqrt{(s_1C + P_1q^2<x - x^2>)}]$$
$$[(a^2 + 2ax + 2x - 1)/(a^2 - 2ax + 2x - 1)]^{1/(2a)} - 1\} \quad [10]$$

where $x = v\sqrt{(CM)}/(P_1q)$ is a parameter and $a = \sqrt{(1 + 4s_1C/[P_1q^2])}$ is a constant.

This equation permits the computation of n for assumed values of v and makes it possible to plot the vn curve.

The duration of the starting period t for a train with n cars may be expressed as

$$t = (v/P_1)(M_1 + Mn) \quad [10a]$$

where v has the value on the vn curve corresponding to the number of the car n. For large values of n the value of v from Equation [7] gives a good approximation. Substituting this latter value in Equation [10a] gives

$$t = [(M_1 + Mn)/\{2\sqrt{(CM)}\}][1 + \sqrt{\{1 + 4s_1C/(P_1q^2)\}}] \quad [11]$$

The distance traveled by the locomotive during the starting period may be expressed as

$$D = s_1n + Aq\sqrt{(M/C)} \quad [12]$$

where A represents the area under the vn curve from the origin to the car number n.

BRAKING A TRAIN

The following equations, governing the braking of a train, apply also, if the proper constants are used, to its behavior during a change in the grade of the track:

A train constant, which is very important since it affects practically every characteristic of a train, is its "propagation ratio" p.

The value of p is computed from the equation

$$p = (t_1/q)\sqrt{(C/M)} \quad [13]$$

Braking a Train Without Free Slack. If the train is bunched when the brakes are applied from the front or stretched when they are applied from the rear, its behavior will correspond to that of a solid elastic bar to which uniformly distributed external forces are serially applied.

It will be different, depending upon whether the propagation ratio is higher than, equal to, or lower than unity and these three cases will therefore be treated separately.

Case 1. Propagation ratio is higher than unity: The relative impact speed between adjacent cars in such a train is zero, since the compression speed between adjacent cars gradually increases from zero.

The time required for the brake application to reach the first car in the train will be designated as t_1, which is also the time interval between the brake application on adjacent cars; hence, the brakes will be applied to car n at the time nt_1. Maximum gear compression and coupler pressure is reached at the time

$$t = 2nt_1/(p + 1) \quad [14]$$

This maximum coupler pressure may be expressed as

$$P_m = 2Fnp/(p + 1)^2 \quad [15]$$

It is located at car number n_2, counted from the locomotive; it is

$$n_2 = 2n/(p + 1) \quad [16]$$

The contraction of the train during the time t is

$$D = (Fq^2n^2/c)(p/[p + 1]^2) \quad [17]$$

Case 2. Propagation ratio is equal to unity:

The maximum coupler pressure amounts to

$$P_m = Fn/2 \quad [18]$$

It occurs at the car number $n_2 = n$, counted from the front end of the train.

The relative car impact speed, due to the instantaneous rise of pressure is

$$v = Fqn/[2\sqrt{(CM)}] \quad [19]$$

The time t required for the coupler pressure and for the force application to reach the end of a train of n cars is

$$t = nt_1 \quad [20]$$

The contraction of the train during the time t is

$$D = Fq^2n^2/(4C) \quad [21]$$

Case 3. Propagation ratio is lower than unity:
The maximum coupler pressure in such a train amounts to

$$P_m = Fnp/2 \quad [22]$$

and occurs at car number n_2 from the front end, expressed as

$$n_2 = n(p + 1)/2 \quad [23]$$

The relative impact speed between adjacent cars is zero. The time t required for the maximum coupler pressure to form may be expressed as

$$t = nt_1(p + 1)/(2p) \quad [24]$$

The contraction of the train at the time t may be expressed as

$$D = Fq^2n^2p/(4C) \quad [24a]$$

Braking a Train With Free Slack. If a train is stretched when the brakes are applied from the front, or bunched when they are applied from the rear, a certain amount of free slack will be taken up during the braking period.

In such a train the conditions will be different, depending upon whether the car under consideration is located:

1 Before the passing point or in a train which has no passing point.
2 At the passing point.
3 Beyond the passing point.

These three cases will be considered separately.

Case 1: Conditions in a train without a passing point or before that point is reached:
The relative car impact speed v at which the car $(n + 1)$ collides with a string of n bunched cars is

$$v = Fnt_1/(2M) \quad [25]$$

The time t' at which the car number $(n + 1)$ collides with the string of n bunched cars is

$$t' = s_1M/(Ft_1) + nt_1(2p + 1)/(3p) \quad [26]$$

According to this equation the time t', plotted against the car number n, is a straight line, beginning at the point $n = 0$, $t' = s_1M/Ft_1$ and rises from the n axis at a slope of $t_1(2p + 1)/(3p)$. For $p = 1$, nt_1 and t' are represented by parallel lines, while for $p < 1$ these lines are divergent and in neither case has the train a passing point.

For $p > 1$ and only in that case, the lines are convergent, and the train has a passing point.

The contraction of the train at the time t' is

$$D = s_1^2M/(2Ft_1^2) + s_1n(2p + 1)/(3p) + [Fn^2t_1^2/(2M)]\left(\frac{1}{9} + \frac{5}{18p} + \frac{1}{9p^2}\right) \quad [27]$$

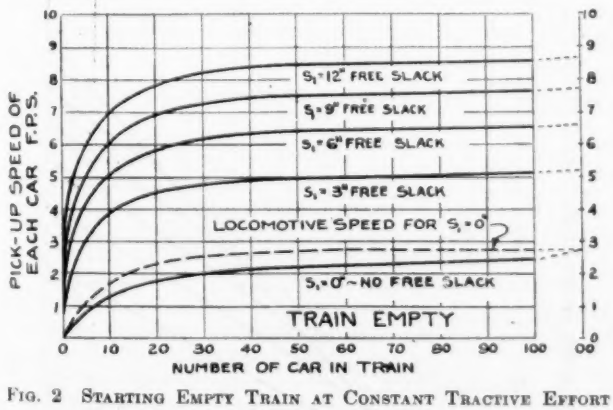

FIG. 2 STARTING EMPTY TRAIN AT CONSTANT TRACTIVE EFFORT

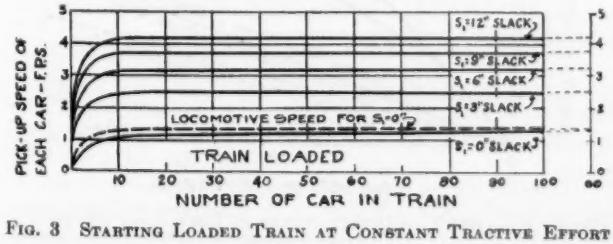

FIG. 3 STARTING LOADED TRAIN AT CONSTANT TRACTIVE EFFORT

Case 2. Conditions in a train at the passing point:
The location of the passing point at car number n_1 is expressed as

$$n_1 = [Ms_1/(Ft_1^2)][3p/(p - 1)] \quad [28]$$

The relative car impact speed v_1 of the number n_1 car is

$$v_1 = (s_1/t_1)[3p/[2(p - 1)]] \quad [29]$$

The time t_2 at which the passing point is reached is

$$t_2 = [s_1M/(Ft_1)][3p/(p - 1)] \quad [30]$$

The contraction of the train at the time t_2 is

$$D_1 = [s_1^2M(Ft_1^2)][3p(4p - 1)/[4(p - 1)^2]] \quad [31]$$

Case 3. Conditions in a train beyond the passing point:
In braked trains with a propagation ratio greater than unity and small or moderate amounts of free slack, and in trains with any reasonable amount of slack, subjected to a change in grade of the track, the car impact point will pass beyond the point of force application and from then on the relative car impact speed v will increase in a much slower tempo.

The relationship between the loss in speed of a group of n bunched cars, assumed to travel at a uniform speed, or their relative collision speed with the car number $(n + 1)$, as yet unretarded, is expressed by the equation

$$dv/dn = \sqrt{[2F/(Mt_1)]}[s_1/\sqrt{(vn)} + (t_1/p)\sqrt{(v/n)}] - v/n \quad [32]$$

The solution of this equation is as yet unknown, and it is therefore necessary to use approximative integration, using the Simpson rule or some equivalent method to construct the nv curve for cars beyond the passing point.

From the origin and up to the passing point n_1v_1 the nv curve is computed from Equation [25] and is thus a straight line. At that point it bends sharply to the slope dv/dn expressed by the equation

$$dv/dn = [Ft_1/M][(p + 2)/(6p)] \quad [33]$$

It can be seen from this equation that all the v-n curves have the same slope at the passing point, regardless of the location of the latter which is governed by the amount of train slack.

The time t' required to bunch a group of n cars may be expressed as

$$t' = nt_1 + s_1A_1/L_1 \quad [34]$$

where A_1 is the area in the $\frac{1}{v}$ n diagram, located between the $\frac{1}{v}$ curve and the n axis, and between the verticals at n_1 and n.

The amount of contraction of the train after the bunching of n cars is

$$D = 3Ms_1/t^2 + s_1n + A(t_1/p) \quad [35]$$

where A is the area in the n-v diagram, located between the v-curve and the n axis and between the verticals n_1 and n.

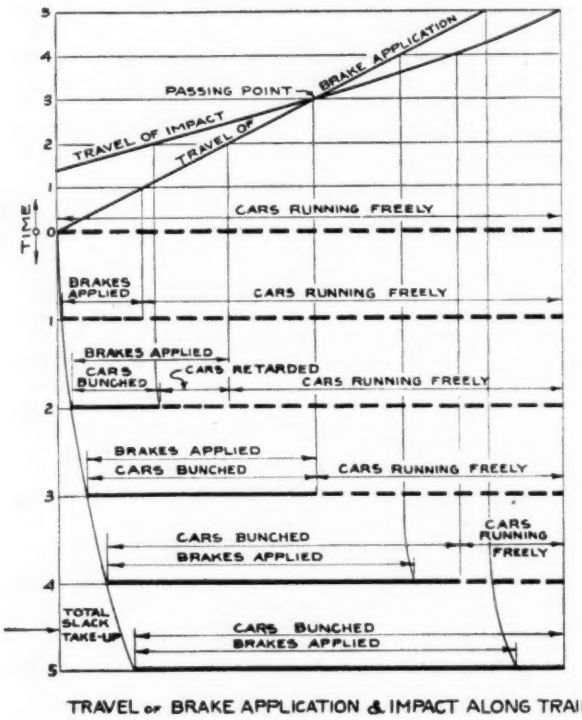

FIG. 4 TRAVEL OF BRAKE APPLICATION AND IMPACT ALONG TRAIN

BRAKE ACTION IN A LONG TRAIN

Fig. 4 illustrates, in diagram form, the conditions under which the brake application and the resulting car impacts proceed in a train with free slack.

The freely running train is represented at the time zero by a horizontal broken line, in which each dash represents a car or a group of cars. Before the application of the brakes, the cars are assumed to be moving uniformly toward the left. The brakes are applied aerially from the front of the train.

The forward motion of the train as a whole is not shown.

The conditions of the train after the periods of time, represented by the horizontals 1 to 5 above the zero line, are shown on the horizontal train diagrams below the zero time line, designated by the same numbers.

Fig. 4 represents a case where the propagation ratio of the train is $p > 1$ and the two inclined diagram lines intersect at the "passing point."

If $p = 1$ these lines are parallel, if $p < 1$ they are divergent, and in neither case has the train a passing point.

CRITICAL TRAIN SLACK

Beyond the passing point, the impact speed v increases at a slower rate and the critical slack, defined as the amount of free plus residual slack per coupling, which will place the passing point at the end of the train therefore produces the highest possible car impact speed.

In a train of n cars, the critical slack s_2 may be computed from Equation [28] by substituting $s_2 = s_1$ and $n = n_1$

$$s_2 = [Ft^2n/(3M)]/[(p-1)/p] \quad \ldots\ldots\ldots\ldots [36]$$

In cases where p is equal to or smaller than unity, s_2 is infinite, and the car impact speed is entirely independent of the amount of free or residual slack in the train.

APPLICATION OF EQUATIONS

The use of the equations will be illustrated by a few examples, in which they will be applied to assumed test trains made up of identical cars. The following values are given:

C = capacity of one draft gear, 26,300 ft-lb
g = total travel of each gear = 0.219 ft (= $2^5/_8$ in.)
F = external force acting on each car during emergency-brake application
= 7500 lb, when type K brake is used
= 3750 lb, when type AB brake is used as an initial application, which has the main purpose of bunching a stretched train before the full retarding force of 7500 pounds is applied
M = mass per car
= 1550 for empty car weighing 50,000 lb
= 6500 for loaded car weighing 210,000 lb
M_1 = mass of locomotives and tender
= 17,100 for a combined weight of 550,000 lb
P_1 = tractive effort of locomotive, = 80,000 lb
P = drawbar pull of locomotive, lb
t_1 = time between emergency-brake application on adjacent cars, sec
= 0.092 sec for type K brake
= 0.0612 sec for type AB brake

Example 1. A locomotive of constant drawbar pull starts a stretched train:

In this case the pickup speed v of the individual cars is constant during the whole starting period and can be computed from Equation [2].

For the empty test train, it is represented in Fig. 1, by the vertical OA. For the loaded one it is represented by the vertical OB in the same figure.

Example 2. A locomotive of constant tractive effort starts a stretched train:

In this case the speed v of the locomotive at the time of starting of each individual car is different, depending upon the car number

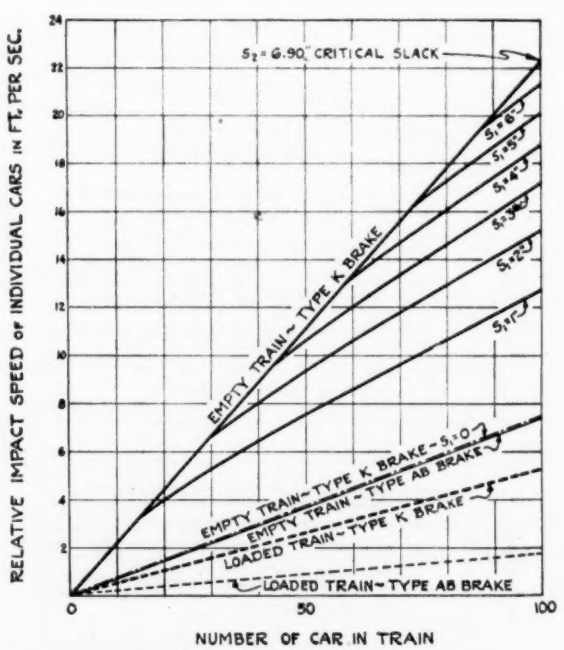

FIG. 5 RELATIVE CAR IMPACT SPEEDS IN EMERGENCY BRAKING OF LONG TRAINS

n counted from the locomotive, and may be computed from Equation [5a].

For the empty train, this speed is represented in Fig. 2 by the dotted curve marked "locomotive speed" for $s_1 = 0$. For the loaded train it is represented by the corresponding dotted curve in Fig. 3.

Example 3. A locomotive of constant drawbar pull starts a train with free slack:

For a given train slack, the pick-up speed of the individual car is constant during the entire starting period and can be computed from Equation [7].

The computed car impact speeds for the empty and loaded test trains are plotted in Fig. 1, against the amount of free plus residual slack per coupling. It will be seen from the curves that the constant pickup speed v of the individual cars in empty as well as in loaded trains increases sharply with the amount of free and residual slack between the individual cars.

Fig. 1 shows that the pickup speed of the loaded train is only about one half that of the empty one, but the mass of the individual car is about 4 times larger, and thus the impact energies of the individual cars are the same regardless of whether the cars are loaded or empty.

Example 4. A locomotive of constant tractive effort starts a train with free slack:

Referring to Fig. 2, the pickup speeds of the individual cars, from 1 to 100 in the empty train have been computed from Equation [10], and for various values of the free plus residual slack s_1 from 0 to 12 in. per coupling under the assumption that the tractive effort P_1 of the locomotive is constant.

It is seen that these curves, rising from zero at the first car, rapidly approach horizontal asymptotes, which latter represent the pickup speeds of all the cars in the train under the assumption of a constant drawbar pull P_1 equal to the tractive effort of the locomotive.

It will be seen that beyond car 50, the computed pickup speed would be practically the same regardless of whether the train were started with a constant drawbar pull or an equal constant tractive effort.

Example 5. Computation of the propagation ratios during emergency braking of the assumed test trains:

By substituting the proper constants in Equation [13], the values of p, listed in Table 1, are obtained.

TABLE 1 PROPAGATION RATIOS p FOR VARIOUS TEST TRAINS

	Type K brake	Type AB brake
Empty train, p =	1.73	1.155
Loaded train, p =	0.845	0.563

Example 6. Relative car impact speeds:

How to compute the relative car impact speeds of all the cars in a 100-car train in case of emergency braking from the front.

(*a*) *Empty Train, Type K Brakes.* In all the empty trains, the relative car impact speeds before the passing point are independent of the draft-gear characteristics and are located on the straight line through the origin defined by Equation [25].

The location of the passing point on this line at car n_1 and the corresponding relative car impact speed v_1 are determined by Equations [28] and [29], respectively.

The relative impact speeds of the cars beyond the passing point are governed by the differential Equation [32].

Fig. 5 shows in heavy full lines the nv curves of the empty train with type K brakes for various values of the free plus residual slack s_1 up to its critical value, $s_2 = 6.90$ in., the latter to be computed from Equation [36].

The curves beyond the passing point were constructed by approximative integration from Equation [32], using a method similar to the Simpson rule.

(*b*) *Loaded Trains, Type K Brakes.* For these trains the propagation ratio is less than unity, as shown in Table 1. The relative car impact speeds v are therefore independent of the amount of free plus residual slack per coupling s_1 and may be computed from Equation [25]. They are shown in heavy dotted lines in Fig. 5.

Example 7. Computation of the propagation ratios for a train passing through a change in the grade of slack:

Let us assume that the test trains coast at a speed of 40 mph and are subjected to a change in grade of 4 per cent.

The gravitational forces will produce a change in force per car equal to 4 per cent of its weight, and therefore

$$F = 0.04 \times 50{,}000 = 2000 \text{ lb for empty cars and}$$
$$= 0.04 \times 210{,}000 = 8400 \text{ lb for loaded cars}$$

The time t_1 between force applications on adjacent cars at a train speed of 40 mph (= 58.6 fps) and for a car length of 50 ft is

$$t_1 = 50/58.6 = 0.852 \text{ sec}$$

Substituting these constants in Equation [13], the propagation ratios are found to be recorded as follows:

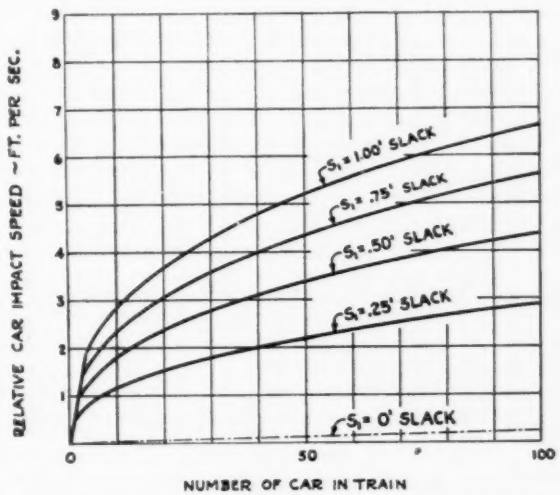

FIG. 6 RELATIVE CAR IMPACT SPEEDS IN EMPTY TRAINS RUNNING THROUGH DIP IN TRACK AT 40 MPH, 4 PER CENT CHANGE IN TRACK GRADE

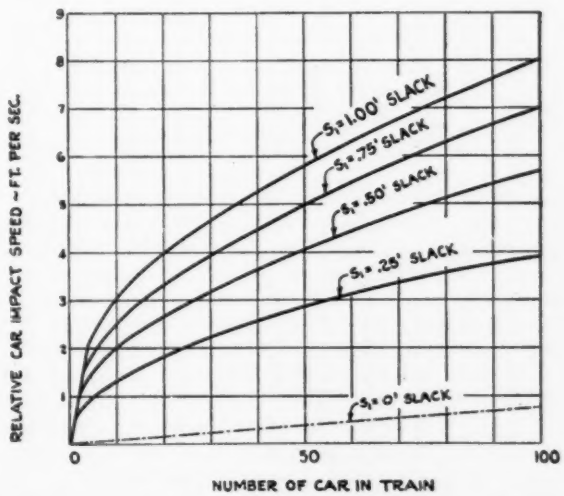

FIG. 7 RELATIVE CAR IMPACT SPEEDS IN LOADED TRAINS RUNNING THROUGH DIP IN TRACK AT 40 MPH, 4 PER CENT CHANGE IN TRACK GRADE

TABLE 2

In empty trains, $p = 16.1$
In loaded trains, $p = 7.83$

Example 8. Relative car impact speeds:

This covers the computation of the relative car impact speeds of all cars in the test trains when passing through a 4 per cent dip at a train speed of 40 mph for different values of the free plus residual slack per coupling. For all the cars before the passing point, these speeds are located on the straight line through the origin, defined by Equation [25]. The locations of the passing points on this line are computed from Equations [28] and [29] and are plotted in Fig. 6.

The nv curves for empty and loaded trains beyond the passing point were computed by approximate integration from Equation [33] and plotted in Fig. 6 for empty trains, and in Fig. 7 for loaded trains.

Energy Intake and Gear Reaction

The foregoing equations and examples refer mostly to gear reactions in trains without free or residual slack, and to relative car impact speeds in trains with free and residual slack. A few remarks regarding the relationship of car impact speeds to energy intake and gear reaction are therefore indicated.

If two cars, each of the mass M, collide at the relative impact speed v, their draft gears will be compressed until the car speeds are equalized. At that time one of the cars will have gained and the other one will have lost a speed, equal to $v/2$ and, disregarding the elasticity of the car bodies, the energy taken up by each of the two coacting gears is, therefore

$$(1/2)M(v/2)^2 = Mv^2/8$$

Likewise, if a single car strikes a group of cars and if the draft gears of the struck cars were fully expanded before the impact occurred, the same relative impact speed v will cause the same energy intake per gear as just given.

If, however, a car strikes a group of bunched cars with fully compressed draft gears, the relative kinetic energy of the moving car, amounting to $Mv^2/2$, will be taken up by the two impacting gears, each taking up the energy $Mv^2/4$.

In the latter case and if the draft gears have a capacity of C ft-lb and a total travel of q ft, the gear reaction P produced by the energy intake of $Mv^2/4$ would be the one given in Equation [2].

Instead of computing the gear reaction from this equation and since most draft gears do not have a straight compression line, it is recommended to use a curve, obtained by laboratory test, where the gear reaction, as established by drop test, is plotted against the energy intake of the gear.

Draft-Gear Recoil

The foregoing equations as well as the curves plotted from the computations in the various examples show, and practical experience confirms, that free and residual slack increases the relative car impact speeds, and causes undesirably high gear reactions in a train, during starting, braking, and passing over changes in the grade of the track.

The free slack is mainly composed of clearances in couplers and draft-gear attachments, and is therefore largely beyond the control of the draft-gear designer.

The residual slack, which is equally undesirable, is caused by sticking draft gears and by gears of insufficient recoil energy to expand a partly or fully compressed train or to contract a partly or fully stretched one.

It is therefore desirable to design draft gears with ample recoil energy so as to prevent sticking and reduce the residual slack.

It is also desirable to design them with high initial recoil force in order to reduce the residual slack, even after comparatively light train compressions.

The author is indebted to the Edgewater Steel Company for sponsoring this investigation; to Mr. L. H. Fry for deriving some of the more important equations by a different method, thus checking the validity of the elastic-bar method; and to Dr W. M. Dudley for helpful suggestions.

Temperature Distribution Within Boiler Tubing Under Oblique Radiation

By W. S. KIMBALL,[1] ANNAPOLIS, MD.

The surface and interior temperature distribution in a section of boiler tubing under normal symmetric radiation from the furnace has been investigated by G. M. Dusinberre and others, and reported on in a discussion of data furnished by W. F. Davidson.[2] In the same issue such problems in heat conduction are also treated by Paschkis[3] using the method of electrical analogy, and by Emmons[4] using the numerical method of obtaining approximate solutions; and in the reported discussion of the latter Dusinberre points out that the numerical method, carried out to the needed accuracy, checks the analytical solution and results are obtained with greater ease. The analytical method of Fourier, previously confined to the symmetric case of normal radiation, is here extended to the unsymmetric case where radiation from the fire is received obliquely and with consequent shadowing effect from adjoining tubes. An advantage of this investigation is that it supplies a general mathematical expression for temperature distribution under parallel radiation received at any angle with the boiler wall normal, thus affording a check on results that sometimes may be obtained easier by other methods. A further advantage is that this general mathematical expression makes it fairly easy to compare temperature gradients and hence rates of the heat transfer as done herein for various obliquity angles of received radiation.

IN the present study of temperature distribution in boiler tubing, it is assumed that interface resistance and external convection and conduction are negligible. These assumptions are in line with the conclusions of the authors mentioned, when conduction is ruled out by having insulated refractory backing at practically tube-surface temperature. Thus no heat transfer across the outer tube surface occurs except by radiation.

It is further assumed, as formerly, that a tube receives radiation uniformly per unit projected area as from a distant source. For symmetric radiation previously treated this leads to the temperature-slope condition at the outer tube surface

$$\frac{\partial T}{\partial r} = \frac{Q}{K} \cos \theta$$

where θ is the angle between the received radiation and the tube surface normal. For oblique radiation now treated, the foregoing condition is replaced by condition, Equation [3] with $\theta - \beta$ in place of θ, since β measures the obliquity of the radiation.

The general temperature expression here derived includes the special symmetric case where the obliquity angle is zero and the received radiation comes in normal to the boiler wall with formula given by Equation [13] of the Davidson paper[2] and graphed in his Fig. 48. In all cases herein parallel radiation is assumed,[5] making a given obliquity angle β with the boiler wall normal, and the wall is made up of cylindrical tubes in contact.

This new general temperature expression is here studied for a series of obliquity angles for the received radiation. With all of these, the surface exposed to radiation is reduced by shadowing of adjoining tubes below the 180 deg exposure, or semicircumference opposite the fire for normal radiation.

Special attention and graphs are given for four typical cases, (*a*) where 120 deg of tube surface is exposed to radiation of exactly three quarters of the amount of normal heat radiation, (*b*) where 90 deg of tube surface is exposed, receiving exactly one half the amount of normal radiation per tube, (*c*) where 60 deg of tube surface is exposed, receiving exactly one quarter of the normal radiation per tube, and (*d*) where 30 deg of tube surface is exposed, receiving one fifteenth of the normal radiation.

For the 120-deg exposure or two thirds the normal, the radiation comes in at an obliquity angle of 41°25′ with the boiler wall normal. For 90 deg or one half the normal exposure to radiation, the radiant heat comes in at a 60 deg angle of obliquity with the boiler wall normal, and for a 60-deg tube exposure or one third the normal, the radiation comes in at a 75°30′ angle with the boiler wall normal. When only 30 deg or one sixth of the tube surface is exposed, the radiation comes at an angle of 86 deg with the boiler wall normal, being only 4 deg short of the grazing angle of tangency with the wall, with the amount of received radiation one fifteenth that of the normal radiation per tube.

The temperature graphs show that the hot point of highest temperature is not where the oblique radiation comes in normal to the tube surface, but is shifted back toward the symmetric point opposite the fire cavity where the tube surface parallels the boiler wall, and where the hot point would be in case of radiation normal to the boiler wall. This hot-point shift occurs in the direction of the geometrical center of the received radiation, as is to be expected.

A most interesting result is the way the temperature gradient or difference between outer and inner tube-surface temperatures falls off with increased angle of obliquity, assuming the same density of radiation. Where the received radiation is three quarters the normal radiation, and comes at a 41-deg angle with 120 deg of tube surface exposed to it, there is only a 2 per cent drop in temperature gradient, the distribution being merely shifted around the tube in the direction of the received radiation.

When one half the normal radiation is received over 90 deg of exposed surface, coming in at 60 deg to boiler wall normal, there is a 14 per cent loss in the temperature gradient, and when only one quarter of normal radiation is received over one third as much tube surface exposed (60 deg), then the loss in temperature drop is 50 per cent, as compared with that for normal radiation.

[3] Ibid., p. 587, discussion by V. Paschkis.

[4] "The Numerical Solution of Heat-Conduction Problems," by H. W. Emmons, Trans. A.S.M.E., vol. 65, 1943, pp. 607–612.

Contributed by the Heat Transfer Division and presented at the Spring Meeting, Birmingham, Ala., April 3–5, 1944, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[5] See reference 2, Appendix, p. 581, Max Jakob.

And when about one fifteenth the normal radiation is received at only 4 deg short of grazing angle with 30 deg of exposed surface (one sixth of the normal), then the temperature drop is about 15 per cent of normal radiation, representing an 85 per cent reduction in gradient.

These results indicate that the ease or efficiency with which heat is disposed of decreases with increased obliquity angle, since the shortage of heat supplied from the fire falls off with increasing obliquity angle much faster than the corresponding temperature gradients.

A further point to be noted is that the sum of these temperature expressions as solutions of Laplace's equation is still such a solution and would represent a physical situation corresponding to a superposition of the conditions they separately represent, likewise, if different values of Q, the normal heat flux per unit area, were used for the various cases. Thus any condition equivalent to and separable into two or more cases of parallel radiation acting in unison could be represented by a temperature expression given by the sum of such series as here shown.

Nomenclature

The following nomenclature will be used in succeeding sections of the paper:

T = temperature
T_0 = temperature at inner tube radius $r_0 (= 0$, for convenience)
r = radial distance from tube center
θ = angle measured from an axis normal to boiler wall and extending into fire
r_0 = inside radius of boiler tube
r_1 = outside radius of boiler tube
Q = maximum heat flux at r_1, i.e. the density of radiant heat
K = thermal conductivity of metal
β = angle between boiler wall normal and direction of oblique radiation
γ = shadow angle, measuring from boiler wall, the extent of tube surface that receives no radiation owing to shadow from the adjoining tube (see Fig. 1).
$\pi - \beta - \gamma = \pi - 2\alpha$ = angular range of received radiation on a tube
$\alpha = \dfrac{\beta + \gamma}{2}$ = auxiliary angle, measuring one half reduction in angular range from π, corresponding to normal radiation
$\phi = \theta - \dfrac{\beta - \gamma}{2} = \theta - (\beta - \alpha)$ = position angle measured from the mid-point, $\beta - \gamma/2$ of angular range exposed to oblique radiation (see Fig. 1)
$\rho = \dfrac{r}{r_0}$ = dimensionless ratio for radial distance r
$\rho_1 = \dfrac{r_1}{r_0}$ = dimensionless ratio at outer tube radius r_1 (= 1.5 throughout this paper)
A_m, B_m, A'_m, B'_m are Fourier constant coefficients evaluated later

Assumptions and Boundary Conditions

Three basic assumptions are made as follows

$$T_0 = \text{constant } (= 0) \qquad [1]$$

at inner boundary where $r = r_0$ which implies negligible interface resistance at the inside of the tube in contact with the steam.

$$\left(\frac{\partial T}{\partial r}\right)_{r=r_1} = 0 \qquad [2]$$

for $$\left(\frac{\pi}{2} - \gamma\right) < \theta < \left(\frac{3\pi}{2} + \beta\right)$$

Condition Equation [2] says there is no heat transfer across the entire outer boundary where $r = r_1$ except where radiation is received between angles β and γ shown in Fig. 1. The back part is assumed to be insulated and the part of the circumference toward the fire that receives no radiation is assumed to be in equilibrium with the surroundings.

The third basic assumption gives the condition for absorption of radiant energy, as follows

$$\left(\frac{\partial T}{\partial r}\right)_{r=r_1} = \frac{Q}{K}\cos(\theta - \beta) \qquad [3]$$

for $$-\left(\frac{\pi}{2} - \beta\right) < \theta < \left(\frac{\pi}{2} - \gamma\right)$$

This condition refers to parallel radiation of uniform density received on the tube surface at angle $\theta - \beta$ with the tube surface

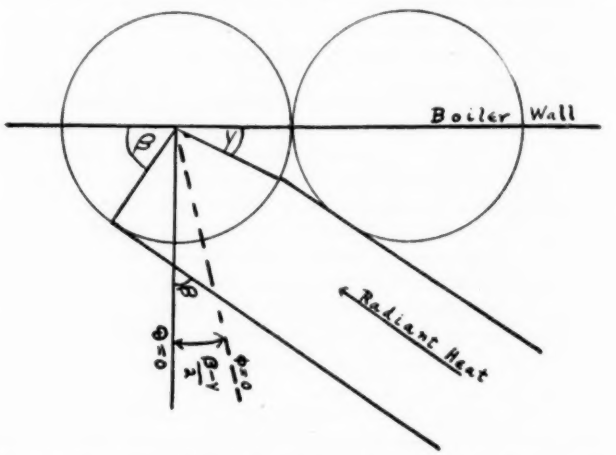

Fig. 1 Obliquity Angle β, Shadow Angle γ, and Mid-Point $\theta = \dfrac{\beta - \gamma}{2}$ of Surface Exposed to Oblique Radiation

normal. Unit cross section of radiation will be spread over an area equal to sec $(\theta - \beta)$ so that the fraction of Q, the radiation density that is conducted away through unit surface area, will be reduced by this same proportion according to Equation [3].

When conditions, Equations [2] and [3], are referred to the angle ϕ and constant angle α which are symmetric about the dotted center line $\phi = 0$ of exposed tube surface, shown in Fig. 1, Equations [2] and [3] take a symmetric form adapted to computation of the Fourier coefficients.

$$\left(\frac{\partial T}{\partial r}\right)_{r=r_1} = 0 \qquad [4]$$

for $$\left(\frac{\pi}{2} - \alpha\right) < \phi < \left(\frac{3\pi}{2} + \alpha\right)$$

$$\left(\frac{\partial T}{\partial r}\right)_{r=r_1} = \frac{Q}{K}\cos(\phi - \alpha) = \frac{Q}{K}(\cos\alpha\cos\phi + \sin\alpha\sin\phi) \qquad [5]$$

for $$-\left(\frac{\pi}{2} - \alpha\right) < \phi < \left(\frac{\pi}{2} - \alpha\right)$$

Relation Between Obliquity Angle β, and Shadow Angle γ

The relation between the obliquity of radiation β and the shadow angle γ is most easily obtained by applying the law of sines to the triangle made by extending the straight-line tangent to the right-hand circle in Fig. 1, until it hits the line of centers of the two circles. We then have

$$\cos(\beta + \gamma) = 2\cos\beta - 1 = \cos 2\alpha \quad \ldots\ldots\ldots\ldots\ldots [6]$$

where on the right the symmetric auxiliary angle α is introduced, defined according to the nomenclature. This relation is essential to obtaining the graphs which follow. Note $\cos^2\alpha = \cos\beta$.

Temperature Within a Boiler Tube Under Oblique and Normal Radiation

Expressions for the temperature within a boiler tube under radiation are obtained by solving Laplace's equation and computing the Fourier coefficients in the usual way. When the exposed surface includes the angular range $\pi - 2\alpha = \pi - \beta - \gamma$, according to the nomenclature, we have in terms of α and the ratios $\rho = \frac{r}{r_0}$ and $\rho_1 = \frac{r_1}{r_0}$ of the radii

$$\left.\begin{aligned} T = \frac{Qr_1}{\pi K}\Bigg[& \cos^2\alpha \log\rho + \frac{\rho_1}{2\rho}\left(\frac{\rho^2-1}{\rho_1^2+1}\right)\Big\{(\pi - 2\alpha \\ & - \sin 2\alpha)\sin\alpha\sin\phi + (\pi - 2\alpha + \sin 2\alpha)\cos\alpha\cos\phi\Big\} \\ & + \frac{\rho_1^2}{6\rho^2}\left(\frac{\rho^4-1}{\rho_1^4+1}\right)\Big\{(3\cos\alpha + \cos 3\alpha)\sin\alpha\sin 2\phi \\ & + (3\cos\alpha - \cos 3\alpha)\cos\alpha\cos 2\phi\Big\} \\ & + \frac{\rho_1^3}{12\rho^3}\left(\frac{\rho^6-1}{\rho_1^6+1}\right)\Big\{(2\sin 2\alpha + \sin 4\alpha)\sin\alpha\sin 3\phi \\ & + (2\sin 2\alpha - \sin 4\alpha)\cos\alpha\cos 3\phi\Big\} \\ & - \frac{\rho_1^4}{60\rho^4}\left(\frac{\rho^8-1}{\rho_1^8+1}\right)\Big\{(5\cos 3\alpha + 3\cos 5\alpha)\sin\alpha\sin 4\phi \\ & + (5\cos 3\alpha - 3\cos 5\alpha)\cos\alpha\cos 4\phi\Big\} + \ldots\ldots\ldots \end{aligned}\right\} \ldots [7]$$

The most important special case of Equation [7] occurs when the radiation is normal to the boiler wall and the angular range of exposed tube surface is 180°, with obliquity angle $\beta = 0$. We see from Equation [6] and Fig. 1, that in this case angles α and γ are also zero, hence $\sin\alpha = 0$ and $\cos\alpha = 1$, and likewise with the sines and cosines of all multiples of α. Hence Equation [7] reduces to

$$T = \frac{Qr_1}{\pi K}\left[\log\rho + \frac{\pi\rho_1}{2\rho}\left(\frac{\rho^2-1}{\rho_1^2+1}\right)\cos\theta + \frac{\rho_1^2}{3\rho^2}\left(\frac{\rho^4-1}{\rho_1^4+1}\right)\cos 2\theta - \frac{\rho_1^4}{30\rho^4}\left(\frac{\rho^8-1}{\rho_1^8+1}\right)\cos 4\theta + \frac{\rho_1^6}{105\rho^6}\left(\frac{\rho^{12}-1}{\rho_1^{12}+1}\right)\cos 6\theta + \ldots\right] [8]$$

This is the same temperature expression as given by Equation [13] in the appendix of the Davidson paper[2] and graphed there in Fig. 48. Equation [8] herewith is expressed in terms of the dimensionless variable $\rho = \frac{r}{r_0}$ and constant $\rho_1 = \frac{r_1}{r_0}$ instead of the r's, thus checking the previous result.

Temperature Distribution Under Radiation of 41°25′ Obliquity and 120° of Exposed Tube Surface With Three Quarters of the Heat Supply of Normal Radiation and 2 Per Cent Loss of Temperature Gradient

The angular range (see nomenclature) determines α

$$\pi - 2\alpha = \frac{2}{3}\pi, \text{ therefore } \alpha = \frac{\pi}{6} = 30 \text{ deg}$$

Hence from Equation [6]

$$\cos\beta = \frac{3}{4}; \quad \beta = 41°\,25'$$

$$\gamma = 18°35'$$

and the mid-point of the angular range of exposed radiation (nomenclature) is

$$\theta_0 = \beta - \alpha = 11°25'$$

where $\phi = 0$.

Since Q, the radiation density, is the same as for normal radiation, and since the entire beam of received radiation is for 120 deg of exposed surface, just $^3/_4$ the breadth of the normal radiation beam, we see that the total heat supplied is exactly $^3/_4$ of that supplied under normal radiation.

Using $\alpha = \frac{\pi}{6}$ in Equation [7] gives the formula for this distribution

$$\left.\begin{aligned} (a)\quad T = \frac{Qr_1}{\pi K}\Bigg[& \frac{3}{4}\log\rho + \frac{\rho_1}{4\rho}\left(\frac{\rho^2-1}{\rho_1^2+1}\right)\Big\{\Big(\frac{2}{3}\pi \\ & - \frac{\sqrt{3}}{2}\Big)\sin\phi + \Big(\frac{2}{3}\pi + \frac{\sqrt{3}}{2}\Big)\sqrt{3}\cos\phi\Big\} \\ & + \frac{\rho_1^2}{8\rho^2}\left(\frac{\rho^4-1}{\rho_1^4+1}\right)\Big(\sqrt{3}\sin 2\phi + 3\cos 2\phi\Big) \\ & + \frac{\rho_1^3}{16\rho^3}\left(\frac{\rho^6-1}{\rho_1^6+1}\right)\Big(\sqrt{3}\sin 3\phi + \cos 3\phi\Big) \\ & + \frac{\rho_1^4}{80\rho^4}\left(\frac{\rho^8-1}{\rho_1^8+1}\right)\Big(\sqrt{3}\sin 4\phi - 3\cos 4\phi\Big) + \ldots\ldots \end{aligned}\right\} \ldots [9]$$

Temperature Distribution Under Radiation of 60 Deg Obliquity and 90 Deg of Exposed Tube Surface With One Half the Heat Supply of Normal Radiation and 14 Per Cent Loss of Temperature Gradient

Angle α is determined by the exposed angular range

$$\pi - 2\alpha = \frac{\pi}{2}; \quad \alpha = \frac{\pi}{4} = 45°$$

Hence from Equation [6]

$$\cos\beta = \frac{1}{2}; \quad \beta = 60°$$

$$\gamma = 30°$$

and the mid-point of angular range exposed to radiation is

$$\theta_0 = \beta - \alpha = 15°$$

where $\phi = 0$.

With the same radiation density Q as before and one half the breadth of the beam, we have exactly one half the heat supply. We note that the hot point is now at only 86 per cent of the 100 deg taken as a comparison standard, being the temperature drop for the hot point under normal radiation. The hot point here

is no longer under the radiation that hits the tube normally at $\theta = 60$ deg because this is the outer edge of the radiation beam, but is shifted some 25 deg or 30 deg toward the center of the radiation beam.

The formula for this distribution is given by Equation [7] using $\alpha = \frac{\pi}{4}$

$$(b)\quad T = \frac{Qr_1}{\pi K}\left[\frac{1}{2}\log\rho + \frac{\rho_1\sqrt{2}}{4\rho}\left(\frac{\rho^2-1}{\rho_1^2+1}\right)\left\{\left(\frac{\pi}{2}-1\right)\sin\phi + \left(\frac{\pi}{2}+1\right)\cos\phi\right\}\right.$$
$$+ \frac{\rho_1^2}{6\rho^2}\left(\frac{\rho^4-1}{\rho_1^4+1}\right)(\sin 2\phi + 2\cos 2\phi)$$
$$+ \frac{\sqrt{2}\rho_1^3}{12\rho^3}\left(\frac{\rho^6-1}{\rho_1^6+1}\right)(\sin 3\phi + \cos 3\phi)$$
$$\left. + \frac{\rho_1^4}{60\rho^4}\left(\frac{\rho^8-1}{\rho_1^8+1}\right)(4\sin 4\phi + \cos 4\phi) + \ldots\right] \quad \ldots [10]$$

TEMPERATURE DISTRIBUTION UNDER RADIATION OF 75°30′ OBLIQUITY AND 60° OF EXPOSED TUBE SURFACE WITH ONE QUARTER OF THE HEAT SUPPLY OF NORMAL RADIATION AND 50 PER CENT LOSS OF TEMPERATURE GRADIENT

Angle α is determined by the exposed angular range

$$\pi - 2\alpha = \frac{\pi}{3} = 60° = \alpha$$

Hence from Equation [6]

$$\cos\beta = 1/4;\ \beta = 75°30'$$
$$\gamma = 44°30'$$

and the mid-point of the angular range exposed to radiation is

$$\theta_0 = \beta - \alpha = 15°30' \text{ where } \phi = 0$$

The temperature distribution of Fig. 4 is given by using $\alpha = \frac{\pi}{3}$ in Equation [7]

$$T = \frac{Qr_1}{\pi K}\left[\frac{1}{4}\log\rho + \frac{\rho_1}{4\rho}\left(\frac{\rho^2-1}{\rho_1^2+1}\right)\left\{\left(\frac{\pi}{\sqrt{3}}-\frac{3}{2}\right)\sin\phi\right.\right.$$
$$\left.+\left(\frac{\pi}{3}+\frac{\sqrt{3}}{2}\right)\cos\phi\right\} + \frac{\rho_1^2}{24\rho^2}\left(\frac{\rho^4-1}{\rho_1^4+1}\right)(\sqrt{3}\sin 2\phi$$
$$+ 5\cos 2\phi) + \frac{\rho_1^3}{16\rho^3}\left(\frac{\rho^6-1}{\rho_1^6+1}\right)(\sin 3\phi + \sqrt{3}\cos 3\phi)$$
$$\left. + \frac{\rho_1^4}{240\rho^4}\left(\frac{\rho^8-1}{\rho_1^8+1}\right)(7\sqrt{3}\sin 4\phi + 13\cos 4\phi) + \ldots\right] \quad \ldots [11]$$

TEMPERATURE DISTRIBUTION UNDER RADIATION OF 86°10′ OBLIQUITY, RECEIVED OVER 30° OF EXPOSED TUBE SURFACE ABSORBING ONLY ONE FIFTEENTH OF THE NORMAL RADIATION, AND WITH TEMPERATURE GRADIENT 15 PER CENT OF THE GRADIENT UNDER NORMAL RADIATION

The angular range determines angle α

$$\pi - 2\alpha = \frac{\pi}{6};\ \alpha = \frac{5}{12}\pi = 75°$$

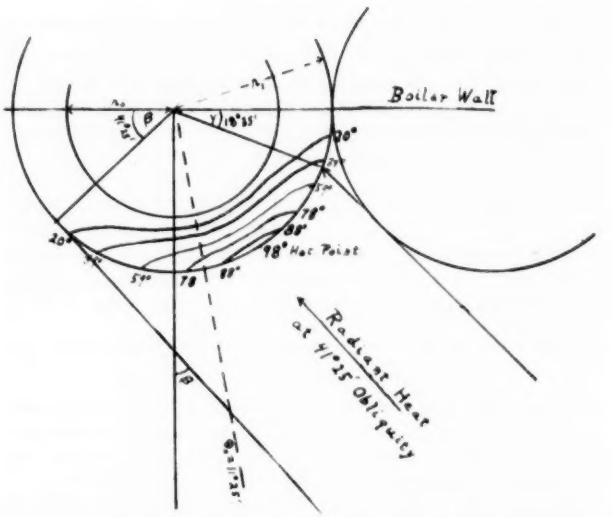

FIG. 2 RADIATION AT 41°25′ OBLIQUITY, OF THREE QUARTERS THE AMOUNT, AND RECEIVED BY TWO THIRDS THE SURFACE EXPOSED TO NORMAL RADIATION

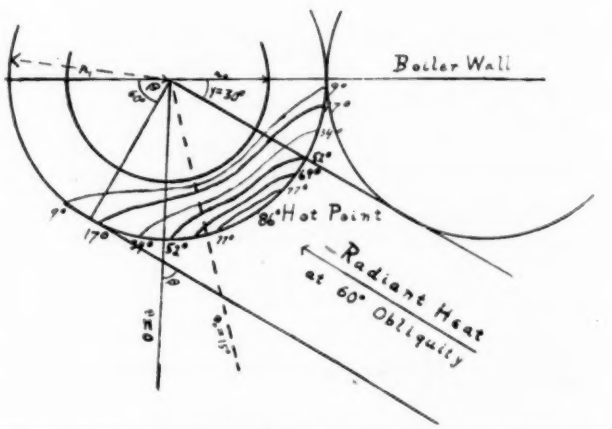

FIG. 3 RADIATION AT 60 DEG OBLIQUITY, OF ONE HALF THE AMOUNT, AND RECEIVED BY ONE HALF THE SURFACE EXPOSED TO NORMAL RADIATION

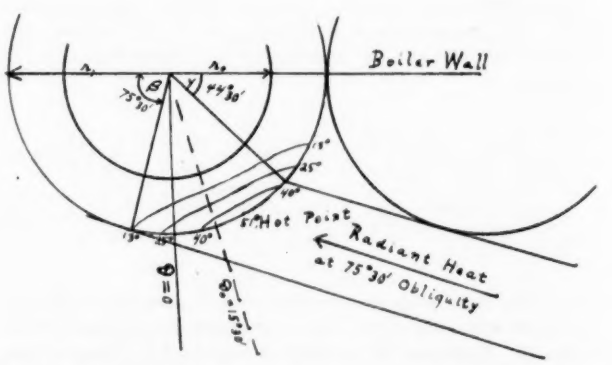

FIG. 4 RADIATION AT 75°30′ OBLIQUITY, OF ONE QUARTER THE AMOUNT, AND RECEIVED BY ONE THIRD THE SURFACE EXPOSED TO NORMAL RADIATION

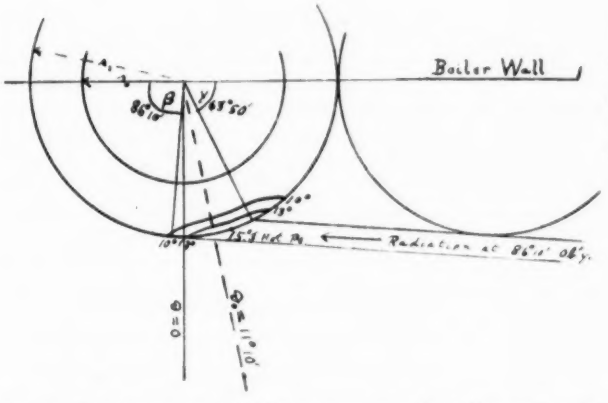

FIG. 5 RADIATION AT 86°10′ OBLIQUITY, OF ONE FIFTEENTH THE AMOUNT, AND RECEIVED BY ONE SIXTH THE SURFACE EXPOSED TO NORMAL RADIATION

Hence from Equation [6]

$$\cos \beta = 0.067; \ \beta = 86°10'$$
$$\gamma = 63°50'$$

and the center line of the exposed surface is at

$$\theta_0 = \frac{\beta - \gamma}{2} = 11°10'$$

where $\phi = 0$.

The temperature expression for the foregoing distribution comes from introducing $\alpha = 75$ deg in Equation [7]

$$T = \frac{Qr_1}{\pi K}\left[0.067 \log \rho + \frac{1}{4}\frac{\rho_1}{\rho}\left(\frac{\rho^2 - 1}{\rho_1^2 + 1}\right)\right.$$
$$\left\{\left(\frac{\pi}{3} - 1\right)0.9659 \sin \phi + \left(\frac{\pi}{3} + 1\right)0.2588 \cos \phi\right\}$$
$$+ \frac{\rho_1^2}{6\rho^2}\left(\frac{\rho^4 - 1}{\rho_1^4 + 1}\right)(0.0657 \sin 2\phi + 0.3294 \cos 4\phi) \quad \left.\right\} \ldots [12]$$
$$+ \frac{\rho_1^3}{12\rho^3}\left(\frac{\rho^6 - 1}{\rho_1^6 + 1}\right)(0.129 \sin 3\phi + 0.4829 \cos 3\phi)$$
$$\left. + \frac{\rho_1^4}{60\rho^4}\left(\frac{\rho^8 - 1}{\rho_1^8 + 1}\right)(0.616 \sin 4\phi + 1.65 \cos 4\phi) + \ldots\right]$$

HEAT TRANSFER PER DEGREE OF TEMPERATURE DROP AS A FUNCTION OF OBLIQUITY ANGLE

The radiant heat transfer per unit tube length is evidently $H_0 = 2r_1Q$ for the normal radiation case where $2r_1$ is the breadth of the beam and Q is its density or heat flux per unit cross section. In case heat comes obliquely, the total amount received per tube is seen to be $H = H_0 \cos \beta$ since the breadth of the beam received by a tube is now $2r_1 \cos \beta$. Note that when only one fourth the normal radiation is received (Fig. 4) over one third the normal receiving area, the temperature drop is only one half that for normal radiation, showing that the heat disposed of per degree of temperature drop between outer and inner tube is one half as great for 75 deg obliquity of radiation as for normal radiation, due possibly to less cramped (from adjoining beams) means of heat disposal. This result, for various obliquity angles, may be graphed most conveniently by plotting H/T against cos β. Thus, in Fig. 6 the ordinate is heat transfer per tube per temperature drop between outer and inner tube since $\Delta T = T - T_0 = T$ taking $T_0 = 0$ according to the nomenclature.

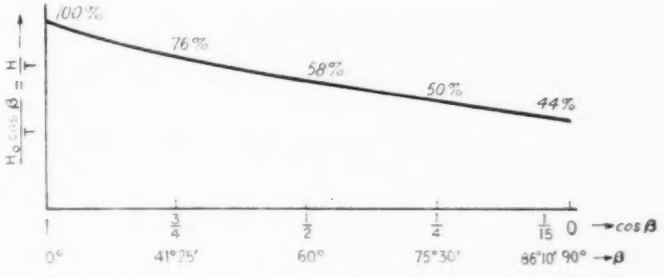

FIG. 6 DECREASE IN HEAT TRANSFER PER DEGREE OF TEMPERATURE GRADIENT AS OBLIQUITY OF RADIATION INCREASES

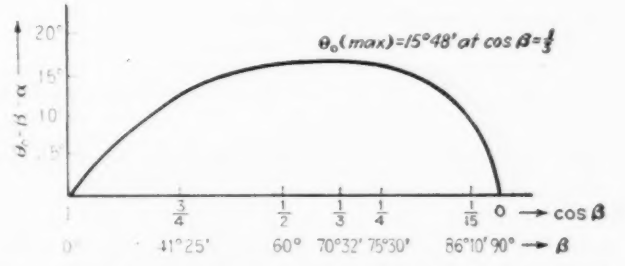

FIG. 7 SHIFT θ_0 OF CENTER OF RECEIVED RADIATION AS A FUNCTION OF OBLIQUITY AND OF COS β

These are shown in percentages of heat transfer per degree, relative to the ratio for normal radiation taken as 100 per cent. They are not efficiencies in the true sense of the term, since there are no heat losses under any of the situations here treated (true efficiencies are all 100 per cent) but are perhaps due to greater spreading of heat through areas not exposed under oblique radiation.

SUMMARY OF RESULTS

The distribution of temperature inside boiler tubes in contact under parallel oblique radiation of any obliquity angle β is given by Equation [7], assuming no heat transfer at back or anywhere across outer tube surface, except where it is under radiation from the fire.

The hot point on the boiler tube is near the center of the received radiation beam but shifted toward the surface point where the radiation strikes or would strike (except for shadowing) the surface normally for that obliquity angle.

The temperature drop between outer and inner tube surface is greater for a given quantity of received oblique radiation than for normal radiation, up to angles of extreme obliquity approaching 90 deg. This may be due to greater concentration of heat under oblique radiation, corresponding to greater ease in disposing of it under normal radiation. Fig. 6 shows how the heat transfer per degree of temperature drop decreases under oblique radiation continuously.

The center of the tube-surface area exposed to radiation given by $\theta = \beta - \alpha$ does not shift from its normal position $\theta = 0$ opposite the fire in the same way as the obliquity angle does, due to shadowing effect of adjoining tubes. Its maximum (see Appendix 2) occurs at radiation obliquity of $\beta = 70°32'$, where the central angle θ_0 of surface exposed to radiation is 15°48′ representing maximum eccentricity of received radiation. When the eccentricity angle θ_0 is plotted against the cosine of obliquity angle β for received radiation, we have a graph of Equation [6] which is shown in Fig. 7.

Appendix 1

Derivation of Temperature Distribution Under Oblique Radiation

Taking account of the first assumption or boundary condition, Equation [1], we have for the solutions of Laplace's equation

$$T = (r^m - r_0^{2m} r^{-m})(A_m \sin m\theta + B_m \cos m\theta);\ m \neq 0 \quad \ldots\ldots [13]$$

$$T = c \log \frac{r}{r_0};\ m = 0$$

which includes terms in sin $m\theta$ as well as in cos $m\theta$ because of the unsymmetric type of distribution. We now introduce variable angle ϕ, measured from the center of the area exposed to radiation, and related to θ according to the nomenclature. Then, using new Fourier coefficients A' and B' in Equation [13], we have for our temperature expression

$$T = c \log \frac{r}{r_0} + \sum_{m=1}^{\infty} (r^m - r_0^{2m} r^{-m})(A'_m \sin m\phi + B'_m \cos m\phi) \quad [14]$$

where, according to the nomenclature, the constants are related by

$$\begin{aligned} A_m &= A'_m \cos m(\alpha - \beta) - B'_m \sin m(\alpha - \beta) \\ B_m &= A'_m \sin m(\alpha - \beta) + B'_m \cos m(\alpha - \beta) \end{aligned} \quad \ldots\ldots [15]$$

The Fourier coefficients of Equation [14] are computed in the usual way taking account of Equations [4] and [5]

$\frac{\partial T}{\partial r}$ at $r = r_1$ is, for the mth term of the series Equation [14]:

(for $m \neq 0$)

$$\left(\frac{\partial T}{\partial r}\right)_{r=r_1} = \frac{m}{r_1}\left(\frac{r_0^{2m} + r_1^{2m}}{r_1^m}\right)(A'_m \sin m\phi + B'_m \cos m\phi)$$

$$= \frac{Q}{K}(\sin\alpha \sin\phi + \cos\alpha \cos\phi)$$

The odd series coefficients are obtained by multiplying the foregoing odd functions by sin $m\phi$ and integrating, and the even terms by multiplying the even functions by cos $m\phi$ and integrating (between limits 0 to π on left and from 0 to $\frac{\pi}{2} - \alpha$ on the right). Thus

$$\frac{m}{r_1}\frac{(r_0^{2m} + r_1^{2m})}{r_1^m} A'_m \frac{\pi}{2} = \frac{Q}{K}\sin\alpha \int_0^{\frac{\pi}{2}-\alpha} \sin\phi \sin m\phi d\phi$$

$$= \frac{Q}{2K}\sin\alpha \int_0^{\frac{\pi}{2}-\alpha} [\cos(m-1)\phi - \cos(m+1)\phi]\, d\phi$$

$$\frac{m}{r_1}\left(\frac{r_0^{2m} + r_1^{2m}}{r_1^m}\right) B'_m \frac{\pi}{2} = \frac{Q}{K}\cos\alpha \int_0^{\frac{\pi}{2}-\alpha} \cos\phi \cos m\phi d\phi$$

$$= \frac{Q}{2K}\cos\alpha \int_0^{\frac{\pi}{2}-\alpha} [\cos(m-1)\phi + \cos(m+1)\phi]\, d\phi$$

where the integral on the right vanishes according to Equation [4] beyond the indicated upper limit of integration. When the values of A'_m and B'_m so determined are substituted in Equation [14] we have

$$T = \frac{Qr_1}{\pi K}\left[\cos^2\alpha \log\frac{r}{r_0} + \frac{r_1}{2}\frac{(r - r_0^2 r^{-1})}{(r_1^2 + r_0^2)}\left\{(\pi - 2\alpha - \sin 2\alpha)\sin\alpha\sin\phi + (\pi - 2\alpha + \sin 2\alpha)\cos\alpha\cos\phi\right\}\right.$$
$$+ \frac{r_1^2}{6}\left(\frac{r^2 - r_0^4 r^{-2}}{r_0^4 + r_1^4}\right)\left\{(3\cos\alpha + \cos 3\alpha)\sin\alpha\sin 2\phi + (3\cos\alpha - \cos 3\alpha)\cos\alpha\cos 2\phi\right\}$$
$$+ \frac{r_1^3}{12}\left(\frac{r^3 - r_0^6 r^{-3}}{r_0^6 + r_1^6}\right)\left\{(2\sin 2\alpha + \sin 4\alpha)\sin\alpha\sin 3\phi + (2\sin 2\alpha - \sin 4\alpha)\cos\alpha\cos 3\phi\right\}$$
$$\left. - \frac{r_1^4}{60}\left(\frac{r^4 - r_0^8 r^{-4}}{r_0^8 + r_1^8}\right)\left\{(5\cos 3\alpha + 3\cos 5\alpha)\sin\alpha\sin 4\phi + (5\cos 3\alpha - 3\cos 5\alpha)\cos\alpha\cos 4\phi\right\} + \ldots\ldots\right] \quad \ldots [16]$$

When the dimensionless variable and constant $\rho = \frac{r}{r_0}$ and $\rho_1 = \frac{r_1}{r_0}$ are used in Equation [16], we obtain series Equation [7].

Appendix 2

Center of Area Exposed to Radiation as a Function of Obliquity Angle

If we solve Equation [6] for α, we have

$$\alpha = {}^1/_2 \text{ arc cos } (2\cos\beta - 1) \quad \ldots\ldots [17]$$

and hence for the center of the area exposed to radiation according to Fig. 1 and the nomenclature

$$\theta_0 = \beta - \alpha = \beta - {}^1/_2 \text{ arc cos } (2\cos\beta - 1) \quad \ldots\ldots [18]$$

The derivative of this is readily seen to be

$$\frac{d\theta_0}{d\beta} = 1 - \frac{\sin\beta}{2\sqrt{\cos\beta - \cos^2\beta}} \quad \ldots\ldots [19]$$

Setting this equal to zero gives

$$\left.\begin{aligned} \cos\beta &= {}^1/_4 \\ \beta &= 70°32' \end{aligned}\right\} \quad \ldots\ldots [20]$$

for the obliquity angle of maximum θ_0 being the center of the area exposed to radiation. The position of this maximum shift of the center is obtained by substituting Equation [20] in Equation [18].

$$\theta_{0(\max)} = \beta - {}^1/_2 \text{ arc cos } (-{}^1/_4) = \beta - {}^1/_2\,(109°28')$$
$$\theta_{0(\max)} = 70°32' - 54°44' = 15°48' \quad \ldots\ldots [21]$$

This is the most eccentric position of the surface exposed to oblique radiation. Note that it is less than 1 deg out from the center of the radiation beam of 60 deg obliquity ($\theta_0 = 15°$) and of 75°30′ obliquity ($\theta_0 = 15°30'$) of Figs. 3 and 4, and greater than 70°32′ angles of obliquity reduce the eccentricity of the exposed surface. Thus Fig. 5 shows that for an 86°10′ obliquity angle the center of the area exposed to radiation is given by $\theta_0 = 11°10'$, being less eccentric than the distribution of Fig. 2, for 41 deg obliquity of radiation when the eccentric angle $\theta_0 = 11°25'$ gives the shift of the center from its position $\theta_0 = 0$ opposite the fire in case of normal radiation.

Discussion

G. M. Dusinberre.[6] The section, "Heat Transfer per Degree of Temperature Drop as a Function of Obliquity Angle β," opens an interesting line of study, for it shows that the maximum temperature gradient in the metal falls off surprisingly slowly as the heat transfer decreases (owing to location of the tube), under the author's assumptions. As the heat transfer and internal turbulence decrease, the temperature gradient between metal and boiling liquid will no longer be negligible. But according to the studies of Jakob[7] this gradient may well be constant about the inner circumference. If so, the author's temperature distributions would remain qualitatively correct. Now, if the interior surface gradient should become greater than the decrease of gradient in the metal, then a tube at the end of the wall, although receiving less heat, might attain a higher surface temperature than a tube opposite the flame. This high temperature would, moreover, be quite localized.

The practicing engineer who has not the author's thorough command of differential equations will find that solutions of this type of problem are readily obtained by the numerical method outlined by Emmons.[4] The precision of the method depends only upon the time spent, and this is equally true of the analytical solution, for one computes only as many terms of the series as is judged to be necessary for the purpose at hand. For a degree of precision consistent with that of most engineering data, the numerical method offers a tremendous saving of time.

The writer's experience shows that a particular case, such as is represented by one of the author's diagrams, can be solved from the beginning in the time required for the final computations alone in the analytical solution. Thus one saves the time required for solving the differential equation and for calculating the numerical constants in the series. The numerical method is also more flexible. As Emmons has pointed out, there is only slightly more difficulty in the treatment of a fin or stud tube, whereas these would greatly complicate an analytical solution. The same may be said for the effect of a slag layer such as occurs in pulverized-coal firing.

Author's Closure

The main advantage of the present treatment over the numerical method discussed by Mr. Dusinberre seems to lie in its dual nature in that it supplies first the mathematical formula and secondly the graph for any oblique distribution within the scope of the subject matter, such as the four special series herein and their temperature distribution graphs. Its application involves, of course, the selection of a given obliquity angle β and its incorporation into Equation [7] and corresponding graph as preliminary to any special detailed study of the situation it represents; but now that [7] is supplied, the time involved may be of the same order of magnitude as for obtaining from the beginning a graph by the numerical method. And the present method is then roughly of twice the productivity in that it supplies the mathematical series as well as the graph.

One does not need to enlarge upon the power and completeness of any mathematical solution that is true to the facts of any problem. It usually involves hidden truths to be unraveled by further study of the formulas, as well as often unexpected though mathematically obvious relations such as that herein shown and discussed concerning the temperature drop as a function of the obliquity angle.

The greater flexibility of the numerical method is readily conceded, but flexibility of method is usually accompanied by corresponding handicaps. A more flexible analytical method is usually the more difficult one, witness Weierstrass elliptic functions as compared with the more frequently used Legendre functions. In the present instance the flexibility of the numerical method is obtained at the expense of any mathematical representation at all, and so in this regard it has only half the thoroughgoing completeness of the twofold treatment herein.

Ratio and Multiple-Fuel Controls in the Steel Industry

By HERBERT ZIEBOLZ,[1] CHICAGO, ILL.

The need for accurate control of the furnace atmosphere in the steel industry has brought about the development of a variety of designs and basic circuits to solve this problem. The methods used and the apparatus which were developed are briefly discussed, i.e., (1) the basic ratio control, (2) the control mixing stations, and (3) the controls available for burning several fuels simultaneously with only one common supply for combustion air.

Reason for Use of Ratio Controls in Steel Industry

THE development of automatic controls and instruments in the steel industry followed a course somewhat different from that in other industries. Relatively great forces had to be handled. Many of the plants were old and out-dated, and the original designers had rarely considered the requirements of controls and instruments. Consequently, most of the installations had to be designed to meet individual requirements.

The last ten years have fortunately brought about a better understanding of the mutual problems, and the importance of this co-operation can hardly be overemphasized.

Generally speaking, there are three major problems, typical of the steel industry:

1 Chemically changing the material handled.
2 Changing its physical shape.
3 Raising its temperature prior to (1) and (2).

The diagram, Fig. 1, showing the variables entering into problem 3, i.e., the heating of carbon steel, gives a general view of the subject covered by this paper. The vertical *Z* axis shows the products of combustion of the most expensive fuel in the entire steel plant, i.e., scale. The *X* axis gives the percentages of excess and deficiency of combustion air, the *Y* axis gives various steel temperatures. It will also be noticed that the heating time, during which the steel is exposed to these temperatures and atmospheres, is indicated. This diagram gives in concise form the story of heating steel, and it will be observed that if it is required to bring a piece of steel to a given temperature with a minimum and controlled type of scale formation, two variables must be taken into account, as follows:

(*a*) Rate of temperature increase.
(*b*) Atmosphere control.

The purpose of this paper is to discuss the latter problem and, in particular, the mechanisms developed for combustion or atmosphere control. This includes the premixing of fuels to be used in the burners.

An attempt will be made to show the reasoning behind various solutions from the viewpoint of the oft forgotten designer, as a more general knowledge of his problems may well be of value in the future development of the art.

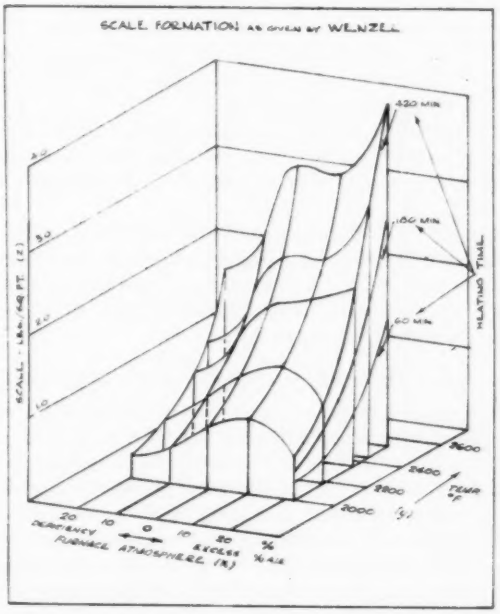

Fig. 1 Scale Formation of Carbon Steel as Function of Atmosphere, Temperature, and Heating Time for Carbon Content of 0.35 to 0.61 Per Cent

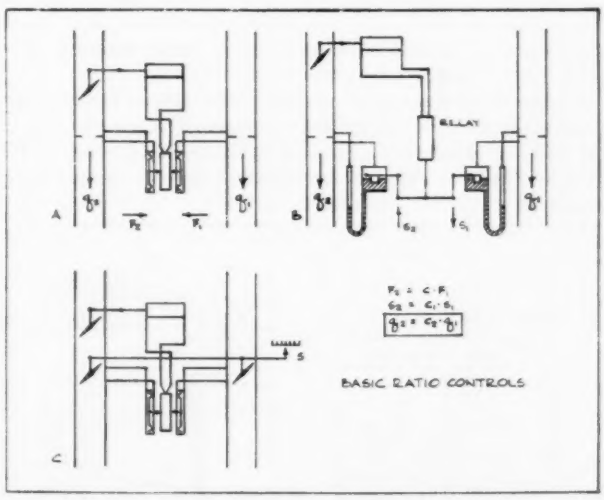

Fig. 2 Basic Ratio Controls

(*A*, Balancing of forces produced by pressures across fixed orifice plates. *B*, Balancing of movements created by pressures across fixed orifice plates *C*, Balancing of forces produced by pressures across orifice plates.)

Basic Ratio-Control Principles

In order to control the proportion between fuel and air, and thus atmospheres, we must first measure the rates of flow. Two alternate methods are generally available:

1 The use of a fixed orifice with varying differential.
2 The use of a variable orifice with a fixed differential.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

It should also be borne in mind that most ratio- or mixing-control jobs demand a constant or varying ratio on a weight basis rather than on a volumetric basis. Thus the factor of density enters into the picture, and we can expect that in the future more consideration will be given to its measurement. Keeping this in mind, we can now consider basic solutions of ratio-control problems.

Fig. 2(*A*) shows the typical method of balancing two differentials against each other. As long as the two forces F_2 and F_1 are proportional the corresponding pressure drops and thus the rate of flows q_2 and q_1 are proportional. We shall use this diagram as a symbol rather than as representative of a particular design in the following schematic sketches.

As an alternative, we can match the strokes S_1 and S_2, Fig. 2(*B*), instead of forces, if we make provision that these movements are proportional to the differential pressures. The diagram is self-explanatory.

In Fig. 2(*C*) we find the same ratio control as in Fig. 2(*A*), with the modification that variable orifices are used to increase the range of operation. In this particular instance, butterflies of identical characteristics (with geometric proportionality and with the same Reynolds numbers) are used.

Central Gas-Mixing Stations for Interchangeable Fuels

Fortunately for the steel industry, it frequently has a number of sources of fuel gas at its disposal. To use these fuels without the need for repeated burner- and combustion-control adjustments, it is necessary to provide central or individual gas-mixing stations, in order to provide an interchangeable fuel at all times.

Owing to the wide variations in fuel demand in central mixing stations, it is obvious that only variable orifices can be used in such stations. Fig. 3(*A*) shows a "wide-range mixing station in which the variable orifices are operated by means of a differential controller which keeps constant the pressure drop across one of the variable orifices, q_1. The ratio-controller's job is to proportion the pressure drop produced by the other rate of fluid flow q_2, to that produced by q_1 across the primary variable orifice. Both orifices move simultaneously and are so connected as to give (directly) proportional free areas.

A supervising control, responding to the Btu of the mixture, density, or any other representative variable, is used to correct the ratio by adjusting s. Such additional controls serve at the same time as a correction for discrepancies between the flow characteristics of the variable orifices.

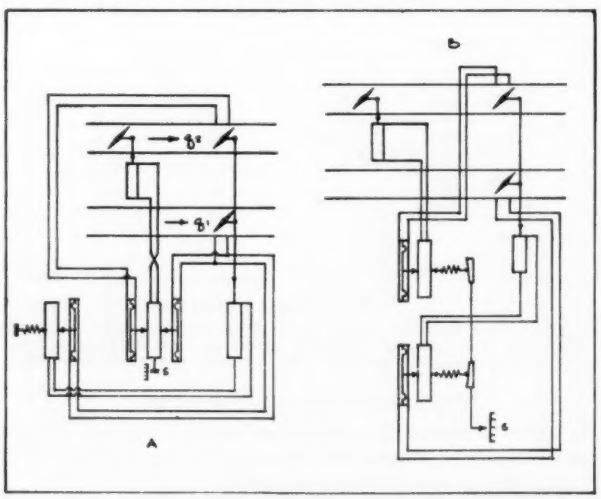

Fig. 3 Wide-Range Ratio Control
(*A*, With one differential and one ratio control. *B*, With two differential controls.)

From the foregoing, it seems logical to develop an alternative scheme, Fig. 3(*B*). If the differential across one of the orifices is kept constant, it is unnecessary to measure it a second time. A spring can thus be substituted for the right-hand diaphragm of Fig. 3(*A*), or to make the control more flexible, a cam can be used which simultaneously changes the differential-pressure settings of the primary- and secondary-flow-rate controllers. An adjustment of the cam s will change the ratio between the two flow rates, and thus obtain any desired relationship between s and the ratio between the two fluids.

Fig. 4 shows how the change of ratio setting is accomplished.

Typical Means for Varying Ratio Setting

The ratio adjuster as shown in Fig. 4(*a*) and in two typical controller designs has a particular characteristic, i.e., the relationship between its stroke and the ratio established for the opposing forces F_1 and F_2.

This ratio is given in Fig. 4(*b*) and represents a hyperbolic function. Fortunately, the hyperbola coincides to an unexpectedly high degree of accuracy with a logarithmic curve within the range of values of R between 2 and 0.5 in., which is typical for ratio adjustments. This makes an adjustment of the ratio slider possible without a recalibration of scales, as any correction factor can be introduced into the mechanism by means of a shift of the ratio scale. The reason for this is the fact that the log of the product of two variables is the sum of the logs of the two variables. It also allows the mechanical addition of movements representing correction factors, such as barometric pressure, temperature, Btu content, humidity, density, and other variables.

This ratio variation, produced by increasing one of the differentials of a ratio control relative to the magnitude of the other is shown in Fig. 4(*d*), where one orifice is fixed, the other variable, and in Fig. 4(*e*), where the free areas of both orifices change in opposite direction.

Another scheme which may at first glance appear rather elaborate is shown in Fig. 4(*f*). A ratio control establishes a pilot flow of low-pressure air which is directly proportional to the main flow. A double orifice of the type shown in Fig. 4(*e*) is used to split this pilot flow into two proportional branches. The flow through one of these branches is used to produce a signal which controls the rate of flow q_2, by means of a second ratio control. Thus depending upon the position of the double orifice in the pilot line, various ratios of q_1/q_2 can be obtained.

Compensation for Air Infiltration or Constant Amount of Primary-Air Supply

So far, we have only considered the control of one rate of flow proportionally to a second one and have solved our multiple-fuel problem by proportioning the individual fuels to each other, so as to produce a new composite fuel which can then be proportioned to air.

The simplest solution of a multiple-fuel problem is to provide a separate air supply for each fuel. Although this design is quite frequently used, it requires surplus capacity of fans and ducts, as, if 100 per cent of any fuel should be used at any time, the total air must be delivered from its particular source.

In this connection it may be well to recommend thinking of air as a fuel of about 100 Btu per standard cu ft which can be burned with various fluids.

Given two fluids with flows q_a and q_b, which are measured by their respective pressure drops h_a and h_b, with the flow constant c_a and c_b, the problem of controlling a third rate of flow q_c with h_c and c_c proportional to their sum takes the following form

$$(q_a + q_b) = q_c$$
$$(c_a \sqrt{h_a} + c_b \sqrt{h_b}) = c_c \sqrt{h_c}$$

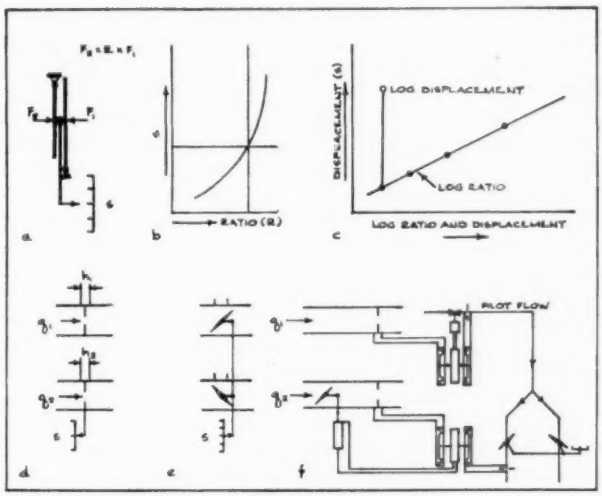

FIG. 4 RATIO-VARYING DEVICES

(*a*, Ratio slider; *b* and *c*, relationship between stroke and ratio; *d* and *e*, ratio change by means of variable orifice; *f*, ratio change by means of controlling pilot flows.)

$$(c_a^2 \cdot h_a + c_b^2 \cdot h_b) + 2 \cdot c_a \cdot c_b \cdot \sqrt{h_a \cdot h_b} = c_c^2 \cdot h_c$$

This equation shows that h_c cannot be made proportional to $c_a^2 \cdot h_a + c_b^2 \cdot h_b$, as is time and again suggested even by engineers who should know better.

One typical example is the case where the fuel has to be proportional to the sum of two air flows. These two air supplies may be as follows:

(*a*) Combustion air + air infiltration; or
(*b*) Combustion air + primary air.

It is in such cases often erroneously suggested to provide an additional spring loading on one of the diaphragms to compensate for or to represent the rate of air infiltration or primary-air flow which is assumed to be constant.

In Fig. 5, the result of this method is shown giving the possible compensation for constant "air infiltration" of 5 per cent and 15 per cent maximum flow q_2.

The diagram, Fig. 6, proves that it is possible to improve greatly the effect of this compensation by using 3 times the equivalent force of the amount of infiltration as the spring tension to be added. This gives satisfactory results down to as low as 30 per cent of the maximum rate of flow.

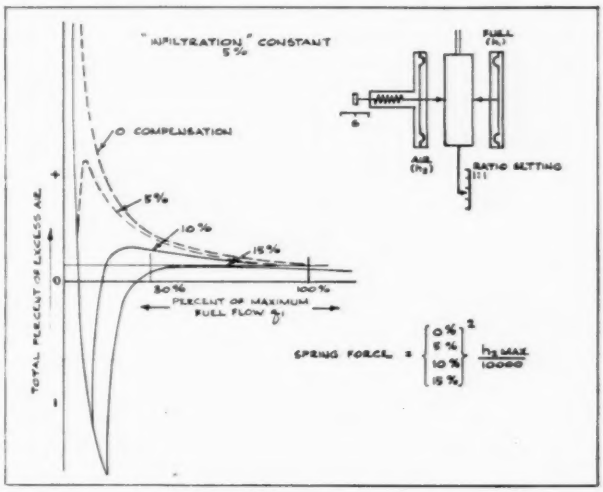

FIG. 6 EFFECT OF VARIABLES OR CONSTANT FORCES ADDED TO RATIO REGULATORS FOR COMPENSATION OF INFILTRATION

However, since at 10 per cent flow, the force of the diaphragm is equal to $^1/_{100}$ of the maximum force obtained from full flow, it becomes apparent how critical is this adjustment and that it should be used only in emergencies, and by men who know exactly its effect. A variation of infiltration with time, and an attempt to compensate for it by the foregoing method seems therefore not to be too desirable as a plant-maintenance job.

It seems promising to try a solution in which a model of the actual flow distribution is established and the same flow pattern is repeated on a smaller scale. Fig. 7 shows this method. A pilot flow is established, which is directly proportional to the total air requirements of the fuel q_1. Downstream from the pilot-flow valve, an orifice produces a signal differential which is used to act upon the main air-flow regulator. The orifice for the first ratio control, which establishes the pilot flow, is upstream from the pilot-flow valve. By bleeding various amounts of air between this valve and the upstream orifice, an amount of air can be deducted from the downstream pilot flow which is directly proportional to the air infiltration.

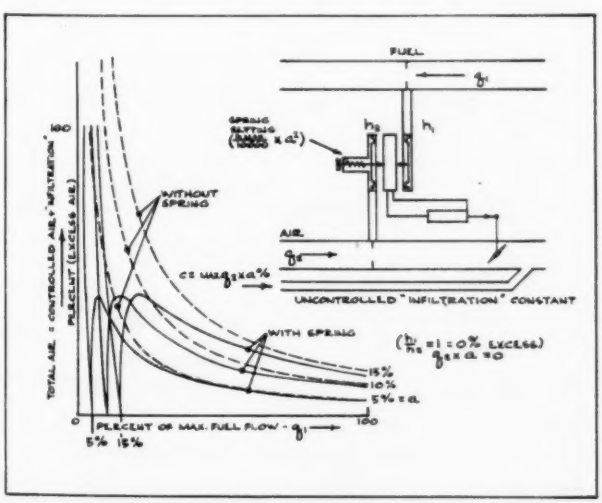

FIG. 5 CORRECTION FOR INFILTRATION BY ADDING CONSTANT FORCES ON RATIO REGULATORS

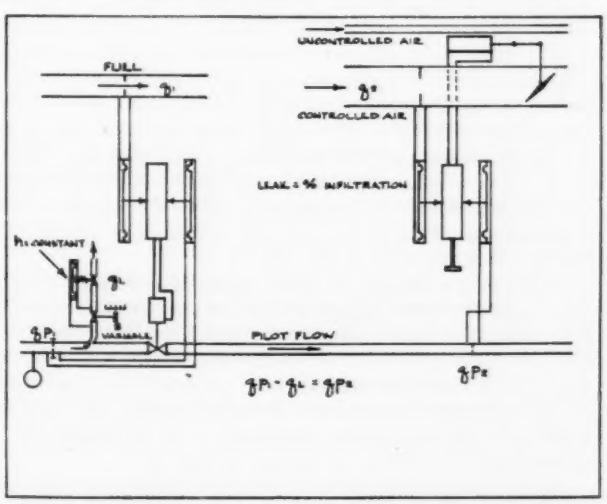

FIG. 7 CORRECTION FOR UNCONTROLLED AIR FLOW BY MEANS OF PILOT FLOWS

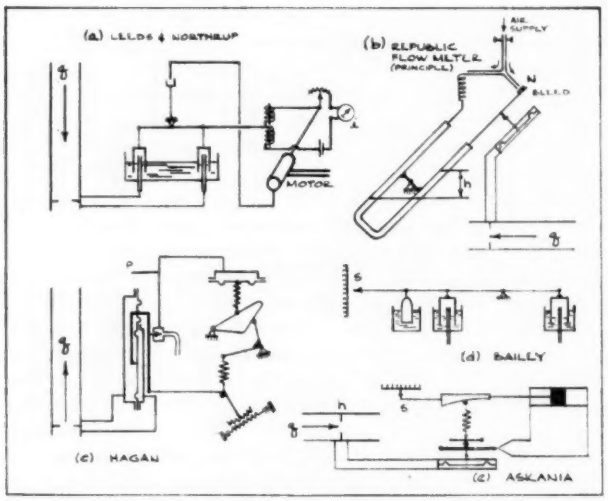

FIG. 8 VARIOUS METHODS TO EXTRACT SQUARE ROOTS AND FOR GETTING SECOND-POWER FUNCTIONS

A differential regulator is shown making the adjustment of the bleed-off valve a direct function of the bleed-off flow.

The basic reason for the success of this arrangement is the fact that the square functions, i.e., the differential pressures, are converted into linear functions of flow rates. These functions can then be added or subtracted without introducing an error.

METHODS AND DEVICES FOR "MODULATING" SIGNALS

It has been shown that the basic problem in multiple-fuel control is the conversion of square functions into linear functions, and the provision of means for adding and subtracting values representing individual flow rates or air requirements.

It seems desirable therefore to study some of the methods developed by various designers to solve this problem before we discuss the complete controls available for multiple-fuel-control problems.

In Fig. 8(*a*), one solution is found in the use of a Kelvin balance (Leeds & Northrup Company) which produces a "pilot" flow of electrical current which is directly proportional to the fuel flow or its air requirements.

As the force developed by the two coils in series is proportional to the square of the current flowing through them, and the force exerted on the pressure bells is proportional to q^2, we obtain a current which is directly porportional to the flow rate q. The current is controlled by a rheostat and a motor which reverses its direction of rotation, depending upon the direction of the unbalanced movement of the instrument. While previously an energy rate of flow was obtained in the form of a fluid pilot flow, the device mentioned produces a directly proportional electric-energy flow rate represented by the current i. This current, as we shall see later, lends itself just as well as the fluid pilot flow to summarizing and subtracting problems.

In Fig. 8(*b*), a mechanical device is shown in which the differential pressure across an orifice (a second power function of the flow rate) is translated into a pressure which is a linear function of the flow. The differential across the orifice tilts a U-tube and thereby simultaneously increases the pressure in a relay nozzle N. The pressure thus produced is transmitted to one leg of the U-tube and thereby causes the liquid level to change by an amount h.

As the counteracting or feedback moment is proportional to h times the distance of the displacement center of gravity ($c_1 \cdot h$) the moment becomes equal to ($c_1 \times h^2$), or, when in the balanced condition, h becomes directly proportional to q. The device thus takes the square root out of the flow signal. Reversing the design, it is possible to produce an h_2 which is porportional to the square of h_1 (Republic Flow Meters Company's "modulator").

Another company (Hagan Corporation) introduces the additional parameter s, a stroke. The differential pressure acts upon a diaphragm, Fig. 8(*c*), thus creating a force directly proportional to the square of the flow rate q. This force is transmitted to the outside through a stuffing box (diaphragm type) and controls a relay valve which produces a pressure on top of a spring-opposed diaphragm. For every pressure on the diaphragm, a stroke is obtained which is modified by a cam, and reconverted into a force which finally opposes the primary-flow-rate signal. Thus a feedback establishes a balance between forces and produces a pressure p which, by use of a proper cam, can be made directly proportional to q.

A ratio adjuster working on the force-vector principle allows a change of the proportionality factor. The translation is thus accomplished in steps following the sequence:

From flow energy to differential pressure to force(I) to stroke; to a modified stroke to a force(II), with a feedback circuit between force(I) and force(II).

We will find such translators in series in most of our multiple-fuel-control solutions. Again the device can be reversed, with slight changes, to produce a differential h^2 for any given p or h.

In Fig. 8(*d*), the same problem is solved (by Bailey Meters Company) with the use of displacement bodies and floating inverted bells.

The translation follows the lines:

Energy flow—differential pressure—force(I)—stroke—force(II) (counteracting buoyancy). Feedback is established between force(I) and force(II) with the result that the stroke s becomes directly proportional to q, the flow rate.

Fig. 8(*e*) shows another method (Askania Regulator Company) in which the translation is obtained by means of a force feedback, represented by a spring counteracting the diaphragm force. By the use of an adjustable cam, which can be easily adjusted in the field, any relationship between h and s can be produced. This is particularly advantageous if the flow signals, as frequently happens, do not follow second power or any other predictable or simple laws.

We recall that the reason for the existence of all these translating devices is that the square of the sum is not equal to the sum

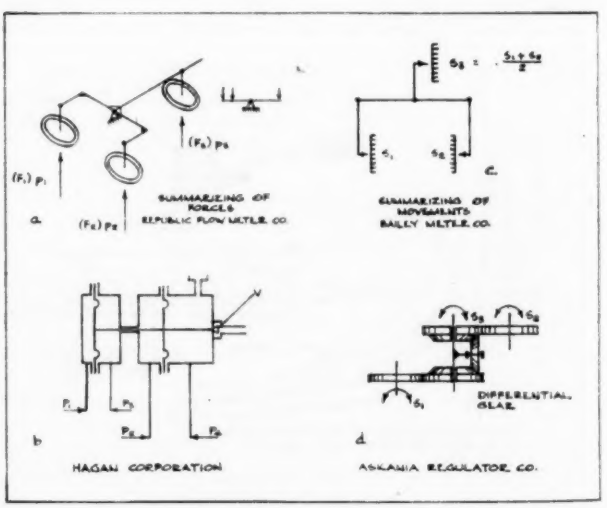

FIG. 9 VARIOUS SUMMARIZING DEVICES FOR FORCES *a* AND *b* AND MOVEMENTS *c* AND *d*

of the squares, and that directly proportional variables must be obtained for summarization.

Means for Summarization of Signals Representing Flow Rates

Before describing the individual basic solutions of the multiple-fuel problem as they are now available to the steel industry, we shall discuss briefly some typical summarizing devices for pressures and strokes as they are found in many various controllers. As it is impossible to summarize pressures directly, a detour becomes necessary.

Fig. 9(*a*) uses for that purpose a forked lever with pressures p_1 and p_2 applied to individual diaphragms. A pilot (not shown) produces a pressure p_3, which is used as a feedback into a third diaphragm, producing a balancing force F_3. Then F_3 becomes the sum of $(F_1 \cdot c_1 + F_2 \cdot c_2)$ with c_1 and c_2 as constants (Republic Flow Meters Company). Basically, the same idea is used in design Fig. 9(*b*), in which two or three pressures are added or subtracted by means of diaphragms in series. Pressure p_4 is the resulting pressure counteracting $(c_1 \cdot p_1 + c_2 \cdot p_2 - c_3 \cdot p_3)$ and controlled by a bleed-off valve v (Hagan Corporation).

In the class of the stroke summarizers, we find the whiffletree, Fig. 9(*c*) (Bailey Meter Company), and the differential gearbox Fig. 9(*d*) (Askania Regulator Company). Both of these devices are too well known to need any further explanation.

Methods and Devices for Combustion Controls Using Several Fuels but Only One Air Supply

Thus prepared, we can finally analyze the various designs of actual controllers used in multiple-fuel controls.

We have seen that producing a proportional pilot-flow model offers a particularly flexible solution. In Fig. 10 (Leeds & Northrup Company), we note that the summarization is accomplished by the addition of two (or more) currents which are directly proportional to the individual air requirements.

New in this picture is the use of a positive-displacement meter for measuring the fuel-oil rate of flow by means of a generated voltage directly proportional to the speed of the meter. The generated voltage is balanced by a potentiometer controller against the voltage due to the current (i_2 current) flow in the pilot circuit. The potentiometer adjusts the rheostat to maintain this voltage. This current is added to that produced by the Kelvin bridge. The square-root symbol indicates the linearity of the controlled strokes. No special summarizing devices are necessary,

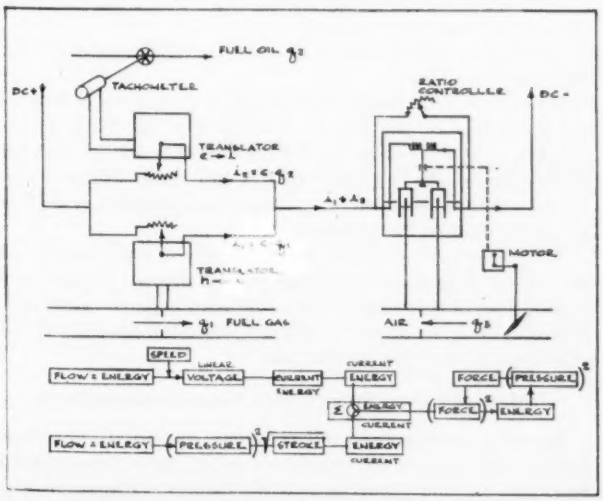

Fig. 10 Multiple-Fuel Control; Leeds & Northrup Company

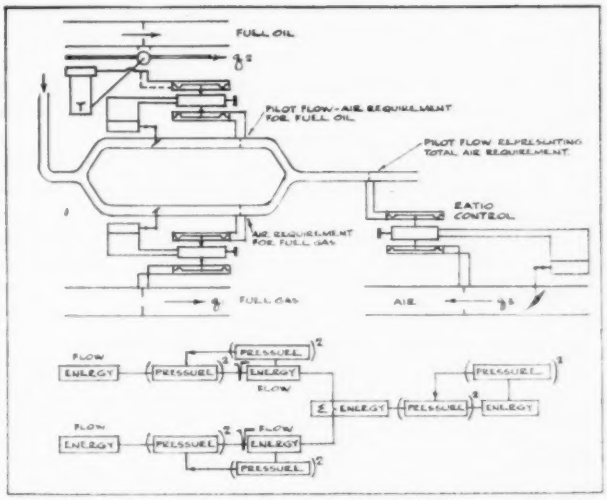

Fig. 11 Multiple-Fuel Control; Askania Regulator Company

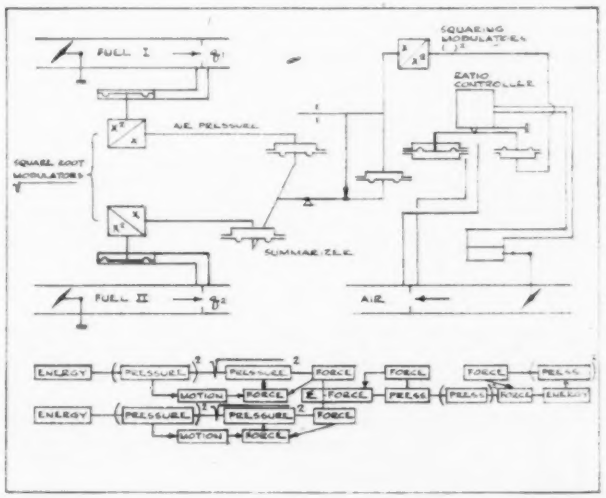

Fig. 12 Multiple-Fuel Control; Republic Flow Meters Company

as the currents flow together in accordance with Kirchhoff's law. The sum total produces a force proportional to i^2 and controls the flow of air needed for combustion.

The ratio controller is basically the Kelvin balance in reverse. The air-flow energy produces a second-power pressure, which, translated into a force, is fed back against the current force.

A ratio adjuster in the form of a rheostat permits the adjustment of the ratio from excess to deficiency.

An attempt is made in Fig. 10 and the following diagrams to present the individual steps of translations in a block diagram.

For want of a definite standard way of using symbols for such translators these diagrams are tentative only and should be modified as soon as a general agreement on these symbols has been or can be reached. For the purpose of the present paper, however, these diagrams may be sufficiently clear to demonstrate the approach to the circuit analysis, although it would be desirable to develop a more universally acceptable way of presentation.

Fig. 11 is basically the same circuit with the exception that fluid pilot flows are used instead of the electrical currents (Askania Regulator Company).

Of interest is the possibility of using alternative fuels by the application of the device which translates the speed of the posi-

tive-displacement oil meter into square-function air pressures. By matching the fluid pressure produced by this device to that obtained from an orifice in the alternate fuel line in such a manner that it represents the same air requirement, the pneumatic tachometer T can be switched off, and its signal can be replaced by the gas differential without any changes in the circuit.

For convenience, the orifices in the pilot lines are adjustable, thus greatly facilitating adjustments for varying operating conditions.

As the two pilot flows can be easily combined and the totalized flow produces a square function across the totalizer orifice in the common conduit, no additional translating devices are needed. Feedback is established by balancing pressure differentials, or to be more precise, forces.

In Fig. 12, the summarization is accomplished by adding pressures or forces which are directly proportional to the flow rates (Republic Flow Meters Company). To do this, "modulators" converting square functions into linear functions (symbol x^2/x) are used, and summarizers as shown in Fig. 9(a). The sum is "modulated" into a square function (symbol x/x^2) and applied to a ratio regulator which controls the total combustion air. The air differential is fed back into the ratio control to re-establish balance.

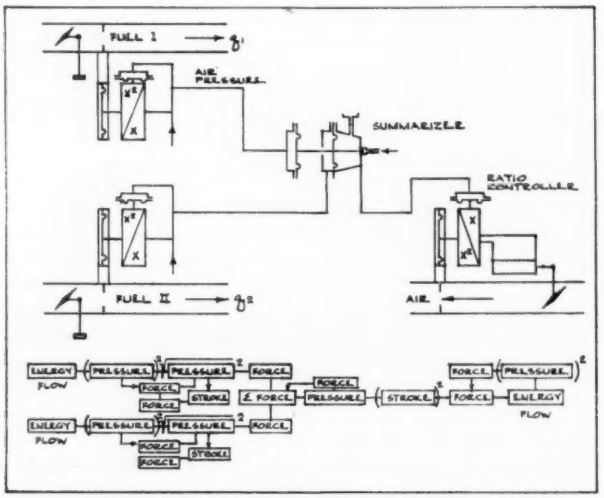

FIG. 13 MULTIPLE-FUEL CONTROL; HAGAN CORPORATION

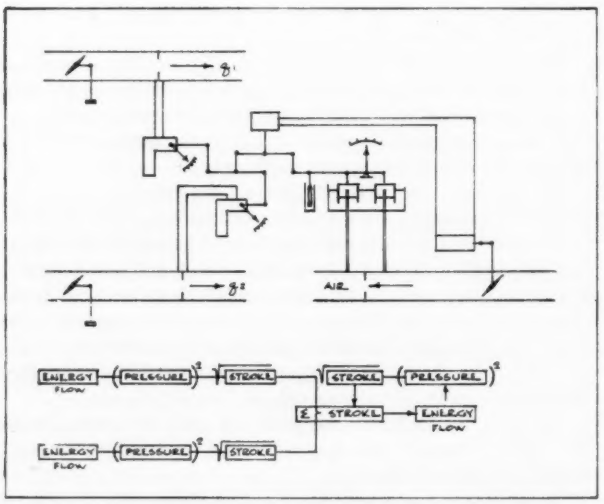

FIG. 14 MULTIPLE-FUEL CONTROL; BAILEY METER COMPANY

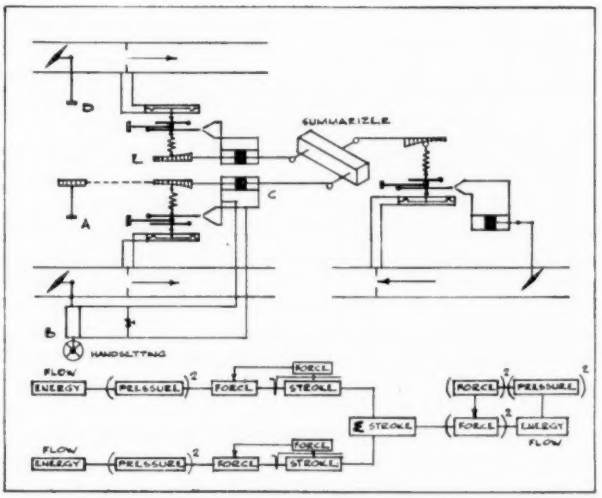

FIG. 15 MULTIPLE-FUEL CONTROL; ASKANIA REGULATOR COMPANY

Basically, the same line of thinking is found in the solution of Fig. 13 (Hagan Corporation), although, as previously shown, the details of the modulator design are different. For the purpose of clarity the same box symbols for the modulators are shown as in Fig. 12.

In Fig. 14, the summarization is accomplished by means of the whiffletree shown in Fig. 9. Individual flowmeters add their pointer movements (without additional power amplifiers) and produce linear movements by suitable float arrangements (stroke modulators) or displacement bodies (force modulators) (Bailey Meter Company). The diagram is self-explanatory. Feedback is accomplished by comparing movements of "strokes."

The last example, Fig. 15, shows a stroke feedback with power amplification (Askania Regulator Company). The modulator, previously discussed in connection with Fig. 8(e), will be recognized.

The diagram shows an alternative adjustment of A or B. If the cam is set by hand, adjustment A, the butterfly valve is controlled, and thus the fuel flow becomes constant, regardless of any variations in the fuel-supply line. If B is set by hand, the flow regulator acts as a "flowmeter." Adjustable cams permit not only correction for second-power flow signals, but permit also:

(a) Correct compensation for any air infiltration (either constant or varying with the load).

(b) The varying of setting of excess and deficiencies of air for different heat inputs.

How this same principle can be applied to wide-range flow-mixing or combustion problems is shown in Fig. 16. With the same number of controls as in Fig. 15, and variable orifices, any turndown range can be handled. In this case again strokes are used as the common parameters, strokes are summarized, and strokes are used in the feedback system.

With these tools available, we are finally in a position to solve practically all problems of multiple-fuel controls. As most of the applications have been previously discussed in papers given by the individual manufacturers, a detailed discussion would only be a repetition of available information.

MAKE-UP FUEL STARTED AT A PREDETERMINED RATE

Recently another problem has become more and more important, i.e., the need for starting the secondary fuel at some minimum flow rate, as there is usually a certain minimum rate below which a burner cannot operate satisfactorily. If a deficiency of pri-

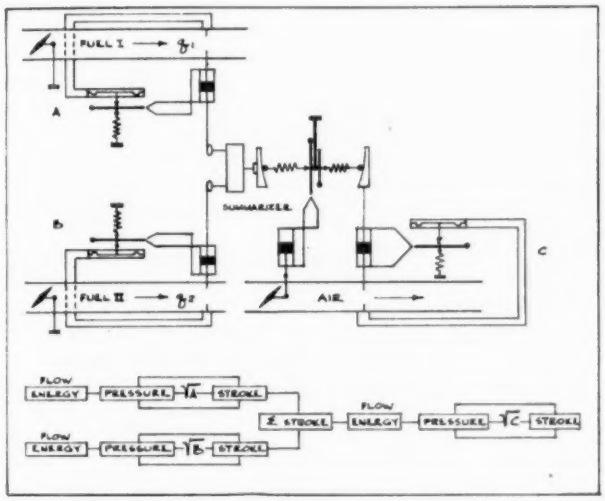

FIG. 16 WIDE-RANGE MULTIPLE-FUEL CONTROL; ASKANIA REGULATOR COMPANY

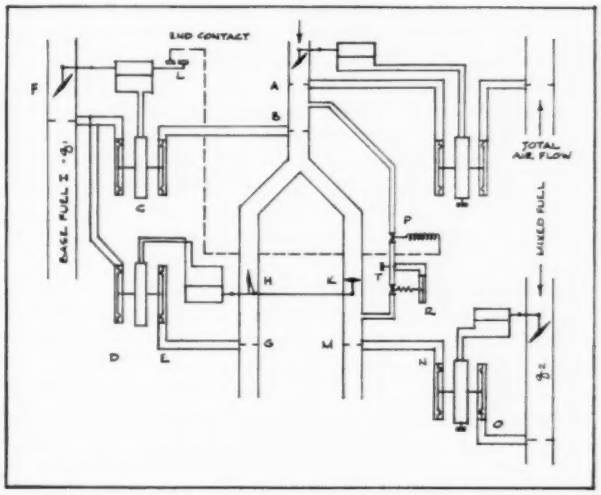

FIG. 17 MULTIPLE-FUEL CONTROL WITH MINIMUM SETTING OF SECONDARY FUEL

mary fuel therefore demands a start of secondary fuel, means have to be found to start the secondary-fuel flow at once at this minimum rate, and simultaneously to reduce the primary-fuel flow by an equivalent amount of Btu supply.

Fig. 17 shows one possible solution which uses pilot flows to represent air flow or Btu rates per time unit (Askania Regulator Company). The total air flow, or the rate of total Btu supply, is replaced by a pilot flow which branches into two lines representing the Btu rates of the individual fuels.

An orifice in the main pilot line B produces a signal representing a certain amount of Btu of fuel I (q_1). As long as ratio regulator C can satisfy this demand, and controls butterfly F, the differential acting on D is equal or slightly greater than that produced by G. Under these conditions, butterfly H is open and butterfly K closed.

Both butterflies are operating in opposite directions H, opening when K closes and vice versa.

If there is a deficiency of the primary fuel, butterfly F opens wide in an attempt to satisfy the demand, and thus closes contacts L, which energize a solenoid valve P, and thereby a passage for bleeding a definite amount of pilot flow from a point between A and B to a point ahead of M, which determines the rate of fuel demand for the secondary fuel.

This fuel rate is controlled by means of the ratio regulator N–O. A differential control valve in R the by-pass, and an adjustable restriction T, assure a definite rate of flow which represents the minimum flow rate for the secondary-fuel burner.

It will be noted that the diversion of flow from the left branch to the right decreases the loading on ratio control C. Butterfly F therefore reduces the flow rate (q_1) by at least the amount of the by-passed pilot flow, and ratio control D–E cuts down the pilot flow through H and increases the flow through K so that the difference is always diverted to orifice M. The design is intentionally so arranged that the secondary-fuel burners remain in operation until an operator manually disconnects them from the line. All that is necessary for this purpose is to de-energize solenoid P, which incidently can also be done automatically.

It appears that all of the foregoing solutions offer a great help to the operator and simplify his job of operating a furnace.

The question which is still open, and which this paper did not attempt to cover, is: What is the best setting of these calculating and controlling devices assuming optimum operating conditions?

We must not forget that the equipment, even if its performance is beyond reproach, is just as capable of maintaining the wrong operating conditions as it is of maintaining the correct ones.

Discussion

C. J. GEISER.[2] The author has contributed a commendable paper, presenting the general problems of ratio and multiple-fuel controls in the steel industry and a brief description of the various designs of systems used to solve these problems.

The problem of uncontrolled air infiltration has always presented difficulties on actual applications. Limitations of burners at low rates of firing and limitations as to the minimum amount of combustion air (cold or preheated) required at the burner at low rates of firing for proper combustion will necessarily limit the extent to which full compensation can be provided. Each individual furnace usually presents an individual problem in this respect requiring extensive test work to determine optimum settings

[2] Republic Flow Meters Company, Chicago, Ill.

for various firing rates and for various phases of the furnace cycle.

The method of compensation described by the author, and illustrated in Figs. 5 and 6, is useful for obtaining a close approximation of theoretically correct total combustion air for the limited firing range specified. Whether or not a furnace will give its best performance with theoretically correct total combustion air (full air-infiltration compensation) at the lower rates of firing, say between 50 and 30 per cent of maximum, can be determined only by actual tests. Due to other considerations, partial compensation (illustrated by the 10 per cent curve of Fig. 6) may possibly give superior over-all results.

It is obvious that higher percentages of air infiltration adversely affect the range of operation of fuel-air ratio control and the attempts to compensate for the infiltration. For example, as an extreme condition, if the air infiltration is equal to 50 per cent of the controlled maximum air flow, the ratio regulator could not possibly control the first $33^1/_3$ per cent of total air flow. Also, using the method of compensation illustrated in Fig. 6, the fuel-flow range would be reduced to a range of approximately 60 per cent to 100 per cent.

The means of compensation shown in Fig. 7 of the paper provides a method for obtaining the correct characteristic for a constant quantity of air infiltration for a particular setting of variable S. It may not be immediately apparent that another means of obtaining exactly the same characteristic is available on the design shown in Fig. 12. Having established an air pressure which is directly proportional and linear with respect to fuel-flow (or total fuel flow on the multiple-fuel control), spring or weight loading of an air-pressure relay (or the summarizer) will exactly compensate for a constant quantity of air infiltration.

Generally, the application of ratio and multiple-fuel controls, particularly on fuel-fired furnace in the steel industry, might be divided into two very broad divisions:

1 The applications on newly designed and built furnaces.
2 The applications on outmoded, existing furnaces.

New furnaces which are carefully designed to minimize air infiltration and to accommodate a wide range of firing, will unquestionably prove the most easily adaptable to the application of these controls. However, the possibilities of applications to the older, existing equipment cannot be overlooked, merely because these applications may introduce difficult problems of maintaining the required combustion analysis due to excessive air infiltration or other limitations. While the older equipment may introduce greater problems for successful application, careful attention by the plant combustion personnel in applying the control, to obtain optimum control settings, will show a great improvement in over-all furnace performance compared to uncontrolled operation.

The vast majority of ratio and similar controls, applied to the steel industry, are entirely dependent upon the judgment of combustion engineers (or other authorized operators) to determine and set the values of pressure, flow, ratio, etc., which the control will maintain throughout the various cycles of the process. As pointed out by the author (and possibly this point cannot be overemphasized), "the control is just as capable of maintaining the wrong operating conditions as it is of maintaining the correct ones." The personnel factor, therefore, enters into the over-all application problem to a large degree and should be given very serious consideration when determining the features which are to be incorporated into any particular design of these controls for a particular application. Considering the physical condition and other limitations of older, existing mill equipment, as well as the deep-rooted precedents which have been established during a long period of use by the operators, the greatest care and attention are required for the successful application on old furnaces.

Summarizing the features of combustion-control equipment which is today available to progressive combustion engineers:

1 Standard fuel-air ratio controls may be compensated for air infiltration, within limits.

2 An almost unlimited number of control-characteristic combinations are available to permit addition and subtraction, multiplication and division of control factors, with designs that can be readily tailor-made to fit the exact requirements of a single application.

3 The extent of control refinements possible is limited in most cases only by the ability of the plant personnel to use the control equipment successfully.

Stress Coefficients for Rotating Disks of Conical Profile

By K. E. BISSHOPP,[1] BELOIT, WIS.

The solution of this problem involves calculations with infinite series which satisfy a hypergeometric differential equation of exponent difference 2. Numerical evaluation of the coefficients is facilitated by employing the linear relations between the hypergeometric functions of arguments x and $1 - x$. These linear relations are derived by an elementary method, which it is believed, has not been described heretofore in engineering literature. The formulas obtained by this method were used to compile tables of the hypergeometric function and the related stress coefficients for various values of Poisson's ratio. The application of these stress coefficients to an illustrative example which had been calculated with a system of uniform disks clearly shows the advantages obtainable with a system of conical profiles.

Nomenclature

THE following nomenclature is used in the paper:

a, b, c α, β, γ	=	elements of hypergeometric equation
A, B	=	arbitrary constants
C_1, C_2, C_3	=	constants which express linear relations between the hypergeometric functions of x and $1 - x$
h	=	one-half thickness of disk at any radius
m, n	=	integers
p, p', p''	=	radial stresses
q, q', q''	=	tangential stresses
r	=	radius
t	=	$1 - x$
u_n	=	coefficient of x^n
x	=	r/R
P	=	$(1 - x)p$
Q	=	$P + xdP/dx$
R_m	=	remainder term
$S_1(x), S_4(x)$	=	infinite series involving x
$S_2(t), S_3(t)$	=	infinite series involving t
Φ_n		defined by Equation [24] or [38]
$\psi(x)$		defined by Equation [25]
$\Psi(x)$		defined by Equation [27]
$\Gamma(x)$	=	Gamma function
γ	=	0.577,215,665 . . . (Euler's constant)
σ	=	Poisson's ratio
ρ	=	mass density
ω	=	angular velocity, radians per sec.

Presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until April 10, 1944, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Purpose of Study

Stress coefficients for rotating disks of conical profile were obtained from power-series solutions of a hypergeometric differential equation (1)[2] of integral exponent difference by Martin (2) and Honegger (3), who recognized the objections to this method of calculation. Numerical evaluation of the coefficients corresponding to the values of the argument near which these series converge slowly or diverge becomes laborious, and in some cases asymptotic approximations may be necessary. Furthermore, the inadequacy of power series alone for calculating uniformly accurate coefficients is shown by the limitations of the published tables. This paper describes a more convenient form of the solution which avoids these difficulties of computation and at the same time substantiates the results of previous investigators.

The easiest solutions to construct are the two series in ascending powers of x and $1 - x$, respectively, given by Martin (2) and Honegger (3). There are also two other expansions in terms of x and $1 - x$ which the integral exponent difference of the differential equation shows involve logarithms. A more convenient method of calculation can be obtained by using linear combinations of all four solutions. The appropriate factors are determined by the asymptotic behavior of the hypergeometric function and/or its derivatives in the neighborhood of the poles. This procedure gives the principal part of the logarithmic solution in finite form near $x = 0$ instead of a slowly convergent series in powers of $1 - x$. The method retains its advantages when applied to the evaluation of the power series solution near $x = 1$ even though this series does converge absolutely at that point.

The difficulties of the power-series method cannot be removed by transformation since the singularities of the stress functions remain unchanged. This can be seen in reference (3), where the solution is obtained from a differential equation of exponent difference 2, involving the radial strain. Except for small differences, Honegger's results can be verified from the tables at the end of this paper by introducing factors of proportionality which are finally absorbed in the arbitrary constants of the general solution. The point of view assumed here in deriving the basic differential equation parallels Martin's analysis which gives the stress coefficients directly without transformation.

Derivation of Differential Equation (4)

In Fig. 1, let p and q denote mean radial and hoop stresses at r, and let the variable thickness be $2h$ so that for a conical profile $2h = 2H(1 - r/R)$ where H is a constant. If ρ is the mass density of the material and ω the angular velocity of rotation in radians per second, there is obtained by equating forces acting on an infinitesimal element of volume

$$4hqdr \sin {}^1/_2(d\theta) - 2d(hrp)d\theta = 2\rho h\omega^2 r^2 dr d\theta \ldots\ldots [1]$$

$$(1 - r/R)q - (1 - 2r/R)p - r(1 - r/R)dp/dr = \rho\,(1 - r/R)\,r^2\omega^2 \ldots\ldots [2]$$

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

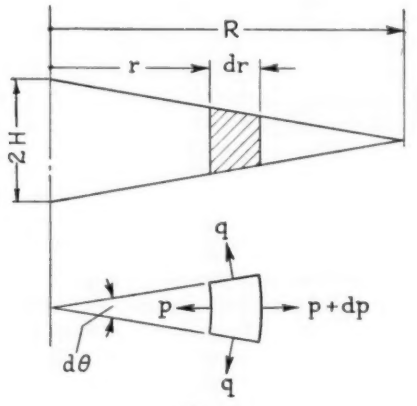

FIG. 1

The condition for compatibility between stress and strain requires

$$p - \sigma q = d/dr(rq - \sigma rp) \quad \ldots\ldots [3]$$

where σ is Poisson's ratio.
Differentiating Equation [2] and setting $r = Rx$ gives

$$x\frac{d^2p}{dx^2} - \frac{3x-2}{1-x}\cdot\frac{dp}{dx} - \frac{dq}{dx} - \frac{p}{(1-x)^2} = -2\rho R^2\omega^2 x \quad \ldots [4]$$

The result of eliminating q and dq/dx from Equations [2], [3], and [4], after making the substitution $P = (1-x)p$ is

$$x(1-x)\frac{d^2P}{dx^2} + (3-2x)\frac{dP}{dx} + (1-\sigma)P = -(3+\sigma)\rho R^2\omega^2 x(1-x) \quad \ldots [5]$$

the left-hand side of which is recognized to be of hypergeometric type, such as (reference 5)

$$x(1-x)\frac{d^2P}{dx^2} + [c-(a+b+1)x]\frac{dP}{dx} - abP = 0 \quad \ldots [6]$$

where $c = 3$, $a + b = 1$, and $ab = \sigma - 1$.
The substitution of $1 - x = t$ in Equation [6] gives

$$t(1-t)\frac{d^2P}{dt^2} + [a+b+1-c-(a+b+1)t]\frac{dP}{dt} - abP = 0 \quad \ldots\ldots [7]$$

the convenience of which will appear later. Since c is independent of σ, the numerical value of c will be used in the remaining equations, except when it is desired to emphasize general characteristics of the hypergeometric function. Numerical calculations were made for fundamental solutions of Equation [6] and the stress coefficients with $\sigma = 0.24, 0.27, 0.30, 0.33$, and 0.36,[3] corresponding to positive values of x between zero and unity.

SOLUTIONS OF THE DIFFERENTIAL EQUATIONS

The general solution of Equation [5] is

$$P(x) = AP_1(x) + BP_2(x) + P_3(x) \quad \ldots\ldots [8]$$

where $P_1(x)$ and $P_2(x)$ are the complementary functions, and $P_3(x)$ is the particular integral. It can be verified by direct substitution or otherwise, that

$$P_3(x) = \rho\frac{R^2\omega^2(3+\sigma)}{11+\sigma}\left[x^3 - \frac{7+2\sigma}{5+\sigma}x^2 - \frac{1-\sigma}{5+\sigma}x + \frac{3}{5+\sigma}\right] \quad \ldots\ldots [9]$$

Referring to Equation [6] the stated relations between the elements a, b, 3, show that the roots of the indicial equation (reference 6) are 0 and -2. The integral which belongs to the exponent 0 is, in the notation of the hypergeometric function

$$F(a, b, 3, x) = S_1(x) = 1 + \frac{a.b}{1\cdot 3}x + \frac{a(a+1)b(b+1)}{1\cdot 2\cdot 3\cdot 4}x^2 + \ldots \quad \ldots\ldots [10]$$

$$\text{Coefficient of } x^n = u_n = \frac{2(a+n-1)\ldots a(b+n-1)\ldots b}{n!(n+2)!} = \frac{2(n+1)}{n+2}\cdot\frac{\Gamma(n+a)\Gamma(n+b)}{\Gamma(a)\Gamma(b)[\Gamma(n+2)]^2} \quad \ldots\ldots [11]$$

The application of Stirling's expansion (7) to the general case yields

$$\lim_{n\to\infty} n^{c-a-b+1}u_n = \Gamma(c)/\Gamma(a)\Gamma(b)$$

The relation between the elements now gives

$$\lim_{n\to\infty} n^2 u_n = 2/\Gamma(a)\Gamma(b) = (2/\pi)\sin a\pi \quad \ldots\ldots [12]$$

since $a + b = 1$ and $\Gamma(a)\Gamma(b) = \pi \csc a\pi$. Comparison of series, Equation [10], with $\sum_{n=1}^{\infty} n^{-2}$ gives the remainder (8) after m terms to be

$$R_m < \frac{(m+2)x^m \sin a\pi}{\pi m^2} \quad \ldots\ldots [13]$$

which may be used to estimate the number of terms required to calculate $S_1(x)$ to any degree of accuracy for suitable values of x. Inspection of the remainder, term [13], shows that there is a value of $m > N_0$ for $|x| \leq 1$ which makes the sum of almost all of the terms in the series arbitrarily small. This proves that the series, Equation [10], is absolutely and uniformly convergent whenever $|x| \leq 1$.

The derived function may be obtained directly from $S_1(x)$ and satisfies the relation

$$d/dx\, S_1(x) = S_1'(x) = \frac{ab}{3}F(a+1, b+1, 4, x) \quad \ldots\ldots [14]$$

In exactly the same manner as before it is found that the remainder after m terms of the derived series is

$$R_m < \frac{2(m+1)x^m \sin a\pi}{\pi m^2}$$

so that this series also is absolutely and uniformly convergent in the interval $|x| \leq 1$.

The next solution in order of difficulty satisfies Equation [7]. In reality this solution is a function of x, but the algebra is simplified somewhat by using t for the independent variable where $1 - x = t$. The roots of the indicial equation are 0 and 2 and the corresponding integral of index 2 is

$$t^2F(a+2, b+2, 3, t) = S_2(t) = \frac{2t^2}{ab+2}\left[\frac{ab+2}{2} + \frac{(a+1)(b+1)}{1!3!}t + \frac{(a+1)(a+2)(b+1)(b+2)}{2!4!}t^2 + \ldots\right] \quad \ldots\ldots [15]$$

[3] Tables for $\sigma = 0.30$ and 0.36 are included in this paper. Copies of the remaining tables may be had on application to Fairbanks, Morse & Company, Beloit, Wis.

$$u_n = \frac{(n+a+1)\ldots(a+1)(n+b+1)\ldots(b+1)}{n!(n+2)!}$$

$$= \frac{n+1}{n+2} \cdot \frac{\Gamma(a+n+2)\Gamma(b+n+2)}{\Gamma(a+1)\Gamma(b+1)[\Gamma(n+2)]^2}$$

$$\lim_{n\to\infty} \frac{u_n}{n} = \frac{\sin a\pi}{\pi ab} \ldots\ldots\ldots [16]$$

The limiting form of the nth term of a hypergeometric series obeys a simple law (9) so that its asymptotic behavior for $\alpha + \beta - \gamma$ an integer exceeding zero is

$$F(x) \underset{x\to 1}{\sim} \frac{\Gamma(\gamma)\Gamma(\alpha+\beta-\gamma)}{\Gamma(\alpha)\Gamma(\beta)} (1-x)^{\gamma-\alpha-\beta} \ldots\ldots [17a]$$

when $\alpha + \beta = \gamma$

$$F(x) \underset{x\to 1}{\sim} \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)} \log_e \frac{1}{1-x} \ldots\ldots\ldots\ldots [17b]$$

The application of this theorem to series, Equation [15], shows that

$$S_2(t) \underset{t\to 1}{\sim} \frac{\Gamma(3)\Gamma(2)(1-t)^{-2}}{a(a+1)b(b+1)\Gamma(a)\Gamma(b)} = \frac{2\sin a\pi}{\pi ab(ab+2)(1-t)^2}$$

which is also the form of the remainder term when t approaches unity. A better approximation to the sum gives

$$S_2(t) = \frac{2t^2}{ab+2}\left[\sum_{n=0}^{m-1} u_n t^n + R_m\right] \ldots\ldots\ldots [18]$$

where

$$R_m < \frac{\sin a\pi}{\pi ab(1-t)}\left[m + \frac{t}{1-t}\right] t^m \ldots\ldots\ldots [19]$$

Similarly

$$S_2'(t) = \frac{2t}{ab+2}\left[\sum_{n=0}^{m-1} (n+2)u_n t^n + R_m\right] \ldots\ldots [20]$$

where

$$R_m < \frac{\sin a\pi}{\pi ab(1-t)}\left\{m(m+2) + \frac{(2m+3)t}{1-t} + \frac{2t^2}{(1-t)^2}\right\} t^m \quad [21]$$

The form of the remainders in Equations [19] and [21] is useful for obtaining greater numerical accuracy from a given number of terms in the series. The accuracy of R_m is equal to the number of significant figures common to $|u_{m-1} - u_m|$ and $\lim_{n\to\infty} \frac{u_n}{n}$.

The remainder, term [13], shows that series, Equation [10], converges so slowly near $x = 1$ that 100 terms would be required to approach an accuracy of 5 significant figures in the sum, while series, Equation [15], diverges when $t = 1$. As would be expected, these difficulties are increased when calculating the derivatives with infinite series for values of x or t near unity.

Numerical results, accurate to 8 significant figures for all positive values of $x \leq 1$ (exclusive of values where the functions are known to be infinite) can be obtained from series, Equations [10], [14], [15], and [20], together with the logarithmic solutions without exceeding 30 terms in any of the expansions involved. The logarithmic solutions introduce two more series which also converge rapidly when x and t are near zero. As a consequence of the relation $1 - x = t$ the latter two series may be used to construct a convenient form of the function for calculation with those values of x and t which previously were troublesome. For the purposes of numerical calculations it was found sufficient to restrict x and t to positive values between 0 and $^1/_2$ in all four series and their derivatives. The first step in the development of this procedure is the derivation of the logarithmic solutions of Equations [6] and [7].

Logarithmic Solutions

The second solution of Equation [7] involves logarithms (10) whenever the difference of the roots is an integer unless a or b is zero or a negative integer not less than $a + b + 1 - c$. According to the general theory, this solution is

$$\bar{S}_2(t) = -\frac{a(a+1)b(b+1)}{2} S_2(t) \log_e t + S_3(t) \ldots [22]$$

where

$$S_3(t) = 1 - abt - \sum_{n=2}^{\infty} \frac{(n-1+a)\ldots a(n-1+b)\ldots b}{n!(n-2)!} t^n \Phi_n$$

$$\ldots\ldots [23]$$

and

$$\Phi_n = \frac{1}{a} + \ldots + \frac{1}{a+n-1} + \frac{1}{b} + \ldots + \frac{1}{b+n-1}$$

$$-1 - \frac{1}{2} - \ldots - \frac{1}{n-2} - 1 - \frac{1}{2} - \ldots - \frac{1}{n} \ldots [24]$$

or

$$\Phi_n = \psi(n-1+a) + \psi(n-1+b) - \psi(n-2) - \psi(n) \ldots [25]$$

The expression for the limiting form of the nth term of $S_3(t)$ requires the evaluation of $\lim_{n\to\infty} \Phi_n$ which can be done with the aid of the logarithmic derivative of the gamma function. The necessary relations are (11, 12), for positive argument,[4] x

$$\Psi(x) = \frac{\Gamma'(x+1)}{\Gamma(x+1)} = -\gamma + \lim_{n\to\infty} \sum_{m=1}^{n} \left(\frac{1}{m} - \frac{1}{m+x}\right) \ldots [26]$$

where $\gamma = 0.577{,}215{,}665 \ldots$ (Euler's constant).
Numerical values of $\Psi(x)$ are obtained readily from the formulas

$$\Psi(x) = \log_e x + \frac{1}{2x} - \frac{1}{12x^2} + \frac{1}{120x^4} - \frac{B_3}{6x^6} + \frac{B_4}{8x^8} - \ldots [27]$$

where the B's are Bernoulli's numbers. When n is an integer

$$\Psi(x+n) = \Psi(x) + \left[\frac{1}{x+1} + \ldots + \frac{1}{x+n}\right] \ldots [28]$$

and generally

$$\Psi(-x) = \Psi(x-1) + \pi \cot \pi x \ldots\ldots\ldots [29]$$

Equation [28] may be used when increasing the argument to a convenient value for calculation with Equation [27]. Equation [29] is used in conjunction with the relation $a + b = 1$.

The form of $\lim_{n\to\infty} \Phi_n$ suitable for numerical evaluation now becomes

$$\lim_{n\to\infty} \Phi_n = 2\left[\frac{1}{a} - \gamma - \Psi(a)\right] - \pi \cot a\pi \ldots\ldots [30]$$

[4] Not to be confused with r/R.

Also

$$\lim_{n\to\infty}\frac{u_n}{n}=\lim_{n\to\infty}\frac{(n-1+a)\dots a(n-1+b)\dots b}{n!(n-2)!n}=\frac{\sin a\pi}{\pi}\qquad\dots\dots[31]$$

After some reduction, the approximate value of $S_3(t)$ is

$$S_3(t)=1-abt-\left[\sum_{n=2}^{m-1}u_nt^n\Phi_n+R_m\right]\qquad\dots\dots[32]$$

$$R_m<\lim_{n\to\infty}\frac{u_n\Phi_n}{n}\left(m+\frac{t}{1-t}\right)\frac{t^m}{1-t}\qquad\dots\dots[33]$$

and

$$S_3'(t)=-ab-\left[\sum_{n=2}^{m}nu_nt^{n-1}\Phi_n+R_m\right]\qquad\dots\dots[34]$$

$$R_m<\lim_{n\to\infty}\frac{u_n\Phi_n}{n}\left\{m(m+2)+\frac{(2m+3)t}{1-t}+\frac{2t^2}{(1-t)^2}\right\}\frac{t^m}{1-t}\qquad\dots\dots[35]$$

The $\lim_{n\to\infty}\frac{u_n\Phi_n}{n}$ is the product of the limits given by Equations [30] and [31]. The accuracy of R_m is the same as in Equations [19] and [21].

Returning to Equation [6], with suitable restrictions on the elements (10), the general theory yields a second solution in the form

$$\bar{S}_1(x)=-\frac{ab(ab+2)}{2}S_1(x)\log_e x+\frac{1}{x^2}-\frac{ab+2}{x}-S_4(x)\qquad[36]$$

$$S_4(x)=\sum_{n=2}^{\infty}\frac{(n+a-3)\dots(a-2)(n+b-3)\dots(b-2)}{n!(n-2)!}\times x^{n-2}\Phi_n\qquad\dots\dots[37]$$

$$\Phi_n=\psi(n-3+a)+\psi(n-3+b)-\psi(n-2)-\psi(n)\qquad[38]$$

$$\lim_{n\to\infty}\Phi_n=\frac{1}{a-2}+\frac{1}{a-1}+\frac{1}{a}-\frac{1}{a+1}-2\gamma-2\Psi(a)-\pi\cot a\pi\qquad\dots\dots[39]$$

$$\lim_{n\to\infty}n^3u_n=\frac{ab(ab+2)\sin a\pi}{\pi}\qquad\dots\dots[40]$$

The remainder after m terms is

$$R_m<\frac{(m+2)x^m}{2m^3}\lim_{n\to\infty}n^3u_n\Phi_n\qquad\dots\dots[41]$$

where $\lim_{n\to\infty}n^3u_n\Phi_n$ is equal to the product of the limits, Equations [39] and [40]. Similarly the remainder for the derived series $S'_4(x)$ is

$$R_m<\frac{(m+1)x^m}{m^3}\lim_{n\to\infty}n^2u_n\Phi_n\qquad\dots\dots[42]$$

Equations [41] and [42] show that both $S_4(x)$ and $S_4'(x)$ are absolutely and uniformly convergent whenever $|x|\leq 1$.

Linear Dependence of the Solutions

The four solutions, Equations [10], [15], [22], and [36] are linearly dependent since they satisfy two second-order differential equations which are connected by a linear transformation that does not alter the common interval of convergence. This property enables the functions of arguments t and x to be correlated by a proper choice of the constants of integration. The elementary method (13) used to obtain these constants depends upon the asymptotic form of the hypergeometric function in the neighborhood of its poles.

Since $1-x=t$, the general solution involving $S_2(t)$ and $\bar{S}_2(t)$ is identically equal to $S_1(x)$ in the interval between zero and unity; that is

$$P(t)=C_2S_2(t)+C_1\bar{S}_2(t)=S_1(x)\qquad\dots\dots[43]$$

where C_1 and C_2 are determined by the following conditions (reference 14):

$$\lim_{t\to0}P(t)=\lim_{x\to1}S_1(x)=\frac{2\sin a\pi}{\pi ab(ab+2)}\qquad\dots\dots[44]$$

$$\lim_{t\to1}P(t)=\lim_{x\to0}S_1(x)=1\qquad\dots\dots[45]$$

Equations [22], [43], and [44] show that

$$C_1=(2\sin a\pi)/\pi ab(ab+2)$$

The remainder formulas [19] and [33] show that $S_2(t)$ and $\bar{S}_2(t)$ have the same order of singularity at $t=1$. The constant C_2 may be chosen so that $\lim_{t\to1}P(t)$ remains finite and satisfies Equation [45]. After some reduction it is found that

$$C_2=\frac{2\sin a\pi}{\pi}\left[\frac{1}{a}-\gamma-\Psi(a)\right]-\cos a\pi\qquad\dots\dots[46]$$

Equations [8] and [43], together with the relation $1-x=t$ give

$$AP_1(x)=AS_1(x)\qquad\dots\dots[47a]$$

$$=A\left\{C_2S_2(1-x)+C_1\bar{S}_2(1-x)\right\}\qquad\dots\dots[47b]$$

Equation [47a] converges very rapidly near $x=0$, while Equation [47b] does the same near $x=1$, which is precisely the most desirable characteristic for making numerical calculations.

The second solution is treated in a similar manner. Let the general solution with argument x be

$$P(x)=C_3S_1(x)+C_4\bar{S}_1(x)\qquad\dots\dots[48]$$

subject to the conditions

$$\lim_{x\to0}P(x)=\lim_{t\to1}S_2(t)\sim\frac{C_4}{(1-t)^2};\quad\lim_{x\to1}P(x)=\lim_{t\to0}S_2(t)=0\qquad\dots\dots[49]$$

Equation [17a] shows that C_4 remains unchanged. Furthermore Equations [14] and [17b] show that $S_1''(x)$ and $\bar{S}_1''(x)$ have a logarithmic singularity at $x=1$ and $\lim_{t\to0}S_2''(t)$ is finite, which gives

$$C_3=\frac{\sin a\pi}{\pi}\lim_{n\to\infty}\Phi_n\qquad\dots\dots[50]$$

where $\lim_{n\to\infty}\Phi_n$ is evaluated by Equation [39]. Equations [8] and [48], together with the relation $1-x=t$ show that

$$BP_2(x)=BS_2(1-x)\qquad\dots\dots[51a]$$

$$=B\left\{C_3S_1(x)+C_4\bar{S}_1(x)\right\}\qquad\dots\dots[51b]$$

which readily is seen to be a convenient form for numerical work. The derivatives with respect to x now can be calculated directly from Equations [47a], [47b], [51a], and [51b].

Stress Calculations

From Equation [2] with $r=Rx$ the relations between P and Q are found to be

$$\left.\begin{aligned} Q_1 &= P_1 + x dP_1/dx \\ Q_2 &= P_2 + x dP_2/dx \\ Q_3 &= P_3 + x dP_3/dx + \rho R^2\omega^2 x^2(1-x) \end{aligned}\right\} \ldots\ldots [52]$$

where $P = (1-x)p$ and $Q = (1-x)q$. Equations [52] give the "stress coefficients"

$$\left.\begin{aligned} p_1 &= P_1/C_1(1-x) \qquad q_1 = Q_1/C_1(1-x) \\ p_2 &= -P_2/(1-x) \qquad q_2 = -Q_2/(1-x) \\ p_3 &= \frac{3+\sigma}{11+\sigma}\left[-x^2 + \frac{2+\sigma}{5+\sigma}x + \frac{3}{5+\sigma}\right] \\ q_3 &= \frac{3+\sigma}{11+\sigma}\left[-\frac{1+3\sigma}{3+\sigma}x^2 + \frac{1+2\sigma}{5+\sigma}x + \frac{3}{5+\sigma}\right] \end{aligned}\right\} \ldots [53]$$

which express the stresses p and q in the following form

$$p = Ap_1 + Bp_2 + \rho R^2\omega^2 p_3 \ldots\ldots [54]$$

$$q = Aq_1 + Bq_2 + \rho R^2\omega^2 q_3 \ldots\ldots [55]$$

Numerical values of the fundamental solutions of the hypergeometric Equation [6] were tabulated for the values of Poisson's ratio (σ) designated in the titles of the tables. The corresponding tables of stress coefficients were calculated from Equations [53] and tabulated at intervals of $r/R = 0.01$ between zero and unity. The tables are accurate to within 5 parts in 2,000,000. Slide-rule accuracy is obtainable from linear interpolation of the tabulated values. If greater accuracy is required for intermediate values, interpolation methods may be used. References (15), (16), and (17) may be consulted with advantage in this connection.

Illustrative Example

An aluminum supercharger rotor, the details of which are shown in Fig. 2, was calculated by replacing the actual disk profile with (I) a system of disks of uniform thickness, and (II) a system of conical profiles. In both cases Poisson's ratio was taken as 0.36 with $\rho = 2.5904 \times 10^{-4}$ for $r < 5^3/_8$ in. and $\rho = 3.6180 \times 10^{-4}$ when $r > 5^3/_8$ in. to compensate for the mass of the vanes.[5]

The tabular solutions about to be described were made for $\omega = 1000$, in order to simplify the calculations. The stresses for any other value of ω are obtained by multiplying the results for $\omega = 1000$ by $\omega^2 \times 10^{-6}$.

Case I. Method of Uniform Disks:

These calculations depend upon the following general formulas for mean radial and tangential stresses in a uniform rotating disk (18)

$$\left.\begin{aligned} p &= A - B/r^2 - {}^1/_8(3+\sigma)\rho\omega^2 r^2 \\ q &= A + B/r^2 - {}^1/_8(1+3\sigma)\rho\omega^2 r^2 \end{aligned}\right\} \ldots\ldots [56]$$

Let r_n be the radius to the nth boundary between approximating disks of different thicknesses, then if p'_n, q'_n and p''_n, q''_n are the corresponding radial and tangential stresses on the material outside and inside of this boundary, respectively, Equations [56] give

$$\left.\begin{aligned} p''_{n+1} + q''_{n+1} &= p'_n + q'_n - {}^1/_2(1+\sigma)\rho\omega^2(r^2_{n+1} - r_n^2) \\ p''_{n+1} - q''_{n+1} &= (p'_n - q'_n)r_n^2/r^2_{n+1} \\ &\quad - {}^1/_4(1-\sigma)\rho\omega^2(r^2_{n+1} - r_n^2)(1 + r^2_n/r^2_{n+1}) \end{aligned}\right\} \ldots [57]$$

Denoting by h_n one half the thickness of the disk whose inner and outer radii are r_n and r_{n+1}, respectively, the following relations are satisfied by the stresses on either side of the $(n+1)$th boundary:

$$\left.\begin{aligned} h_{n+1}p'_{n+1} &= h_n p''_{n+1} \\ q'_{n+1} &= \sigma(h_n/h_{n+1} - 1)\,p''_{n+1} + q''_{n+1} \end{aligned}\right\} \ldots\ldots [58]$$

Equations [57] and [58] can be arranged conveniently for tabular solution in a manner analogous to Donath's sum-and-difference method (18).

Table 1 contains the calculation factors which depend only upon the configuration of the disk, the angular velocity, and the material. The solution for the stresses is obtained by using these factors to calculate Table 1(a) with assumed values of q'_1 for any particular value of p'_1 determined by the hub fit. Calculations with Table 1(a) are repeated until a value of q'_1 has been found which makes the final value of p'' equal to the known radial stress at the periphery of the disk. A refinement of this method (18) makes it possible to obtain the final stresses from three calculations with Table 1(a).

Let it be assumed that the choice of $(q'_1)_1$ does not give the known peripheral stress p_{14}. A suitable static stress distribution which will reduce $(p''_{14})_1$ to its proper value by superposition is obtained as follows:

Table 1(a) is worked out for an arbitrary value of q'_1 say $(q'_1)_2$ with $\omega = 0$, which requires the omission from the calculation of the factors in columns 9 and 10 of Table 1. The final stress distribution which produces the required radial stress at the periphery of the disk is

$$q'_n = (q'_n)_1 + (q'_n)_2\left[\frac{p_{14} - (p''_{14})_1}{(p''_{14})_2}\right] \ldots\ldots [59]$$

together with an analogous equation for p'_n. This stress system

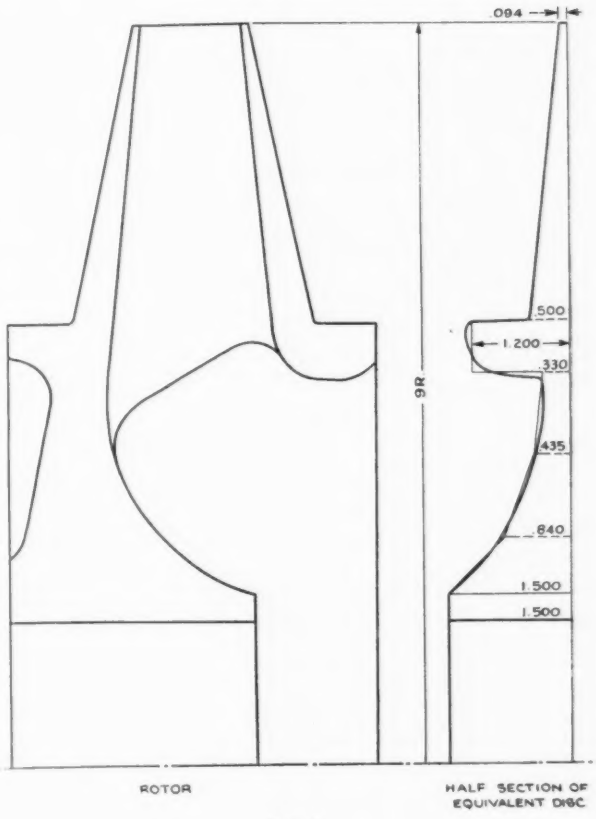

Fig. 2

[5] It is not the purpose of this example to justify the method of determining the equivalent disk.

satisfies the boundary conditions when substituted in Table 1(a) with the original value of ω.

The column numbers from Table 1 have been continued through Table 1(a) to avoid confusion. Table 1(a) appears here in its final form where the last value of $p''_{14} = 1$ which is sufficiently near zero for the number of significant figures carried in the calculation.

Case II. Method of Equivalent Conical Profiles:

This method is based on the replacement of the actual disk by portions of cones, as shown in Fig. 2. Let r_{n+1} be the radius to the intersection of the conical surfaces, whose base radii are R_n and R_{n+1} (Fig. 3), respectively. Using the notation of Case I for boundary stresses, Equations [54] and [55] become

$$\left.\begin{aligned} p'_n &= A_n p'_{1n} + B_n p'_{2n} + \rho R_n^2\omega^2 p'_{3n} \\ q'_n &= A_n q'_{1n} + B_n q'_{2n} + \rho R_n^2\omega^2 q'_{3n} \end{aligned}\right\} \quad \ldots\ldots [60]$$

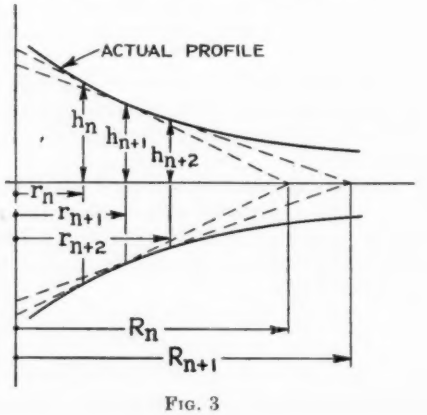

FIG. 3

$$\left.\begin{aligned} p''_{n+1} &= A_n p''_{1n} + B_n p''_{2n} + \rho R_n^2\omega^2 p''_{3n} \\ q''_{n+1} &= A_n q''_{1n} + B_n q''_{2n} + \rho R_n^2\omega^2 q''_{3n} \end{aligned}\right\} \quad \ldots [61]$$

If some of the approximating sections are cylinders, Equations [56] can be expressed in the foregoing form by making the following changes, which were applied to lines 1 and 5 of Table 2.

$$\left.\begin{aligned} p'_{1n} &= q'_{1n} = 1 & p''_{1n} &= q''_{1n} = 1 \\ -p'_{2n} &= q'_{2n} = 1/r^2_n & -p''_{2n} &= q''_{2n} = 1/r^2_{n+1} \\ p'_{3n} &= -1/8(3+\sigma) & p''_{3n} &= p'_{3n}\cdot r^2_{n+1}/r^2_n \\ q'_{3n} &= -1/8(1+3\sigma) & q''_{3n} &= q'_{3n}\cdot r^2_{n+1}/r^2_n \\ R_n &= r_n & R_n &= r_n \end{aligned}\right\} \quad \ldots [62]$$

The twelve quantities $p'_{1n}, \ldots q'_{3n}, p''_{1n}, \ldots q''_{3n}$ appearing in Equations [60] and [61] are obtained from the tables of stress coefficients. The argument for the singly primed quantities is r_n/R_n, while that for the doubly primed ones is r_{n+1}/R_n. The calculation consists of finding A_n and B_n from Equations [60] which values in turn are used to calculate p''_{n+1} and q''_{n+1} with Equations [61]. Following this calculation, p'_{n+1} and q'_{n+1} are found by Equations [58] where h_n and h_{n+1} now are replaced by the half thicknesses of the disk at $r_{n+1} - 0$ and $r_{n+1} + 0$, respectively. This process then is repeated with the indices increased by unity each time until the periphery is reached where the radial stress is known.

The solution can be arranged conveniently in tabular form, as shown in Table 2, where columns 1 to 23, inclusive, contain all necessary calculation constants which do not depend upon the stresses. Columns 7 to 18, inclusive, except lines 1 and 5, were obtained by linear interpolation from the tables of stress coefficients for $\sigma = 0.36$. Beginning with the assumed value of $(q'_1)_1 = 12{,}000$ and $(p'_1)_1 = 0$, the first approximation to the stresses was obtained with Table 2(a). The static stress dis-

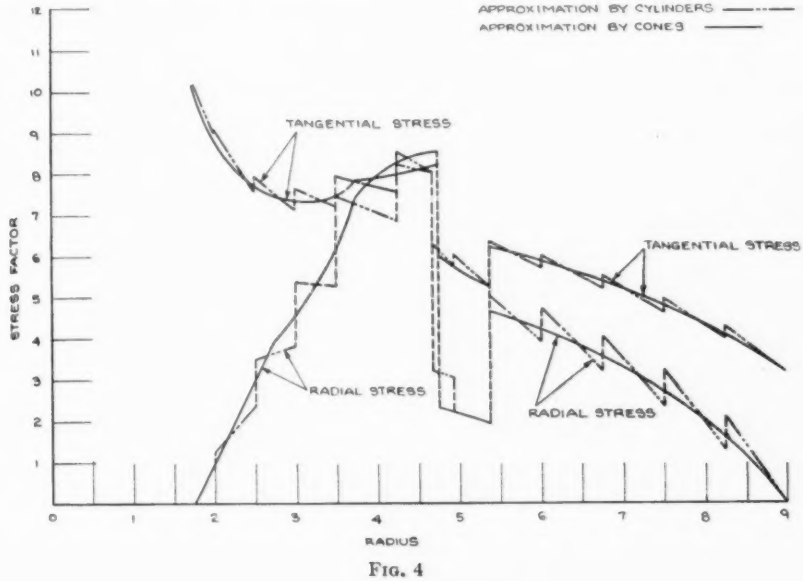

FIG. 4

tribution for $(q'_1)_2 = 1000$ and $(p'_1)_2 = 0$ with $\omega = 0$ was calculated with Table 2(*b*). The resultant stress distribution could have been obtained by interpolating columns 24, 25, 32, and 33 of Tables 2(*a*) and 2(*b*) with Equation [59]; however, a recalculation with Table 2(*c*), using $p_1' = 0$ and $q'_1 = 12{,}000 + (0 - 8407) \times 1000/4370 = 10{,}076$ and $\omega = 1000$ gives this information and at the same time provides a final check on all of the numerical work.

These calculations show that the advantages obtainable by approximating an arbitrary disk profile with portions of cones are as follows:

1 There are no discontinuities in the final stress-distribution curve except those caused by an abrupt change in the actual profile.

2 Considerably fewer steps are required than with the uniform-disk method.

Studies in Three-Dimensional Photoelasticity

Stresses in Bent Circular Shafts With Transverse Holes—Correlation With Results From Fatigue and Strain Measurements

By M. M. FROCHT,[1] PITTSBURGH, PA.

Bent circular shafts with holes in the plane of bending are of frequent occurrence in modern machines. They often form a part of the lubricating system as, for example, in the crankshafts of aircraft engines. Considerable work has been done to determine the maximum stresses and the factors of stress concentration in such shafts. The author presents a simple method of calculating such stresses for transverse holes in pure bending. Experimental photoelastic evidence that led to this method is given. A comparison of the stress-concentration factors obtained by it is made with the published results from fatigue tests and strain measurements from large steel shafts, which were performed a number of years ago at the Westinghouse Research Laboratories.

Introduction

IN this paper are reported the results of a photoelastic investigation of the stress concentrations produced around open transverse holes in circular shafts which are subjected to pure bending, the axis of the hole and the bending couples being in one plane with the axis of the shaft. This problem is not only of scientific interest but is also of practical importance. Open holes in shafts often form a part of the lubricating system of a machine. The oil holes in crankshafts are one example. Considerable research work in that direction has already been done by means of strain gages and fatigue tests.[2] The development of three-dimensional photoelasticity makes it possible to study this problem by the optical method. Some work on this problem has been done by Hetényi.[3]

Method and Models. The method employed was that of freezing or fixing the stresses into a Bakelite model and subsequently cutting it into slices for individual observation in the polariscope.[4] The model shafts were all of Bakelite BT-61-893, approximately 1 in. diam and 7 in. long. They were heated for 2 to 3 hr, and slowly cooled under load to room temperature, the time of cooling being about 12 to 14 hr. A typical frozen stress pattern of a shaft as a whole is shown in Fig. 1. All sections were made perpendicular to the axis of the hole, so that each section represented a plate with a central transverse circular hole. The general dimensions of the models and the manner of slicing will be shown later.

(D = 0.980 in.; r = 0.110 in.; r/d = 0.145, initial dimensions; M = 2.57 lb-in.)

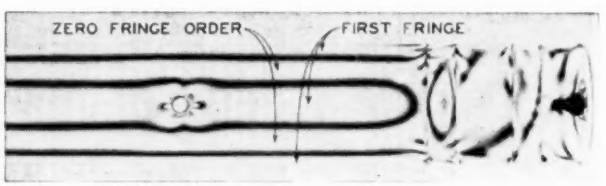

FIG. 2 FROZEN STRESS PATTERN OF A CIRCULAR SHAFT WITH TRANSVERSE HOLE IN PURE BENDING VIEWED WITH LIGHT PARALLEL TO AXIS OF HOLE
(Plane of bending was also parallel to axis of hole. D = 1.058 in.; r = 0.065 in.; r/d = 0.070; M = 3.33 lb-in.)

Boundary Difficulties. The greatest difficulty in studying stress concentrations photoelastically is the difficulty of making the boundaries and the boundary stresses visible, especially at the sources of stress concentration. Unfortunately, these difficulties, which have been successfully disposed of in two-dimensional problems, recur again in three-dimensional work.[5]

The causes of the present boundary disturbances are (1) time stresses, resulting from the relatively long period of time needed for heating, cooling, and machining, and (2) the inevitable deformations and distortions which are present in three-dimensional problems. The presence of time stresses is clearly shown in the stress pattern, Fig. 2. The region in pure bending would all be of zero fringe order were it not for the initial stresses. In view of the care which was taken in the machining of the model the observed effects are in the main due to time stresses.

The use of thin plates or sections effectively removes the shadows or space effects. We have used slices as thin as $^1/_{16}$ in. with fairly good results. When very thin plates are employed, it may

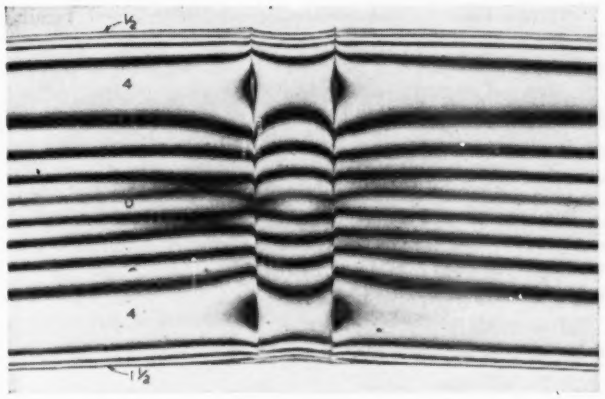

FIG. 3 ENLARGED VIEW OF SECTION AT HOLE OF FROZEN STRESS PATTERN OF CIRCULAR SHAFT WITH TRANSVERSE HOLE IN PURE BENDING

(D = 0.980 in.; r = 0.110 in.; r/d = 0.145, initial dimensions; M = 2.57 lb-in.)

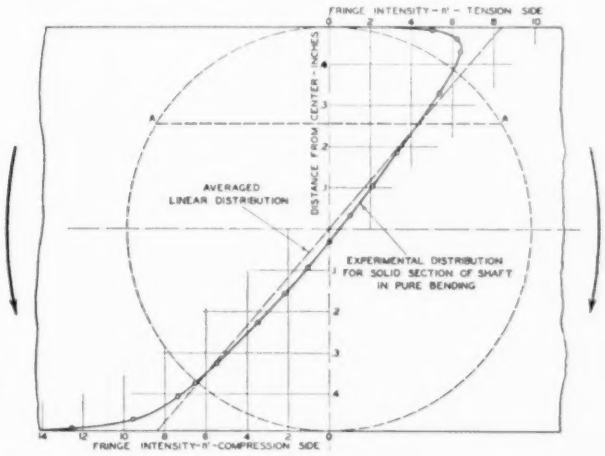

FIG. 4 CURVE SHOWING EFFECT OF TIME STRESSES ON FRINGE INTENSITY, I.E., STRESS IN FRINGES, IN A CIRCULAR SHAFT WITH TRANSVERSE HOLE IN PURE BENDING AT A SECTION AWAY FROM INFLUENCE OF HOLE

(Plotted from stress pattern shown in Fig. 3.)

become necessary to resort to the doubling polariscope, or the Babinet compensator.

Method of Loading. Some difficulty was encountered in producing pure bending. The best alignment was obtained when the metal clevices were replaced by loops of twine or strong string. These were formed into closed bands, put through the holes in the bars of the loading frame, and the ends slipped over the pins passing through the bar. In order to eliminate axial stresses the strings should be fairly long. It should perhaps be added that even greater difficulties are encountered in producing uniform tension or compression.

Fringe Order. In the case of pure bending, the fringe order can be readily determined at every point of the shaft. This is due to the presence of a neutral surface along the middle region of the shaft, which can be used as a reliable origin from which the fringe order at any other point can be determined. The fringe orders are shown in Fig. 3. It should be noted that although the extreme fibers are also of zero fringe order they are not reliable origins. The distances from these edges to the first fringe may be too small for this fringe to be clearly visible in the stress pattern. Inspection of Fig. 3 shows that on the compression side the lowest discernible fringe is of order 1½, although on the tension side it is ½. These difficulties increase under higher loads and are especially troublesome in shafts in pure tension where the zero fringe order is confined to the edges.

The differences in the spacings of the fringes on opposite sides of the shaft is due to the time stresses, which form in Bakelite models after several hours.

Fringe Value. It will be shown later that in the problem under consideration the factor of stress concentration is independent of the fringe value, or more precisely this factor can be determined without the fringe value. Should the fringe value be desired it can be calculated from the established fringe order; care must be taken, however, to eliminate the effect of the time stresses. In the case of pure bending the mean values from the fringe orders on the tension and compression sides cancel effectively the time stresses and yield a good approximation to the true fringe value. In the case of a shaft in tension the determination of the true fringe value is considerably more involved.

The full curve of Fig. 4 shows the effect of the time stresses on the fringe intensities n', which are defined as the number of fringes per unit of thickness measured along a line parallel to the direction of the light, i.e., parallel to the neutral axis in a transverse section of the shaft, such as line A-A. Owing to the fact that the time stresses are compressive on the surface of the shaft, the boundary stresses are considerably reduced on the tension side and increased on the compression side. The mean values of the fringe intensities on opposite sides of the neutral surface fall very close to the straight dashed line in Fig. 4.

Experiments show that in order to bring a shaft 1 in. diam to a uniform temperature at which the primary bonds alone function it is necessary to heat the model considerably above 230 F, which temperature was found sufficient for a bar ¼ in. thick for two-dimensional purposes. We found a temperature of about 260 to 265 F, and a heating time of about 2 hr, to give satisfactory results.

STRESS DISTRIBUTIONS AND FACTORS OF STRESS CONCENTRATIONS IN SHAFTS WITH TRANSVERSE HOLES IN PURE BENDING

Case 1: (r/d = 0.145)

D = diameter of shaft before loading = 0.980 in.

$2r$ = diameter of hole = 0.220 in.

d = $(D - 2r)$ = 0.760 in.

r/d = 0.145 (initial dimensions)

I_1 = moment of inertia of solid transverse section = 0.0453 in.⁴ (initial dimensions)

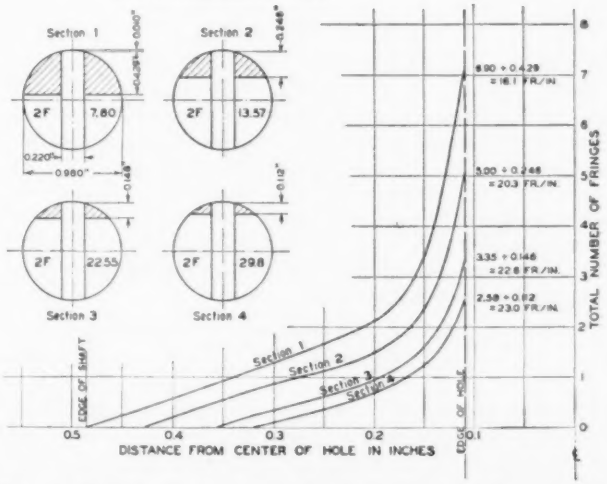

FIG. 5 CURVES OF $(p - q)$ AT SECTION OF HOLE FOR FOUR SUCCESSIVE PLATES TAKEN FROM TENSION SIDE OF CIRCULAR SHAFT WITH TRANSVERSE HOLE IN BENDING; r/d = 0.145

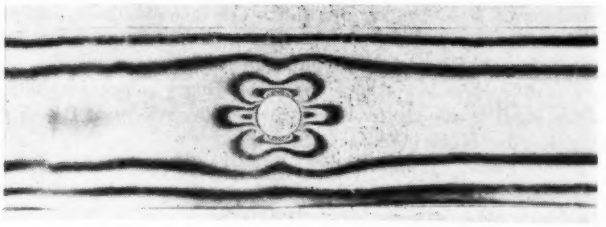

FIG. 6 FROZEN STRESS PATTERN OF TENSION HALF OF CIRCULAR SHAFT WITH TRANSVERSE HOLE IN PURE BENDING
$D' = 0.971$ in.; $r = 0.110$ in.; $r/d = 0.145$; $t = 0.430$; n_{max} [extrapolated] = 6.90 fringes.)

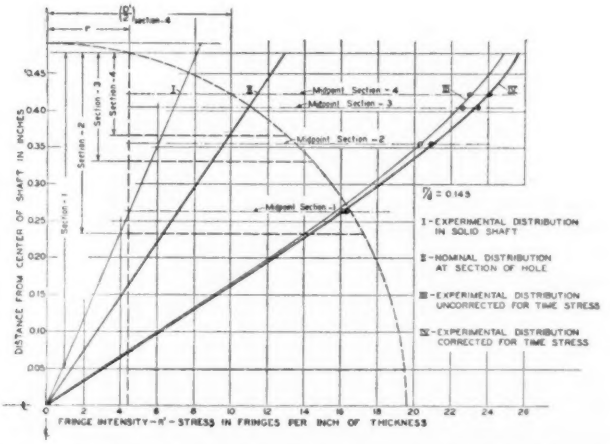

FIG. 7 CURVES SHOWING EXPERIMENTAL STRESS DISTRIBUTION AT SECTION THROUGH HOLE FOR TENSION SIDE AS DETERMINED FROM THE FOUR INDICATED PLATES; $r/d = 0.145$

I_2 = moment of inertia of transverse section through hole = 0.0286 in.^{4}, approx. (initial dimensions)
P = load = 3.50 lb
a = moment arm = 0.735 in. (final dimensions)
M = bending moment = 2.57 lb-in.
N_1' = maximum stress intensity in fringes at solid transverse section in pure bending = 8.3
N_2' = maximum stress intensity in fringes at transverse section through hole determined photoelastically = 25.5
$(N_2')_{\text{nominal}}$ = nominal maximum at hole = 12.8

Fig. 5 shows the dimensions of the four successive plates cut from the tension half of the shaft and the resulting curves of $(p - q)$. A typical stress pattern obtained from these plates is shown in Fig. 6. Fig. 7 shows the nominal and photoelastic stress distributions for a transverse section through the hole. Curve I gives the nominal stresses for a transverse section through a solid portion of the shaft in pure bending. This is the mean curve found in Fig. 4. Curve II of Fig. 7 is the nominal stress distribution through the hole. It is obtained from curve I by means of the simple relation

$$(n_2')_{\text{nominal}} = n_1' \frac{I_1}{I_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

in which n_2' and n_1' are, respectively, the nominal stresses in the same fiber in a solid section in pure bending and at a section through the hole. From Equation [1] it follows that

$$\left(N_2'\right)_{\text{nominal}} = N_1' \frac{I_1}{I_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

Curve III shows the photoelastically determined bending stresses at the hole. On plotting this curve the average fringe intensity obtained for a plate was placed at the mid-point of the plate. The curve obtained in this manner is straight for a considerable distance from the center of the shaft and does not differ radically from a straight line thereafter. The assumption that the mean stress intensity corresponds to the mid-point of the plate is therefore justified for all practical purposes. Curve IV gives the same data as curve III corrected for time stresses. The manner in which the correction is generally obtained in pure bending is shown in Figs. 4 and 11.

Case 2: $(r/d = 0.07)$
D = 1.058 in.
$2r$ = 0.13 in.
d = 0.928 in.
r/d = 0.07
I_1 = 0.0615 in.^{4}
I_2 = 0.049

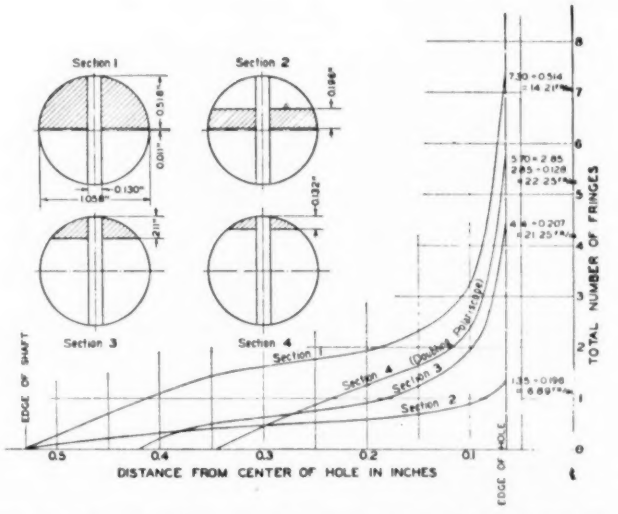

FIG. 8 CURVES OF $(p - q)$ AT SECTION THROUGH HOLE FOR FOUR PLATES TAKEN FROM TENSION SIDE OF CIRCULAR SHAFT WITH TRANSVERSE HOLE IN PURE BENDING; $r/d = 0.070$

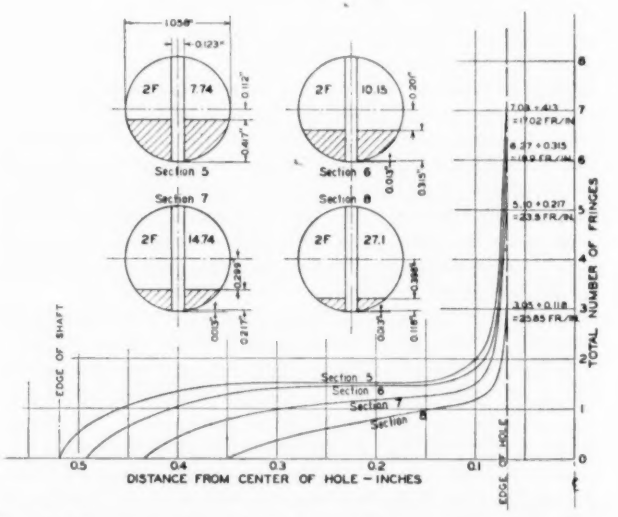

FIG. 9 CURVES OF $(p - q)$ AT SECTION THROUGH HOLE FOR FOUR SUCCESSIVE PLATES CUT FROM COMPRESSIVE SIDE OF CIRCULAR SHAFT WITH TRANSVERSE HOLE IN PURE BENDING; $r/d = 0.070$

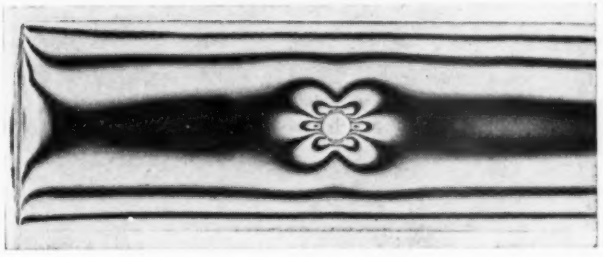

FIG. 10 FROZEN STRESS PATTERN OF TENSION HALF OF CIRCULAR SHAFT WITH TRANSVERSE HOLE IN PURE BENDING
(D' = 1.058 in.; r = 0.065 in.; r/d = 0.070; t = 0.518 in.; n_{max}, [extrapolated] = 7.30 fringes.)

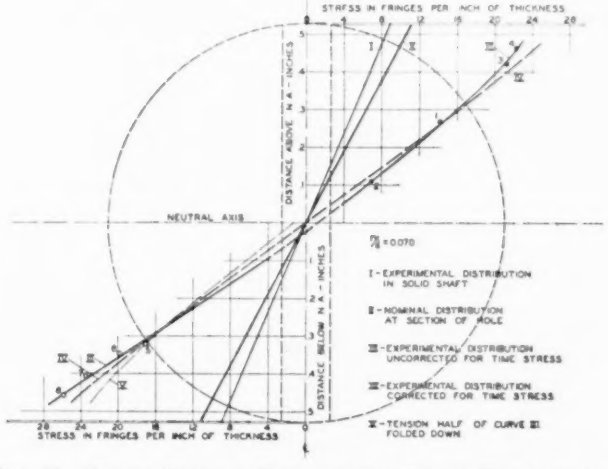

FIG. 11 CURVES SHOWING EXPERIMENTAL STRESS DISTRIBUTION AT SECTION OF HOLE IN CIRCULAR SHAFT WITH TRANSVERSE HOLE IN PURE BENDING; r/d = 0.070

P = 4.44 lb
a = 0.75 in.
M = Pa = 3.33 lb-in.
N_1' = 8.95 fringes per in.
N_2' = 26 fringes per in. at extreme fibers
$(N_2')_{nominal}$ = 11.2 fringes per in.

Figs. 8 and 9 show the plates cut from the tension and compression half, respectively, and the resulting curves of $(p - q)$. A typical stress pattern on which these curves are based is shown in Fig. 10. The resulting stress distribution is shown in Fig. 11.

Photoelastic Factors of Stress Concentration. By definition the factor of stress concentration k_3 is given by

$$k_3 = \frac{\sigma_{max}}{\sigma_{nominal}} \quad \ldots\ldots [3]$$

$$= \frac{N_2' \times 2f}{\frac{Mr}{I_2}} \quad \ldots\ldots [4]$$

in which $2f$ is the fringe value in tension or compression per inch of thickness. Remembering that

$$2f = \frac{Mr}{I_1 N_1'} \quad \ldots\ldots [5]$$

we obtain after substitution

$$k_3 = \frac{N_2' I_2}{N_1' I_1} \quad \ldots\ldots [6]$$

Using Equation [2], this becomes

$$k_3 = \frac{N_2'}{(N_2')_{nominal}} \quad \ldots\ldots [7]$$

Equation [6] shows that the factor of stress concentration k_3 can be calculated without the fringe value or bending moment, thereby eliminating one or two possible sources of error. The only experimental data needed to evaluate this factor are the maximum nominal fringe intensity N_1' in the solid portion of the shaft which is in pure bending and the maximum photoelastic fringe intensity N_2' at the hole. The ratio I_1/I_2 is taken from the initial dimension of the shaft and this may introduce a small error.

For purpose of calculation Equation [7] is the most convenient since both N_2' and $(N_2')_{nominal}$ are given directly by the curves of Figs. 7 and 11. Using these curves, we find that

$$(k_3)_{r/d = 0.145} = \frac{25.5}{12.8} = 1.98 \text{ approx.}$$

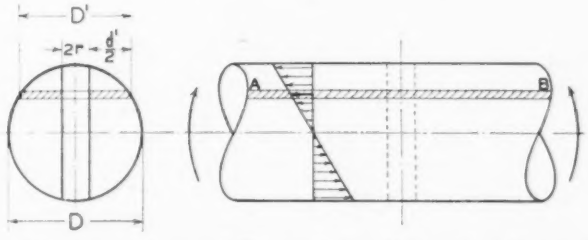

FIG. 12 SKETCH SHOWING NOTATION AND MEANING OF LAMINAR ACTION FOR CIRCULAR SHAFTS IN BENDING

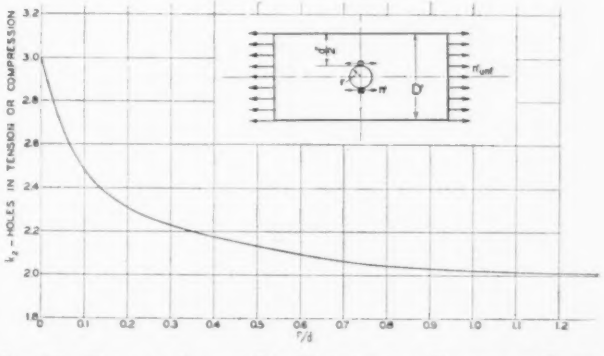

FIG. 13 CURVE OF k_2, THE TWO-DIMENSIONAL FACTORS OF STRESS CONCENTRATION, FOR HOLES IN TENSION OR COMPRESSION AS APPLIED TO A SINGLE PLATE OR LAMINA IN A CIRCULAR SHAFT WITH TRANSVERSE HOLE IN BENDING
(This curve can be found in author's paper "Photoelastic Studies in Stress Concentrations," *Mechanical Engineering*, vol. 58, 1936, pp. 485–489, or in "Strength of Materials," by N. C. Riggs and M. M. Frocht, Ronald Press Company, New York, N. Y., 1938.)

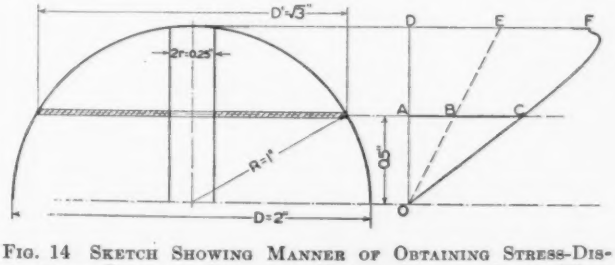

FIG. 14 SKETCH SHOWING MANNER OF OBTAINING STRESS-DISTRIBUTION CURVES AT SECTION OF HOLE IN CIRCULAR SHAFTS WITH TRANSVERSE HOLE IN BENDING BY APPLYING THE THEORY OF LAMINAR ACTION

and

$$(k_3)_{r/d\,=\,0.07} = \frac{26}{11.2} = 2.32, \text{ approx.}$$

A third case in which $r/d = 0.058$ was investigated and it gave a value of $k_3 = 2.16$.

In calculating these factors the experimental curves were extrapolated to the extreme fibers on the assumption that the maximum stresses occur there. It will be shown later that a strong probability exists that this assumption is not always true, and specifically that the maximum bending stress may actually be developed at a point some small distance away from the extreme fibers. The effect of this will be to reduce the factor k_3, for small values of r/d.

Theory of Laminar Action

The experimental results, shown in Figs. 7 and 11, can be explained by assuming:

1 That in transverse sections far from the hole the longitudinal stresses follow the linear distribution given by the elementary flexure formula

$$\sigma = \frac{My}{I} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [8]$$

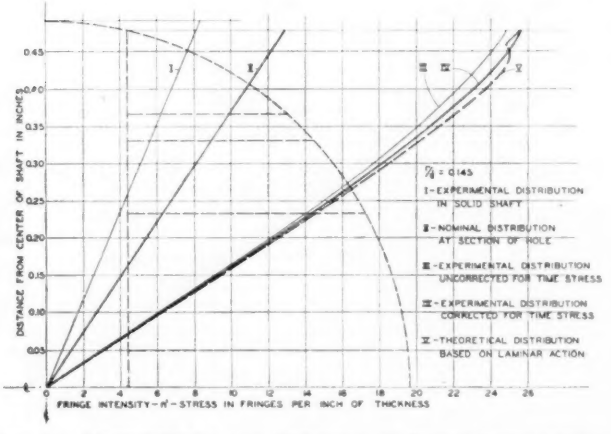

Fig. 15 Experimental and Theoretical Stress Distribution at Section of Hole in Circular Shaft in Pure Bending (Case 1: $r/d = 0.145$.)

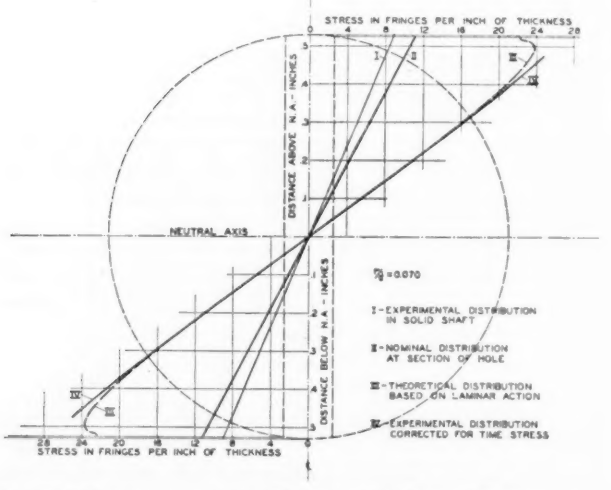

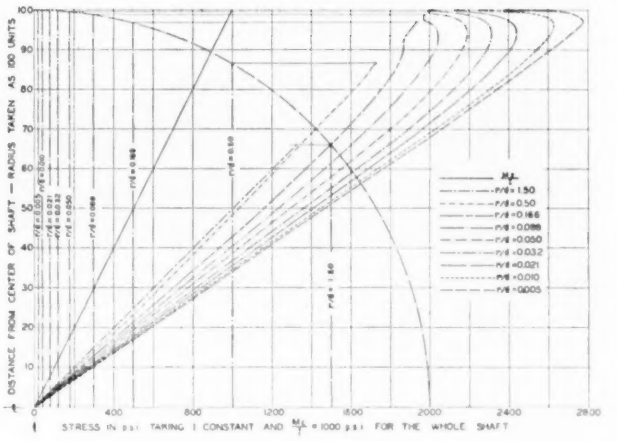

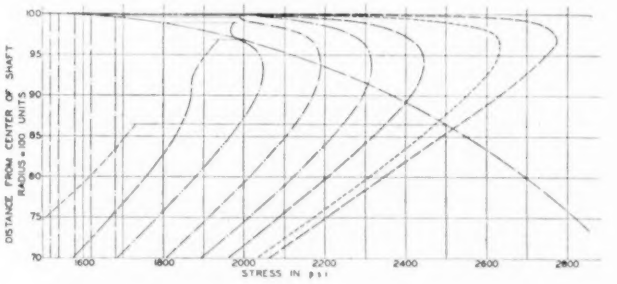

Fig. 16 Experimental and Theoretical Stress Distribution at Section of Hole in Circular Shaft in Pure Bending (Case 2: $r/d = 0.070$.)

(a)

(b)

Fig. 17 Curves Showing Distribution of Bending Stresses (a Curves giving theoretical stress distribution on assumption of laminar action at section of hole. Nine different values of r/d for circular shafts with transverse hole in bending are shown. b Enlargement of top portion of curves in a.)

2 That each thin plate, or lamina, parallel to the neutral surface behaves like a two-dimensional bar in pure tension or compression, Fig. 12.

One consequence of this assumption is that the factor of stress concentration around the hole in each plate is exactly the same as the two-dimensional factor k_2 for the same ratio r/d, Fig. 13.

As an illustration, consider a shaft 2 in diam with a $^1/_4$-in. hole, Fig. 14. At a point $^1/_2$ in. above the neutral axis, the length of the chord $D' = \sqrt{3}$, and $d' = D' - 2r = 1.482$ in. The corresponding r/d' is given by

$$\frac{r}{d'} = \frac{0.125}{1.482} = 0.0843 \text{ in.}$$

From the curve in Fig. 13, we find that the stress-concentration factor k_2 for this plate is 2.53, approximately. The maximum bending stress σ in this strip is then

$$\sigma = 2.53 \times \frac{My}{I}$$

The values of σ would then follow some such curve as OCF, Fig. 14, in which

$$\frac{AC}{AB} = (k_2)_{r/d' = 0.843} = 2.53$$

and

$$\frac{DF}{DE} = (k_2)_{r/d' = \infty} = 2$$

The stress distributions which follow from the foregoing assumptions, and the corresponding photoelastic values for $r/d = 0.145$ and $r/d = 0.070$, are shown in Figs. 15 and 16, respectively. The dashed curves represent the distribution from the assumption of laminar action. The other curves are the same as in Figs. 7 and 11.

The distribution of the bending stresses on the assumption of laminar action for nine different ratios of r/d are shown in Fig. 17 (a), and an enlarged view of the same curves in the proximity of the extreme fibers is shown in Fig. 17(b). Inspection of these curves shows that, for values of r/d less than 0.14, the maximum bending stresses may occur below the extreme fibers. It should, perhaps, be added that the assumption of laminar action satisfies the laws of equilibrium, since the resultant force in each separate lamina remains equal to that given by the flexure formula.

Factors of Stress Concentration on the Assumption of Laminar Action. Assuming laminar action the three-dimensional factors of stress concentrations k_3 would be given by

$$k_3 = \frac{k_2 \dfrac{My_m}{I_2}}{\dfrac{Mr}{I_2}}$$

or

$$k_3 = k_2 \frac{y_m}{r} \qquad [9]$$

in which y_m denotes the distance from the neutral axis to the point of maximum bending stress, in what we may briefly call the theoretical curves, and, for small holes, r equals the radius of the shaft approximately. Inspection of Fig. 17(b) shows that $(r - y_m)$ is very small. Thus for $r/d = 0.005$, $y_m = 0.995\,r$, and for $r/d = 0.9$, $y_m = 0.93\,r$ approx.

Since $\dfrac{y_m}{r}$ is never greater than unity it follows that k_3 is never greater than the maximum value of k_2. From two-dimensional studies we know that the maximum value of k_2 is 3. Hence assuming laminar action, k_3 cannot possibly exceed that value. For r/d greater than 0.14, the maximum bending stress occurs in the extreme fibers and $k_3 = 2$; and for r/d less than 0.14, k_3 is greater than 2.

Comparison With Results From Fatigue Tests and Strain Measurements. Factors of stress concentration k_3, based on the assumption of independent laminar action, i.e., on the curves of Fig. 17, are given by curve I of Fig. 18.

Superimposed over this curve are the three points from the photoelastic tests reported in this paper and seven additional points from fatigue tests and strain measurements determined by Peterson and Wahl.[2] Inspection of this curve shows that all but two, the points from fatigue tests from small shafts (0.5 in. diam), fall well on the curve.

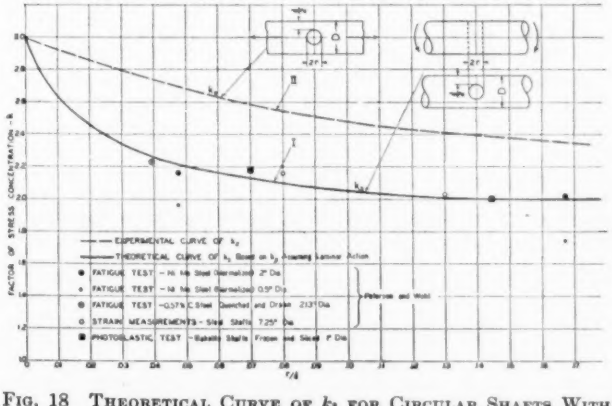

FIG. 18 THEORETICAL CURVE OF k_3 FOR CIRCULAR SHAFTS WITH TRANSVERSE HOLE, BASED ON THE THEORY OF LAMINAR ACTION WITH POINTS FROM A NUMBER OF TESTS MADE AT VARIOUS TIMES USING VARIOUS KINDS OF MATERIAL

(The three photoelastic tests are marked with solid squares.)

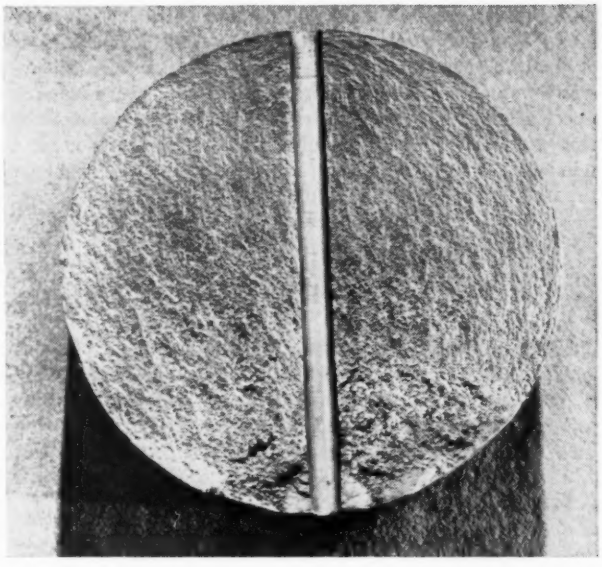

FIG. 19 PHOTOGRAPH OF FRACTURE OF A STEEL SHAFT SHOWING EVIDENCE THAT MAXIMUM STRESS OCCURS BELOW SURFACE OF SHAFT; NOTE CRACK NEAR TOP OF HOLE

($D = 3$ in.; $r = 0.187$ in.; $r/d = 0.0334$. Photograph by courtesy of R. E. Peterson, Westinghouse Electric & Manufacturing Co.)

Moreover there is some direct experimental evidence tending to show that in shafts with small holes the maximum stress is not developed in the extreme fibers but at points some distance below. Examination of fractures from fatigue tests seems to substantiate this conclusion. Fig. 19 shows one such fracture. Inspection of this illustration shows a crack on both sides of the hole well below the extreme fibers. Further, the position of this crack agrees substantially with that given by the theoretical curve for the same ratio r/d.

Returning now to the photoelastic results for curve II, in which $r/d = 0.07$, and assuming that the maximum bending stresses do not occur at the extreme fibers but at the points indicated by the theoretical curves, the factor k_3 from the photoelastic data would become

$$k_3 = \frac{24.4}{11.2} = 2.18$$

instead of the previously calculated 2.32. This value is in closer agreement with the results from fatigue tests and strain measurements, as well as with the curve based on laminar action.

Sources of Errors. Bakelite, which is a well-nigh perfect material, for two-dimensional models at room temperature, has several inherent weaknesses when used for three-dimensional problems. At high temperature it produces large deformations even under moderate stresses, it gives rise to annoying time stresses, and at present it is available only in blocks approximately 12 in. × 7 in. × 1 in. in size.

The main source of error in the work described in this paper arises from the first-mentioned weakness. In order to avoid large deformations and the resulting changes in the shape of the hole and in the value of r/d the bending moment was deliberately kept low. To compensate for the small stresses in the shaft, relatively thick plates or sections were employed. This in turn

obscured the true boundary and made it necessary to resort to extrapolation in the determination of the maximum fringe order at the hole. The main errors spring from the extrapolation. It will be observed, however, Figs. 5 and 9, that near the extreme fibers where the stresses are critical our plates were relatively thin and we employed a doubling polariscope to increase the number of fringes. The use of this plate will in general eliminate the need for extrapolation and should lead to a greater accuracy. But here the time stresses become a disturbing factor. In the problem under consideration the time stresses tend to cancel out and the errors due to this cause are probably small. The same conclusion holds for the error arising from the changes in the values of r/d.

Since the fringe value and the bending moment do not enter into Equation [7], the expression used to calculate the value of k_3, it means that the effect of friction on the load, and the accuracy of measuring the bending moment, do not affect our results, although precautions were taken to free the pivot in the straining machine of frictional forces and to measure the bending moment accurately.

Conclusions

The photoelastic results suggested the hypothesis of independent laminar action, which, although not conclusively proved here, is strongly supported by the available data from fatigue tests and strain measurements. This hypothesis leads to a simple method of calculation of maximum bending stresses and theoretical factors of stress concentrations. The first important conclusion is that the theoretical stress-concentration curve obtained on the assumptions of laminar action is in good agreement with the results from fatigue tests, strain measurements, and the photoelastic tests. We thus have a simple and effective correlation between stress and failure. Large (2 in.) normalized Ni-Mo shafts with transverse holes in pure bending in fatigue seem to break at a stress equal to the endurance limit divided by the theoretical factor of stress concentration. The behavior of such shafts is then similar to that of a brittle material except that the endurance limit replaces the ultimate tensile strength.

We further conclude that, except for the limiting values, the three-dimensional factors k_3 are considerably smaller than the two-dimensional factors k_2 for the same ratio of r/d.

Inspection of Fig. 18 shows that k_3 like k_2 approaches 2 as the lower limit, only k_3 reaches this limit more rapidly than k_2. Thus at $r/d = 0.14$, k_2 is already equal to 2, whereas k_3 approaches this value only when r/d becomes infinite.

The upper branch of the curve of k_3 for values of r/d less than 0.04 is at the moment without experimental corroboration, and further work is needed on shafts with very minute holes. In view of the limitation in the dimensions of good photoelastic material for three-dimensional studies it seems probable that more pertinent information can at the present time be expected from fatigue tests especially designed for this purpose. This would also throw further light on the hypothesis of laminar action. However, further photoelastic work using built-up beams is contemplated.

The scope of three-dimensional photoelasticity is circumscribed only by the quality and size of the material available for models, and the over-all accuracy of three-dimensional photoelastic analyses is at present somewhat lower than that of two-dimensional investigation. Nevertheless, the optical method is yielding valuable stress data for space problems even under the present limitations. With the development of an improved material on which some laboratories are now working, a material which would permit the molding or casting of complicated shapes, which would be optically sensitive and free from time stresses, the power of the photoelastician will sharply mount.

Acknowledgment

The author expresses his acknowledgment to the administration of the Carnegie Institute of Technology for support of this work. Mr. John Robert McDowell, mechanician in the Photoelastic Laboratory, assisted in the calculations, photography, and drawings. Mr. M. M. Leven, now a Lieutenant in the United States Navy, assisted in obtaining the original photoelastic data for cases 1 and 2. The author also wishes to thank Mr. R. E. Peterson from the Westinghouse Research Laboratories for making available to him the photograph of the fracture showing the crack below the extreme fibers.

The Stresses in Cemented Joints

By M. GOLAND,[1] BUFFALO, N. Y., and E. REISSNER,[2] CAMBRIDGE, MASS.

The determination of the stresses in cemented lap joints has become of practical importance because of the development of new methods which permit a strong bond to be established between wood, plastic, or metal sheets, or combinations of them by the use of cement adhesives. In this paper, the problem is divided into two parts, (*a*) determination of the loads at the edges of the joint; (*b*) determination of the stresses in the joint due to the applied loads. Solutions are obtained for two limiting cases, i.e., where the cement layer is so thin that its effect on the flexibility of the joint may be neglected; and where the joint flexibility is mainly due to that of the cement layer. In both cases expressions are obtained for the shearing stresses in the cement, and for the normal stresses in the cement in a direction perpendicular to the plane of the joint.

THE present paper deals with the determination of the stresses in cemented lap joints. The problem has become of practical importance as a result of the development of new methods which permit the joining of wooden or metal sheets, or a combination of the two, by means of cement adhesives in such a manner that a very strong bond is established.

The problem is subdivided into two parts. The first part is concerned with the determination of the loads at the edges of the joint. It is recognized that this is a problem in which the deformation of the jointed sheets must be taken into account, using the finite-deflection theory of cylindrically bent plates. The second part is concerned with the determination of the stresses in the joint due to the applied loads. This problem is formulated as one in plane strain. Explicit solutions are obtained for two limiting cases, (*a*) the case where the cement layer is so thin that its effect on the flexibility of the joint may be neglected; (*b*) the case in which the joint flexibility is mainly due to that of the cement layer. Case (*b*) is significant for the analysis of cemented metal sheets. Case (*a*) is of practical interest in the study of cemented wooden and plastic sheets. In both cases, expressions are obtained for the shearing stresses in the cement and for the normal stresses in the cement in a direction perpendicular to the plane of the joint. For these latter stresses, the name "tearing stresses" is suggested, as they are thought to explain the tearing failures observed to take place at the edges of lap joints.

Related problems on the strength of welded or riveted joints have been considered by several previous writers (1, 2, 3, 4, 5, 6)[3] The main interest in these previous publications was the distribution of the shearing stresses, and neither the effect of the deflection of the jointed members due to plate bending nor the effect of the tearing-stress component was taken into consideration. It is shown here that consideration of these effects is essential for the analysis of cemented lap joints and the mathematical formulation of the problem in this manner leads to a system of equations which, to the authors' knowledge, has not been established previously.

Formulation of the Problem

Given are two rectangular sheets of equal thickness t, of unit width and of length $(l + 2c)$. The two sheets are lap-jointed over the length $2c$. The bond between the two sheets is established by means of a cement layer whose thickness η is small compared with those of the sheets. The unjointed ends of the sheets may be assumed to be simply supported and acted upon by tensile forces of magnitude T per unit of sheet width, Fig. 1.

The main problem is the determination of the shearing and normal stresses in the cement. Due to the fact that the sheet width is large compared with the sheet thickness, this may be considered as a problem in plane strain. The problem is subdivided into two parts. Part one concerns the determination of the loads applied to the rectangular joint section of length $2c$ and thickness $(2t + \eta)$. Assuming that it is satisfactory to approximate the applied loads by a linear normal stress and a parabolic shear distribution, this problem may be considered as one of beam theory, or rather, of cylindrically bent-plate theory. The two overlapping sheets are considered as one homogeneous plate with a discontinuous thickness variation and a neutral plane discontinuous at the ends of the joint section. Moreover, it is found necessary to take into account the effect which the deflection of the joint section has on the moment distribution, Fig. 2. The solution of this problem is given in Part 1 of the present paper.

Having the distribution of loads along the edges of the joint, it remains to solve a problem in plane strain in order to determine the stresses in the cement. The complete solution of this boundary problem is of considerable difficulty. Its proper execution requires that the deformation of the sheets due to the three stress components σ_x, σ_y and τ_{xy} be taken into account, as well as the deformation of the cement layer due to the corresponding three stress components.

However, the relative thinness of the cement layer and the smallness of its elastic moduli, as compared with the elastic moduli of the sheet material, allow several simplifications to be made, i.e., neglect of the normal stress in the cement parallel to the layer and the assumption that the remaining stresses in the cement do not vary across the thickness of the layer.

On the basis of these assumptions, the strain energy of the joint, expressed in terms of the stresses, is given by

$$W = \int_{-c}^{c} \int_{0}^{t} \left\{ \frac{1-\nu^2}{E} \left[\sigma_x^2 + \sigma_y^2 - \frac{2\nu}{1-\nu} \sigma_x \sigma_y \right] + \frac{1}{G} \tau_{xy}^2 \right\} dx dy + \frac{1}{2} \eta \int_{-c}^{c} \left\{ \frac{1}{E_c} \sigma_c^2 + \frac{1}{G_c} \tau_c^2 \right\} dx \quad \ldots\ldots [1]$$

Here E, G, and ν represent the Young's modulus, the shear modulus, and the Poisson's ratio, respectively, of the sheet material and E_c and G_c refer to the Young's and shear moduli, respectively, of the cement material. The sheet normal stress σ_x is parallel to the plane of the joint and the normal stress σ_y is per-

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until April 10, 1944, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

pendicular to this plane. The sheet shear stress τ_{xy} acts on planes parallel to the directions of σ_x and σ_y. The cement stresses σ_o and τ_o represent, respectively, the normal "tearing stress" in the cement and the shear stress acting on planes parallel to that of the cement layer.

The correct stress distribution is distinguished from all stress distributions satisfying the equilibrium equations and the boundary conditions of the joint problem by the fact that it minimizes the strain energy W.

On the basis of this energy consideration, an estimate can be made of the range of validity of the two approximate treatments which are given in what follows.

The first approximate treatment neglects the flexibility of the cement layer; i.e., the work of the stresses σ_o and τ_o in the cement compared with the work of the stresses σ_y and τ_{xy} in the sheet. Since, approximately

$$\int_0^t \frac{\sigma_y^2}{E}\, dy \approx \frac{t}{2E}\,\sigma_o^2 \qquad [2]$$

with a corresponding estimate for τ_{xy}, it follows that the flexibility of the cement layer may be neglected when the following order of magnitude relation is satisfied:

$$\frac{\eta}{E_c} \ll \frac{t}{E}, \quad \frac{\eta}{G_c} \ll \frac{t}{G} \qquad [3]$$

and acceptable results should be obtained when

$$\frac{\eta}{E_c} \lesssim \frac{1}{10}\cdot\frac{t}{E}, \quad \frac{\eta}{G_c} \lesssim \frac{1}{10}\cdot\frac{t}{G} \qquad [4]$$

This inequality means, for example, when the elastic moduli of the cement are 1/100, (1/1000) of the elastic moduli of the sheet material, the thickness of the cement layer must be not more than 1/1000, (1/10,000) of the sheet thickness, in order that this part of the theory give quantitative information.

The second approximate treatment neglects, in effect, the work of the stresses σ_y and τ_{xy} in the sheet as compared with the work of the stresses σ_o and τ_o in the cement. As before, Equation [2] may be assumed to hold, and consequently the order of magnitude relations describing the range of validity of this approximate theory become

$$\frac{t}{E} \ll \frac{\eta}{E_c}, \quad \frac{t}{G} \ll \frac{\eta}{G_c} \qquad [5]$$

which conditions may be replaced by

$$\frac{t}{E} \lesssim \frac{1}{10}\cdot\frac{\eta}{E_c}, \quad \frac{t}{G} \lesssim \frac{1}{10}\cdot\frac{\eta}{G_c} \qquad [6]$$

Thus if the elastic moduli of the cement are 1/100, (1/1000) of the elastic moduli of the sheet material, the thickness of the cement layer must be not less than 1/10, (1/100) of the thickness of the sheet, in order that this part of the theory be applicable.

It is recognized from these order-of-magnitude considerations that the second approximate treatment is well adapted to the analysis of metal joints of the dimensions occurring in airplane structures, while the first treatment is of value in the study of the cementing of relatively thick wood and plastic sheets.

Results and Discussion of Results

The results of major interest are those pertaining to the values of the stresses in the cement layer of a loaded joint. Prior to investigating the cement stresses, however, it is necessary to evaluate the forces and moments transmitted by the unjointed-sheet portions to the lapped-joint portion.

The loads transmitted by the sheets to the edges of the joint consist of a tension T, a moment M_o and a transverse shearing force V_o, each per unit of joint width, Fig. 1. The moment M_o is directed so as to introduce tensile stresses in the sheet fibers nearest to the cement layer. It is found, in section 1, that the magnitudes of the moment M_o and the shearing force V_o are dependent upon the value of the tensile stress p in the unjointed sheet, the joint dimensions, and the physical properties of the sheet material. The precise nature of this dependence is indicated by Table 1 and Fig. 3 of this paper. Fig. 3 is a plot of the nondimensional factor $k = \dfrac{2M_o}{pt^2}$ versus the parameter $\dfrac{c}{t}\sqrt{\dfrac{p}{E}}$, where the factor k is the ratio of the magnitude of the edge moment M_o and the value of this moment in a nondeformable system, and p represents the mean stress T/t in the sheets away from the joint. Values of $\dfrac{V_o c}{pt^2}$ for various $\dfrac{c}{t}\sqrt{\dfrac{p}{E}}$ are given in Table 1.

In representative joints composed of cemented aluminum-alloy sheets, the value of k is reduced to as little as 35 per cent of its initial value, as the sheet stress p is raised from zero to 40,000 psi. The edge-shearing force in these sheets is never in excess of $0.02T$.

For joints with relatively inflexible cement layers, i.e., for joints where $\dfrac{\eta}{E_c} \lesssim \dfrac{1}{10}\cdot\dfrac{t}{E}$ and $\dfrac{\eta}{G_c} \lesssim \dfrac{1}{10}\cdot\dfrac{t}{G}$, very high concentrations of stresses are found at the joint edges. Fig. 7 shows the maximum values of these stresses, plotted as a function of the moment factor k. The normal stress σ_o in the cement, acting in a direction perpendicular to the plane of the joint, has the surprisingly large value 4.3 p for $k = 1.0$. As the value of k is reduced, due to an increase in the applied sheet stress p, the σ_o concentration also decreases, reaching the value 2.1 when $k = 0.4$. The higher sheet stresses are thus accompanied by lower σ_o concentrations. It is to be noted, however, that the numerical magnitude of σ_o increases steadily with the sheet stress p.

The magnitude of the maximum shear stress τ_o in the cement plane is likewise large. At the start of loading ($k = 1.0$), the peak shear stress value is 0.79 p; the shear-concentration factor decreases to 0.45 for $k = 0.4$. The numerical magnitude of the maximum shear stress is again found to increase steadily with the sheet stress p.

It is of extreme interest to note the existence of such large cement stresses, particularly with regard to the σ_o stresses. It is observed, during actual joint tests, that the start of failure is characterized by a splitting apart of the two sheets at the joint edges. This action is explained by the presence of the high σ_o stresses. For easy reference, a descriptive title for the σ_o stresses is desirable; the name "tearing stresses" is suggested as being appropriate for this purpose.

The third stress, shown in Fig. 7, is the longitudinal tensile stress σ_f in the most highly loaded sheet fiber adjacent to the cement layer. As do those of σ_o and τ_o, the concentration factor for σ_f markedly decreases as the joint load increases, i.e., as the value of k decreases.

Fig. 6 shows the stress distribution along the shear plane of the joint in the vicinity of the edges, calculated for a value $k = 1.0$. The σ_o stress is highest at the joint edge and rapidly damps out to a small value (0.1 p) within a distance along the shear plane of about two sheet thicknesses; the reversal of the σ_o stress from a tensile to a compressive stress within this distance is of interest. The τ_o stress has the value zero at the joint edges; it rapidly rises to a peak value and once more decays to almost zero within a distance of two sheet thicknesses. Finally, the sheet fiber stress σ_f rapidly decreases to its nominal value 0.5 p within this same distance along the shear plane. In joints with relatively inflexible cement layers, therefore, the tearing and shear stresses in the

cement are concentrated in small regions near the ends of the joint. The middle-joint portions are under practically pure tension of amount 0.5 p in the sheets.

For joints with relatively flexible cement layers, i.e., for joints where $\frac{t}{E} \leq \frac{1}{10} \cdot \frac{\eta}{E_c}$ and $\frac{t}{G} \leq \frac{1}{10} \cdot \frac{\eta}{G_c}$, results of entirely different nature are obtained. To begin with, whereas the stress distribution in the cement for the inflexible-layer case is independent of both the joint dimensions and the physical properties of the cement material, the cement stresses in flexible layers are dependent upon both of these factors. Furthermore, the cement stresses are no longer restricted to small end zones in flexible layers, but are of appreciable magnitude over the whole of the shear plane.

Fig. 9 shows typical σ_o and τ_o distributions in joints with flexible cement layers, calculated for several k values. The joints are composed of representative materials and dimensions (say, aluminum-alloy sheets cemented with a typical resin adhesive and with a joint overlap to joint thickness ratio of 5), as specified by the values of the parameters given on the sketch. It is evident that the increased flexibility of the cement layer causes the shear stress τ_o in the cement to be more uniformly distributed over the joint shear plane. Nevertheless, the distribution still indicates a sizable concentration of shear in the end regions of the joint. The σ_o stresses again reverse their sign near the joint edges, but are not damped away as quickly as they were in inflexible cement layers. The peak τ_o and σ_o values still occur at the joint edges.

It is at once clear that the magnitudes of the peak cement stresses are very much lower in joints with flexible-cement layers than in joints with relatively inflexible layers. Their orders of magnitudes for representative joints are indicated in Fig. 9. For $\frac{c}{t} = 5$, the maximum σ_o value is about 0.12 p and that of τ_o is approximately the same magnitude. It is to be noted that even more pronounced reductions in the σ_o values than in the τ_o values are brought about by increased cement-layer flexibilities.

Figs. 10 and 11 are plots of the maximum values of the tearing stress σ_o and the shear stress τ_o in the cement. The plots are arranged to include the effects of variations in the semi-lap length to sheet thickness ratio $\frac{c}{t}$, as well as the effects of variations in the sheet and cement materials. The definitions of β and γ, which appear on the figures are

$$\beta = \sqrt{8 \frac{G_c}{E} \cdot \frac{t}{\eta}}, \quad \gamma = \sqrt[4]{6 \frac{E_c}{E} \cdot \frac{t}{\eta}}$$

The flexible-cement-layer analysis is applicable to joints composed of thin metal sheets cemented together. The adhesive materials used in such joints are particularly weak in tension. Hence the σ_o stresses, although smaller than those encountered in inflexible-layer joints, are still of sufficient magnitude to cause a splitting failure at the joint edges.

It may be noted that several interesting extensions of the work presented in this paper are possible. For example, the joint edge loads could be determined for sheets which are not initially flat, but which are instead crimped near the overlap region. By proper crimping, it is possible to greatly reduce the values of the edge bending moments and thereby the values of the tearing stress concentration. The effects of lateral loads, normal to the plane of the sheets, could also be studied. Furthermore, the methods of this paper can be extended so as to cover such cases as the joining of two sheets of unequal thickness and the problem of one sheet, to which are cemented two side sheets (the double shear joint).

DERIVATION OF RESULTS

1 Determination of the Joint Edge Loads

It is proposed to determine the loads acting upon the edges of the joint by considering the joint and the neighboring sheet to act as a cylindrically bent plate of variable cross section and

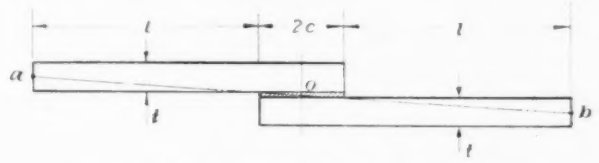

Fig. 1 Profile View of Cemented-Joint System

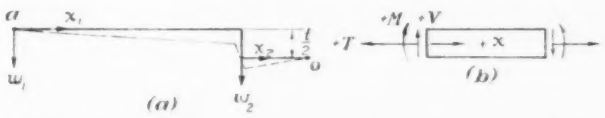

Fig. 2 Load Applied to Cemented-Joint System in Fig. 1 (a, Neutral plane of joint before and after application of load. b, Positive conventions for M, V, and T, as used in Section 1.)

variable neutral plane. The required results indicate that account must be taken of the effects of the transverse deflections of the sheet and joint on the values of the edge loads.

A graphical representation of a section of an unloaded joint is shown in Fig. 1. The joint (overlap) length is notated $2c$, the two joined sheets are considered to be of equal thickness t and are presumed to extend a distance l to either side of the joint. The joint width, in a direction normal to the plane of the section shown, is assumed to be large compared with the sheet thickness. If the system is now loaded by tensile forces T per unit of sheet width at the supports a and b, the line of action of the forces will be aob. The order of magnitudes of the joint edge loads can at once be recognized. For reasonably small deformations of the system, the tensile force in the sheet per unit of width remains very nearly equal to T, and the sheet moment at the joint edges is of the order $\frac{1}{2}Tt$. Since the order of magnitude of the transverse deflections observed during actual joint tests is t, the need for including the effects of the sheet and joint deflections in determining the edge loads is apparent.

The solid line of Fig. 2 represents the elastic axis of a longitudinal cross section of the lap joint. Since the form of the axis will always remain antisymmetrical about the mid-point o of the joint, only the left-hand sheet and the left portion of the joint are shown in Fig. 2. In the cemented region, the axis is along the mid-plane of the joint and hence, presuming always a cement layer of small thickness compared with that of the sheet, the elastic axis has a discontinuity of amount $t/2$ at the joint edges. (The discontinuity is drawn to a magnified scale on the figure for purposes of clarity.) Under load, the elastic axis deflects to some form such as that of the dotted line in Fig. 2. In order to study the system deformations, it is convenient to introduce two coordinate systems (x_1, w_1) and (x_2, w_2). The first system is used to analyze the behavior of the left-hand sheet under load; the x_1 co-ordinate has its origin at the support a, extends along the gravity axis of the sheet and is positive to the right. The w_1 coordinate represents transverse deflections of the sheet from the unloaded condition and is positive downward. A similar definition is taken for (x_2, w_2) with reference to the joint, as shown in Fig. 2.

Setting M_1 equal to the bending moment in the sheet at station x_1 and M_2 equal to the moment in the joint at station x_2, each per unit of width, then

$$\left.\begin{aligned} M_1 &= T[\alpha_n x_1 - w_1] \text{ for } 0 \le x_1 \le l \\ M_2 &= T\left[\alpha_n(l + x_2) - w_2 - \frac{t}{2}\right] \text{ for } 0 \le x_2 \le c \end{aligned}\right\} \quad \ldots\ldots [7]$$

Here α_n represents the angle between the x_1 (or x_2) co-ordinate and the line of action *aob* of the applied forces and is very nearly equal to

$$\alpha_n = \frac{1}{2}\,\frac{t}{(l + c)}$$

The positive conventions chosen for the moments M_1 and M_2 and for the transverse shearing forces per unit of width V_1 in the sheet and V_2 in the joint, to be introduced in the later work, are shown in Fig. 2.

According to the theory for the small bending of thin, cylindrically bent plates, the differential equations for the transverse deflections of the sheet and joint become

$$\left.\begin{aligned} \frac{d^2w_1}{dx_1^2} &= -\frac{M_1}{D_1} = -\frac{T}{D_1}\,[\alpha_n x_1 - w_1],\ 0 \le x_1 \le l \\ \frac{d^2w_2}{dx_2^2} &= -\frac{M_2}{D_2} = -\frac{T}{D_2}\left[\alpha_n(l + x_2) - w_2 - \frac{t}{2}\right],\ 0 \le x_2 \le c \end{aligned}\right\} \quad \ldots\ldots [8]$$

where D_1 and D_2 are the flexural rigidities of the sheet and joint respectively.

The two preceding Equations [8] have solutions of the form

$$\left.\begin{aligned} w_1 &= A_1 \cosh u_1x_1 + B_1 \sinh u_1x_1 + \alpha_n x_1,\ 0 \le x_1 \le l \\ w_2 &= A_2 \cosh u_2x_2 + B_2 \sinh u_2x_2 + \alpha_n\left(l + x_2 - \frac{t}{2}\right),\ 0 \le x_2 \le c \end{aligned}\right\} \quad \ldots\ldots [9]$$

where

$$u_1 = \sqrt{\frac{T}{D_1}} \quad \text{and} \quad u_2 = \sqrt{\frac{T}{D_2}}$$

The four constants of Equations [9] are readily evaluated from the four conditions

$$\left.\begin{aligned} &\text{at } x_1 = 0 && w_1 = 0 \\ &\text{at } x_1 = l,\ x_2 = 0 && w_1 = w_2 \\ &\text{at } x_1 = l,\ x_2 = 0 && \frac{dw_1}{dx_1} = \frac{dw_2}{dx_2} \\ &\text{at } x_2 = c && w_2 = 0 \end{aligned}\right\} \quad \ldots\ldots [10]$$

The moment and shearing force at the transition section then become

$$\left.\begin{aligned} M_o &= (M_1)_{x_1=l} = -D_1\left(\frac{d^2w_1}{dx_1^2}\right)_{x_1=l} \\ &= \frac{Tt}{2}\left\{\frac{\cosh u_2c \sinh u_1l}{\sinh u_1l \cosh u_2c + \dfrac{u_1}{u_2}\cosh u_1l \sinh u_2c}\right\} \end{aligned}\right\} \quad \ldots\ldots [11]$$

and

$$\left.\begin{aligned} V_o &= (V_1)_{x_1=l} = \left(\frac{dM_1}{dx_1}\right)_{x_1=l} \\ &= u_1\frac{Tt}{2}\left\{\frac{\cosh u_2c \cosh u_1l}{\sinh u_1l \cosh u_2c + \dfrac{u_1}{u_2}\cosh u_1l \sinh u_2c}\right\} \end{aligned}\right\} \quad \ldots\ldots [12]$$

Letting p represent the applied tensile stress in the plate (so that $T = pt$) and E and ν the Young's modulus and the Poisson's ratio, respectively, of the sheet material, then since the joint is very nearly twice the thickness of the sheet

$$D_1 = \frac{D_2}{8} = \frac{Et^3}{12(1 - \nu^2)}$$

and

$$\left.\begin{aligned} u_1l &= 2\sqrt{3(1 - \nu^2)}\,\frac{l}{t}\sqrt{\frac{p}{E}} \\ u_2c &= \sqrt{\frac{3(1 - \nu^2)}{2}}\cdot\frac{c}{t}\sqrt{\frac{p}{E}} \end{aligned}\right\} \quad \ldots\ldots [13]$$

In all practical cases, the value of u_1l is sufficiently large to permit taking

$$\sinh u_1l \approx \cosh u_1l \approx \frac{1}{2}\,e^{u_1l} \quad \ldots\ldots [14]$$

Equations [11] and [12] then reduce to the simplified forms

$$M_o = k\,\frac{Tt}{2},\ V_o = kT\sqrt{3(1 - \nu^2)}\,\frac{p}{E} \quad \ldots\ldots [15]$$

where the value of the factor k is dependent upon the sheet stress p, the joint dimensions and the physical properties of the sheet material in the following manner:

$$k = \frac{\cosh u_2c}{\cosh u_2c + 2\sqrt{2}\sinh u_2c} \quad \ldots\ldots [16]$$

Values of $k = \dfrac{2M_o}{Tt}$ and of $\dfrac{V_oc}{Tt}$ for various values of $\dfrac{c}{t}\sqrt{\dfrac{p}{E}}$ are given in Table 1; Fig. 3 is a graphical plot of the factor k versus $\dfrac{c}{t}\sqrt{\dfrac{p}{E}}$. For average values of overlap and for plate stresses as high as 40,000 psi in joints composed of cemented aluminum-alloy sheets, a practical lower limit of about 0.35 is established for k. Hence it is evident that the joint-edge moments are considerably reduced under load from the initial value $^1/_2\,Tt$, the amount of

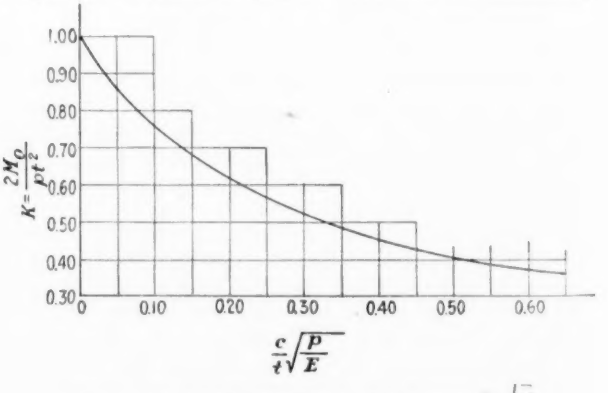

FIG. 3 PLOT OF MOMENT FACTOR k VERSUS $\dfrac{c}{t}\sqrt{\dfrac{p}{E}}$

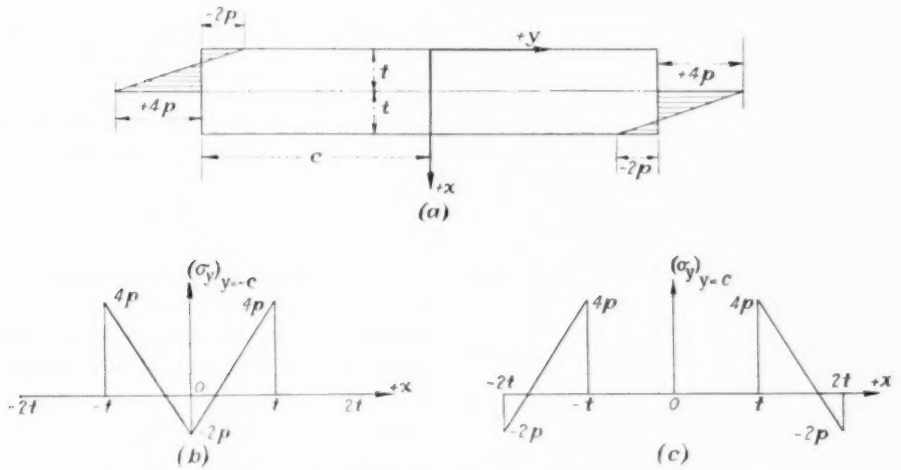

FIG. 4 DIAGRAM OF JOINT WITH RELATIVELY INFLEXIBLE CEMENT LAYER
(*a*, Profile of joint, showing edge stress distribution; *b*, periodic function for stress on joint edge $y = -c$; *c*, periodic function for stress on joint edge $y = c$. For $k = 1.0$.)

reduction being as much as 65 per cent in practical cases. It is also clear, from the values of Table 1, that only small transverse shearing forces are introduced at the joint edges of loaded systems with reasonable overlap. The shearing forces are never in excess of 0.02 T in actual joints.

2 STRESS DISTRIBUTION IN JOINT FOR RELATIVELY INFLEXIBLE CEMENT LAYERS

If the thickness of the cement layer in a joint is exceedingly small compared with that of the sheet, the presence of the cement can be ignored in the calculation of the stress distribution in the joint. For, in the case of very thin layers, the variations in stress and the magnitudes of the deformations in the cement are insignificantly small and, consequently, do not appreciably affect the stress distribution in the two adjoining sheet portions. For purposes of analysis, therefore, the joint can be assumed to consist of a homogeneous slab of thickness $2\ t$, length $2\ c$, large width and with the same physical properties throughout as those of the sheet material. It is to be noted that this treatment is valid even for cement layers of appreciable thickness, providing the cement material is relatively stiff, i.e., providing its physical properties are at least of the same order of magnitude as those of the sheet material.

The loads transmitted by the sheet to the edges of the joint have been determined in Section 1 of the paper. They are found to consist of a tension T, a moment $M_o = k\dfrac{Tt}{2}$ (each per unit of joint width), and a small transverse shearing force. In this first analysis, the transverse shearing forces are neglected, the tension T is assumed to be uniformly distributed over the sheet cross section and the moment M_o is considered to arise from the usual elementary linear stress distribution. It is evident, from past experience with similar problems, that the first two assumptions do not introduce appreciable error; the last assumption implies that sheet cross sections remain plane near the edges of the joint and has, for verification, the results of a series of photoelastic tests. The tests, reported by Tylecote (7), were made on homogeneous, short joints. The departure from a linear normal stress distribution at the joint edges should presumably be a maximum in short joints; the test results indicate, nevertheless, a remarkable degree of linearity.

The normal stresses on the joint edges over the regions where the sheet attaches to the joint are then given by expressions of the type

$$p + \frac{12M_o}{t^3}z$$

where z refers to the distance from the elastic axis of the sheet to a sheet fiber stressed in tension by the bending moment M_o. The normal stress distribution at the two edges is shown schematically in Fig. 4(*a*).

Let a co-ordinate x be defined in the direction of the joint thickness, with its origin at the upper surface of the joint, Fig. 4(*a*). The co-ordinate y is taken with its origin at the mid-point of the joint length and is measured positively to the right. The normal stress distribution of Fig. 4(*a*) then becomes

$$\left.\begin{array}{lll} \text{at} \quad y = -c, (\sigma_y)_{y=-c} & \begin{cases} = p + pk\left(6\dfrac{x}{t} - 3\right), & 0 \leqslant x < t \\ = 0, & t < x \leqslant 2t \end{cases} \\ \text{at} \quad y = c, (\sigma_y)_{y=c} & \begin{cases} = 0, & 0 \leqslant x < t \\ = p + pk\left(9 - 6\dfrac{x}{t}\right), & t < x \leqslant 2t \end{cases} \end{array}\right\} \quad \ldots\ldots\ldots\ldots [17]$$

The evaluation of the stress distribution in the joint is thus transformed to the solution of the plane-strain problem involving the boundary stresses of expressions [17], acting on the edges of a wide, rectangular slab of length $2\ c$ and thickness $2\ t$. The boundary stresses, expressions [17], will first be written as Fourier series, and a stress distribution, satisfying the conditions at the edges $y = -c$ and $y = c$, will be determined with their aid. This solution will, however, introduce undesirable normal and shear stresses on the joint surfaces $x = 0$ and $x = 2t$. An approximate method is used to remove these stresses, employing the known results for a series of concentrated forces distributed over the plane boundary of a semi-infinite elastic solid.

The edge stress conditions, expressions [17], are made into periodic functions as shown in Figs. 4(*b*) and (*c*). Writing

$$\left.\begin{array}{l} (\sigma_y)_{y=-c} = a_o + \displaystyle\sum_{n=1}^{\infty} a_n \cos\frac{n\pi}{2t}x \\ (\sigma_y)_{y=c} = b_o + \displaystyle\sum_{n=1}^{\infty} b_n \cos\frac{n\pi}{2t}x \end{array}\right\} \quad \ldots\ldots [18]$$

the Fourier constants become

$$\left.\begin{aligned} a_o &= b_o = \frac{1}{2}\,p \\ a_n &= \frac{2p}{n\pi}\left\{\frac{12k}{n\pi}\left(\cos\frac{n\pi}{2}-1\right)+(3k+1)\sin\frac{n\pi}{2}\right\} \\ b_n &= \frac{2p}{n\pi}\left\{\frac{12k}{n\pi}\left(\cos\frac{n\pi}{2}-\cos n\pi\right)-(3k+1)\sin\frac{n\pi}{2}\right\} \end{aligned}\right\} \quad \ldots [19]$$

According to the theory for plane strain, there exists a stress function φ_1 such that

$$\sigma_x = \frac{\partial^2\varphi_1}{\partial y^2}, \quad \sigma_y = \frac{\partial^2\varphi_1}{\partial x^2}, \quad \tau_{xy} = -\frac{\partial^2\varphi_1}{\partial x\partial y} \quad \ldots [20]$$

where σ_x, σ_y, τ_{xy} are stress notations as defined in reference 8. It is appropriate to take

$$\varphi_1 = \frac{px^2}{4} + \sum_{n=1}^{\infty} Y_n \cos\frac{n\pi}{2t}\,x \quad \ldots [21]$$

where Y_n is a function of n and the variable y only. The requirement that $\nabla^4\varphi_1 = 0$ fixes the form of Y_n as

$$Y_n = C_1\cosh\alpha y + C_2\sinh\alpha y + C_3 y\cosh\alpha y + C_4 y\sinh\alpha y \ldots [22]$$

where $\alpha = \dfrac{n\pi}{2t}$. Then, denoting the derivatives of Y_n with respect to the variable y by primes, the three stresses become

$$\left.\begin{aligned} \sigma_x &= \sum_{n=1}^{\infty} Y_n''\cos\alpha x \\ \sigma_y &= \frac{p}{2} - \sum_{n=1}^{\infty}\alpha^2 Y_n\cos\alpha x \\ \tau_{xy} &= \sum_{n=1}^{\infty}\alpha Y_n'\sin\alpha x \end{aligned}\right\} \quad \ldots [23]$$

The four constants appearing in the function Y_n are determined from the boundary conditions, previously decided upon

$$\left.\begin{aligned} &\text{at } y = -c, && \tau_{xy} = 0 \\ & && \sigma_y = (\sigma_y)_{y=-c} \\ &\text{at } y = c, && \tau_{xy} = 0 \\ & && \sigma_y = (\sigma_y)_{y=c} \end{aligned}\right\} \quad \ldots [24]$$

and the three stresses σ_x, σ_y, and τ_{xy} then assume the forms

$$\left.\begin{aligned} \sigma_x &= \sum_{n=1}^{\infty}[A_n y_1 + B_n y_2]\cos\alpha x \\ \sigma_y &= \frac{p}{2} + \sum_{n=1}^{\infty}[A_n y_3 + B_n y_4]\cos\alpha x \\ \tau_{xy} &= \sum_{n=1}^{\infty}[A_n y_5 + B_n y_6]\sin\alpha x \end{aligned}\right\} \quad \ldots [25]$$

where $A_n = b_n + a_n$, $B_n = b_n - a_n$ and $y_1, y_2, \ldots, y_6$ are six functions of y only. A typical form is

$$y_1 = \frac{\cosh\alpha y\,(\sinh\alpha c - \alpha c\cosh\alpha c) + \alpha y\sinh\alpha c\sinh\alpha y}{\sinh 2\alpha c + 2\alpha c} \quad \ldots [26]$$

The fact that the length of the joint is always large compared with its thickness leads to a considerable simplification of expressions [25]. For then c is large compared with t and

$$\left.\begin{aligned} \sinh\alpha c &\approx \cosh\alpha c \approx \frac{1}{2}\,e^{\alpha c} \\ \sinh 2\alpha c &\pm 2\alpha c \approx \sinh 2\alpha c \approx \frac{1}{2}\,e^{2\alpha c} \end{aligned}\right\} \quad \ldots [27]$$

Furthermore, confining attention to the joint regions near the edges, where the stress distribution is of most interest, then with small error

$$\sinh\alpha y \approx \cosh\alpha y \approx \frac{1}{2}\,e^{\alpha y}$$

With these approximations, the complexity of the forms describing $y_1, y_2, \ldots, y_6$ is reduced and the stresses can be written as

$$\left.\begin{aligned} \sigma_x &= \sum_{n=1}^{\infty}(A_n + B_n)\left\{\frac{1}{2}\,e^{\alpha(y-c)}\,[\alpha(y-c)+1]\right\}\cos\alpha x \\ \sigma_y &= \frac{p}{2} + \sum_{n=1}^{\infty}(A_n + B_n)\left\{\frac{1}{2}\,e^{\alpha(y-c)}[\alpha(c-y)+1]\right\}\cos\alpha x \\ \tau_{xy} &= \sum_{n=1}^{\infty}(A_n + B_n)\left\{\frac{1}{2}\,e^{\alpha(y-c)}[\alpha(y-c)]\right\}\sin\alpha x \end{aligned}\right\} \quad \ldots [28]$$

where

$$A_n + B_n = 2b_n = \frac{4p}{n\pi}\left\{\frac{12k}{n\pi}\left(\cos\frac{n\pi}{2} - \cos n\pi\right) - (3k+1)\sin\frac{n\pi}{2}\right\} \quad \ldots [29]$$

During the calculation of the values of the stresses, Equations [28] in the vicinity of the joint edges, the series converge fairly rapidly.

It has already been mentioned that the stress function φ_1 does not maintain the necessary stress-free conditions on the joint surfaces $x = 0$ and $x = 2t$. In fact, it is found that large normal and shearing stresses remain on both of these faces. In order to remove these objectionable stresses, an approximate method described in reference (8) is used. It employs the results, first obtained by Boussinesq, for the plane-strain problem of an inclined force applied to the plane edge of a semi-infinite elastic slab.

The left joint edge is shown in Fig. 5 with the joint material arbitrarily extended infinitely to either side of the joint in the x direction. The plane boundary at $y = -c$ is maintained. A series of concentrated forces may now be applied to the plane boundary outside of the region from $x = 0$ to $x = 2t$ without introducing any surface stresses over the joint edge. Either forces parallel or perpendicular to the plane boundary can be applied at will. Let m such separate forces be applied and consider the resulting stresses at points along the two planes $x = 0$ and $x = 2t$. It is obvious that if any combination of m normal and shear stresses σ_x and τ_{xy}, acting at arbitrarily specified points along these planes, are chosen for reference, then the magnitudes of the m applied forces can be so adjusted as to fix these stresses

at any desired values. It is the purpose here to set these m values of σ_x and τ_{xy} of equal magnitude and opposite sign to those remaining on the joint surfaces due to the stress function φ_1, and by choosing m sufficiently large, to obtain reasonable correspondence between the surface stresses due to the two stress systems over the entire semi-length c of the joint. By superposition of the two systems, the surfaces $x = 0$ and $x = 2t$ are then left free of stress. It is allowable then to ignore the portions of the slab outside of the two surfaces and to study only the joint itself. If φ_2 refers to the stress function describing the application of the m forces, the stress distribution in the joint is obtained from the total stress function

$$\varphi = \varphi_1 + \varphi_2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [30]$$

The form of the stress function φ_2 is obtained from well-known results (8) and will not be given here in detail for reasons of brevity.

By trial and error, it is found that six concentrated forces, ap-

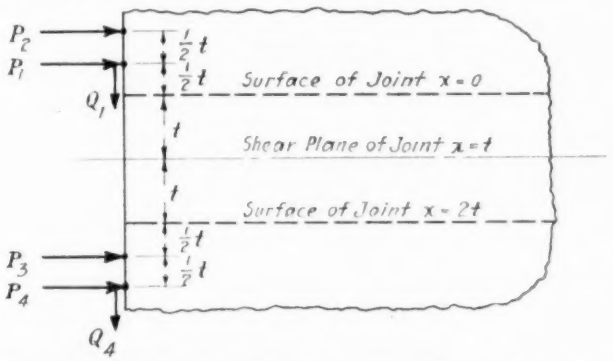

FIG. 5 FORCE PATTERN USED TO CLEAR THE SURFACES $x = 0$ AND $x = 2t$ OF STRESS

plied as shown in Fig. 5, are sufficient to remove almost completely the surface shearing stresses introduced by φ_1. Their positions are dimensioned in Fig. 5, and their magnitudes are, each per unit of joint width

$$\left.\begin{aligned} P_1 &= (-0.07 + 0.77k)\pi tp \\ P_2 &= -0.30k\,\pi tp \\ P_3 &= (0.14 - 0.30k)\pi tp \\ P_4 &= 0.16\,\pi tp \\ Q_1 &= (0.13 - 0.75k)\pi tp \\ Q_4 &= (0.25 - 0.25k)\pi tp \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [31]$$

The values of the shearing stresses yet remaining on the surfaces $x = 0$, $x = 2t$ of the joint in the neighborhood of the joint edge are given in Table 2 and are seen to be quite small for all values of k. The remaining normal stresses σ_x are also given and are of considerably larger magnitude. Since the joint is relatively thin compared with its length, it is allowable to consider the mean of the two remaining surface-pressure distributions to be transmitted directly through the sheet without change of form. Hence, this component can be subtracted from the total stress distribution and the net remaining surface pressures are given by the differences between the original and the removable mean stresses,

as indicated by the last column of Table 2. No attempt will be made to remove the small normal and shearing stresses which persist on the joint surfaces.

It is pertinent to study the probable errors resulting from the small stresses remaining on the surfaces $x = 0$ and $x = 2t$. These are best investigated by noting the effect of changing the magnitudes of the applied concentrated forces on the stress distribution in the joint. It is found that large changes in the values of these forces result in relatively small changes in the stress distribution across the shear plane $x = t$ of the joint. Since this is the region of greatest practical significance, it is concluded that the approximate method used to remove the undesirable surface stresses is of sufficient accuracy.

Fig. 6 is a plot of the stress distribution along the mid-plane $x = t$ of the joint for the case $k = 1$. This plane corresponds with that of the cement layer and hence the stresses τ_{xy} and σ_x shown are those to which the cement material is subjected in a loaded joint. The stresses are highest near the joint edges and only this region is shown in Fig. 6. The stresses in the other regions of the joint are of lesser interest, since joint failure is usually precipitated by fracture of the relatively weak cement material.

It is recognized that the peak values of σ_x and τ_{xy} at the shear plane will change with the factor k. Fig. 7 shows this variation by plotting the maximum values of the cement stresses $\sigma_x = \sigma_o$ and $\tau_{xy} = \tau_o$ as a function of k. The change in the longitudinal stress σ_f in the sheet fibers adjoining the cement, brought about by a change in the value of k, is also indicated on this plot. The significance of Figs. 6 and 7 in explaining joint behavior has already been discussed.

3 Stress Distribution in Joint for Relatively Flexible Cement Layers

In this section, joints are considered for which the following assumption is permissible: The transverse normal strain and shear strain in the jointed sheets are negligibly small compared with the corresponding strains in the cement layer. Assuming, then, that the deformation of the sheets is due solely to the longitudinal normal stress σ_x, it is apparent that the sheets may be treated as cylindrically bent plates, whereas the role played by the cement layer is analogous to that of a system of infinitesimal coil springs positioned between the two plates.

Fig. 8 represents the cemented joint with the loads, as determined in Section 1, applied to it. The co-ordinate x is defined in the direction of the joint length, with its origin at the mid-point of the joint and its positive direction to the right. The bending moments, vertical shear, and axial tension in the sheets are denoted by M, V, and T, respectively, and the subscripts u and l designate quantities pertaining to the upper or lower sheet, respectively. The transverse normal (tearing) stress and the shear stress in the cement are notated σ_o and τ_o, respectively Figs. 8(b) and (c) show elements of the upper and lower sheet, with the sign conventions chosen for moments and forces indicated.

The conditions of moment equilibrium for the elements of the sheet are

$$\left.\begin{aligned} \frac{dM_u}{dx} - V_u + \tau_o \frac{t}{2} &= 0 \\ \frac{dM_l}{dx} - V_l + \tau_o \frac{t}{2} &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [32]$$

The conditions of horizontal force equilibrium are

$$\left.\begin{aligned} \frac{dT_u}{dx} - \tau_o &= 0 \\ \frac{dT_l}{dx} + \tau_o &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [33]$$

The conditions of vertical force equilibrium are

$$\left.\begin{aligned} \frac{dV_u}{dx} - \sigma_o &= 0 \\ \frac{dV_l}{dx} + \sigma_o &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [34]$$

Denoting by v_u and v_l the transverse deflections of the upper and lower sheets, respectively, both measured positively upward, then from thin plate theory

$$\left.\begin{aligned} \frac{d^2v_u}{dx^2} &= -\frac{M_u}{D} \\ \frac{d^2v_l}{dx^2} &= -\frac{M_l}{D} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [35]$$

where $D = \dfrac{Et^3}{12(1-\nu^2)}$ refers to the flexural rigidity of the sheets.

Let u_u and u_l represent the longitudinal displacements of the

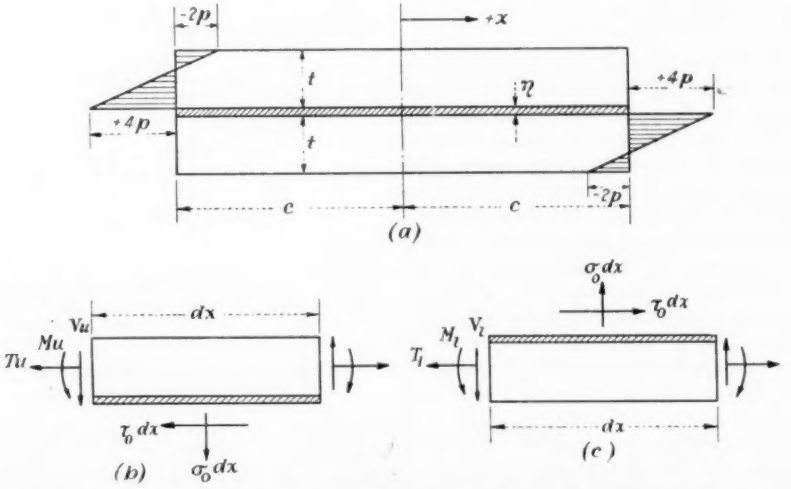

Fig. 8 Diagram of Joint With Relatively Flexible Cement Layer

(a, Profile of joint, showing longitudinal stress distribution on edges; b, element of upper sheet; c, element of lower sheet. For $k = 1.0$.)

sheet at the sheet boundaries adjacent to the cement. Then, the stress-strain relations give

$$\left.\begin{aligned} \frac{du_u}{dx} &= \frac{1}{E}\left(\frac{T_u}{t} - 6\frac{M_u}{t^2}\right) \\ \frac{du_l}{dx} &= \frac{1}{E}\left(\frac{T_l}{t} + 6\frac{M_l}{t^2}\right) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [36]$$

where the terms on the right side of Equations [36] are the known combinations of bending and direct stress in the outermost fibers of a loaded beam.

The required system of equations is completed by the relations between the stresses and strains in the cement. For an elastic cement they are

$$\left.\begin{aligned} \frac{\tau_o}{G_c} &= \frac{u_u - u_l}{\eta} \\ \frac{\sigma_o}{E_c} &= \frac{v_u - v_l}{\eta} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [37]$$

It might be remarked that the linear stress-strain relations of Equations [37] could be replaced by nonlinear expressions without making the solution of the problem of prohibitive difficulty.

The edge conditions for the two sheets are

$$\left.\begin{aligned} &\text{at} \quad x = c, \begin{cases} M_u = T_u = V_u = 0 \\ M_l = M_o,\ V_l = V_o,\ T_l = T \end{cases} \\ &\text{at} \quad x = -c, \begin{cases} M_l = T_l = V_l = 0 \\ M_u = -M_o,\ V_u = V_o,\ T_u = T \end{cases} \end{aligned}\right\} \ldots [38]$$

The system of Equations [32] to [38], inclusive, is now to be reduced to two differential equations for σ_o and τ_o and to boundary conditions in terms of these two quantities. Combining Equations [36] and the first of Equations [37], there follows

$$\frac{\eta}{G_c}\cdot\frac{d\tau_o}{dx} = \frac{1}{E}\left(\frac{T_u - T_l}{t} - 6\frac{M_u + M_l}{t^2}\right) \ldots\ldots [39]$$

Differentiating once and observing Equations [32] and [33]

$$\frac{\eta}{G_c}\cdot\frac{d^2\tau_o}{dx^2} = \frac{1}{E}\left(2\frac{\tau_o}{t} + 6\frac{\tau_o}{t} - 6\frac{V_u + V_l}{t^2}\right) \ldots\ldots [40]$$

Differentiating once more and noting Equations [34], an equation in τ_o only results,

$$\frac{d^3\tau_o}{dx^3} - \frac{8G_c}{Et\eta}\cdot\frac{d\tau_o}{dx} = 0 \ldots\ldots\ldots\ldots [41]$$

An equation for σ_o is found by first differentiating the second of Equations [37] twice and introducing Equations [35]. Then

$$\frac{1}{E_c}\cdot\frac{d^2\sigma_o}{dx^2} = \frac{1}{\eta}\cdot\frac{M_l - M_u}{D} \ldots\ldots\ldots\ldots [42]$$

From Equations [32], it follows that

$$\frac{1}{E_c}\cdot\frac{d^3\sigma_o}{dx^3} = \frac{1}{\eta D}\cdot(V_l - V_u) \ldots\ldots\ldots\ldots [43]$$

and from Equations [34], finally

$$\frac{1}{E_c}\cdot\frac{d^4\sigma_o}{dx^4} = -\frac{2}{\eta D}\sigma_o \ldots\ldots\ldots\ldots [44]$$

or

$$\frac{d^4\sigma_o}{dx^4} + \frac{24(1-\nu^2)E_c}{\eta t^3 E}\sigma_o = 0 \ldots\ldots\ldots\ldots [45]$$

The boundary conditions for τ_o and σ_o are obtained by combining Equations [38], [39], [42], and [43]. The conditions for τ_o are

$$\text{at} \quad x = \pm c, \quad \frac{d\tau_o}{dx} = \mp\frac{G_c}{Et\eta}\left(T + 6\frac{M_o}{t}\right) \ldots\ldots [46]$$

to which is added the equilibrium condition

$$\int_{-c}^{c}\tau_o dx + T = 0 \ldots\ldots\ldots\ldots [47]$$

The conditions for σ_o are

$$\text{at} \quad x = \pm c \left\{\begin{aligned} \frac{d^2\sigma_o}{dx^2} &= \frac{E_c}{\eta D}M_o \\ \frac{d^3\sigma_o}{dx^3} &= \pm\frac{E_c}{\eta D}V_o \end{aligned}\right\} \ldots\ldots [48]$$

It may be noted that Equations [45] and [48] for σ_o are analogous to the equations for the deflection of a beam on elastic foundation, acted upon by edge forces and moments.

On the basis of the differential Equation [41] and the boundary conditions, Equations [46] and [47], the distribution of shear stress in the cement is obtained in the form

$$\frac{\tau_o}{p}\frac{c}{t} = -\frac{1}{8}\left\{\frac{\beta c}{t}(1+3k)\frac{\cosh\frac{\beta c}{t}\cdot\frac{x}{c}}{\sinh\frac{\beta c}{t}} + 3(1-k)\right\} \ldots [49]$$

where

$$\beta^2 = 8\frac{G_c}{E}\cdot\frac{t}{\eta}$$

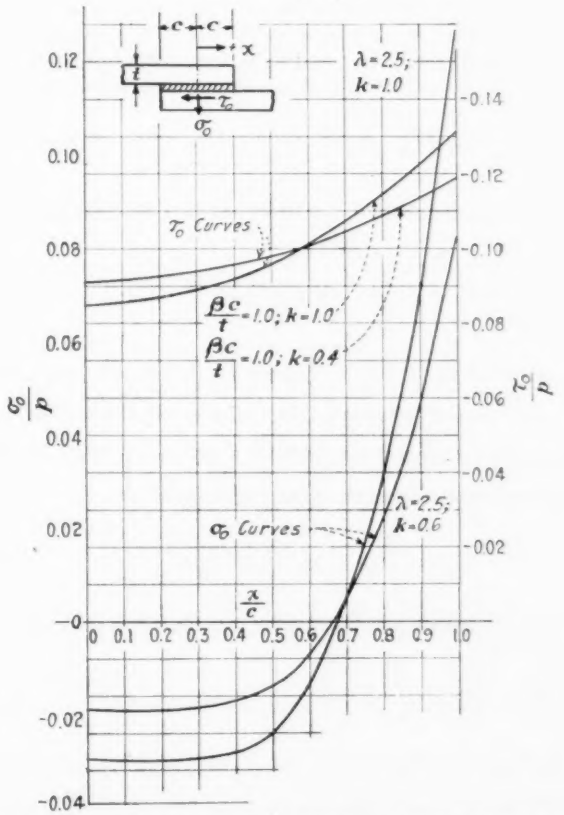

FIG. 9 STRESS DISTRIBUTION IN CEMENT IN JOINTS WITH RELATIVELY FLEXIBLE CEMENT LAYERS

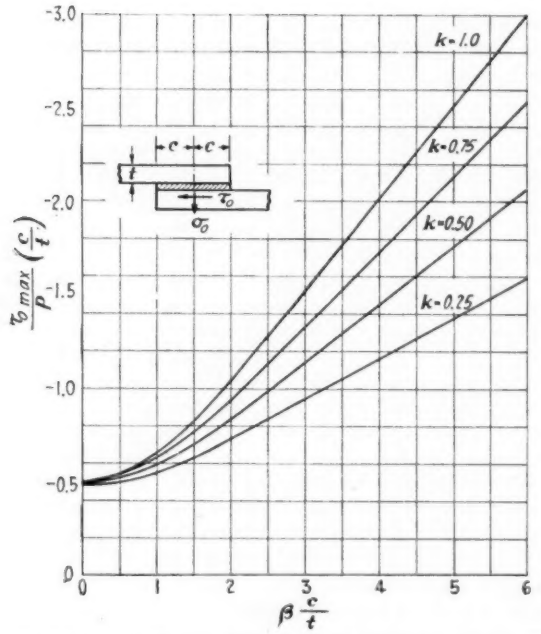

FIG. 10 MAXIMUM SHEAR STRESS IN CEMENT IN JOINTS WITH RELATIVELY FLEXIBLE CEMENT LAYERS

This expression may be compared with the average shear

$$(\tau_o)_{avg} = -\frac{pt}{2c} \quad \ldots\ldots\ldots\ldots\ldots\ldots [50]$$

Fig. 9 shows a typical distribution of τ_o in a joint of representative dimensions and materials and for values of the factor k of 1 and 0.60. It should be noted that, as expected, Equation [49] indicates a substantially uniform shear distribution in short joints. For longer joints, say for $\frac{\beta c}{t} > 0.5$, this is no longer the case.

The maximum value of τ_o is found at the edge of the joint and is

$$\frac{(\tau_o)_{max}}{p}\cdot\frac{c}{t} = -\frac{1}{8}\left[\frac{\beta c}{t}(1+3k)\coth\frac{\beta c}{t} + 3\ (1-k)\right]. \quad [51]$$

Fig. 10 is a plot of $\frac{(\tau_o)_{max}}{p}\cdot\frac{c}{t}$ versus $\frac{\beta c}{t}$ for various values of k. An inspection of Equation [51] indicates that increasing the length of joint beyond the limit $\frac{\beta c}{t} \approx 25$ has no effect on the magnitude of the maximum shear, which remains

$$(\tau_o)_{max} = -\frac{p}{8}\ (1+3k)\sqrt{8\frac{G_c}{E}\cdot\frac{t}{\eta}} \quad \ldots\ldots\ldots [52]$$

The σ_o distribution is found to be, on the basis of Equations [45] and [48]

$$\frac{\sigma_o}{p}\left(\frac{c}{t}\right)^2 = \frac{1}{\Delta}\left[(R_2\lambda^2\frac{k}{2} + \lambda k'\cosh\lambda\cos\lambda)\cosh\lambda\frac{x}{c}\cos\lambda\frac{x}{c} + (R_1\lambda^2\frac{k}{2} + \lambda k'\sinh\lambda\sin\lambda)\sinh\lambda\frac{x}{c}\sin\lambda\frac{x}{c}\right] \quad \ldots\ldots\ldots [53]$$

where $\gamma^4 = 6\frac{E_c}{E}\cdot\frac{t}{\eta}$, $\lambda = \gamma\frac{c}{t}$

$$R_1 = \cosh\lambda\sin\lambda + \sinh\lambda\cos\lambda$$
$$R_2 = \sinh\lambda\cos\lambda - \cosh\lambda\sin\lambda$$
$$\Delta = \frac{1}{2}(\sinh 2\lambda + \sin 2\lambda)$$

and, from Section 1

$$\frac{2M_o}{pt^2} = k, \quad \frac{V_o c}{pt^2} = k'$$

The maximum value of σ_o acts at the joint edges and is given by

$$\frac{(\sigma_o)_{max}}{p}\left(\frac{c}{t}\right)^2 = \lambda^2\frac{k}{2}\cdot\frac{\sinh 2\lambda - \sin 2\lambda}{\sinh 2\lambda + \sin 2\lambda} + \lambda k'\frac{\cosh 2\lambda + \cos 2\lambda}{\sinh 2\lambda + \sin 2\lambda} \quad \ldots\ldots\ldots [54]$$

For long joints, defined by λ greater than, say, 5/2 this becomes

$$\frac{(\sigma_o)_{max}}{p} = \frac{k}{2}\sqrt{6\frac{E_c}{E}\cdot\frac{t}{\eta}} + k'\frac{t}{c}\sqrt[4]{6\frac{E_c}{E}\cdot\frac{t}{\eta}} \quad \ldots\ldots\ldots [55]$$

It is noteworthy that, for long joints, the transverse normal stress and shear stress in the cement layer depend in essentially the same way on the elastic-moduli ratio and the thickness ratio of the sheet and cement. While, however, the shear stress τ_o is due in equal measure to the direct sheet stress and the sheet bending stress, the normal stress σ_o is almost entirely due to the existence of the sheet bending stress.

Fig. 11 is a plot of $\frac{(\sigma_o)_{max}}{p}\left(\frac{c}{t}\right)^2$ versus λ for various values of the factor k. A typical σ_o distribution in a representative joint is shown in Fig. 9. The end concentration of σ_o is of interest, showing the existence of tearing stresses of appreciable magnitude (see section on "Results and Discussion of Results"). It is of interest also to note that increasing overlap ratios c/t result in decreasing values of the maximum tearing stress $(\sigma_o)_{max}$ at the joint edges.

Relations Between the Notched Beam Impact Test and the Static Tension Test

By C. W. MacGREGOR[1] and J. C. FISHER,[2] CAMBRIDGE, MASS.

Results of static tension tests of both notched and uniform bars are compared with notched beam impact tests through the use of true stress-strain values. For the materials tested and under the temperature conditions imposed, it was found that the effect of drawing and testing temperatures on the energy absorbed per unit of volume was essentially the same for both static notched tension and notched beam impact tests.

THE notched-beam impact test has been of considerable value in determining the effect of various metallurgical and mechanical conditions on the suitability of materials for different applications. Experience has demonstrated that the effect of some of these conditions cannot be detected by the ordinary form of tension test. The present state of the notched beam impact test has been thoroughly covered in various papers presented at the "Symposium on Impact Testing" during the 1938 meeting of the American Society for Testing Materials. A very extensive literature has developed on the subject and although space limitations will not permit detailed reference and discussion of many of the individual contributions to the field, mention will be made of some of those more closely related to the immediate problem under discussion. McAdam (1)[3] and Clyne (1) have given a very complete discussion of the effects of such variables as heat-treatment, testing temperature, the geometry of the test bar, velocity, etc., on the energy values obtained in the notched bar impact test as reported by many of the early investigators in the field such as Greaves and Jones, Maurer and Mailander, Moser, Stribeck and others.

The ratio of the technical cohesive strength to the shear strength and its effect on impact values has been discussed by Hoyt (2) and McAdam and Clyne (1). The technical cohesive strength has been the subject of considerable study by Kuntze (3), Gensamer (4), McAdam (5, 6) and Mebs (6) and others.

One of the shortcomings of the notched beam impact test has always been that it provides only energy values and hence gives no stress-strain information which might be used directly in design. Realizing this, a number of studies (7–12) have been made in recent years of the stress-strain relations in rapid tension or tension impact tests. Most of these have shown for the ductile metals, excluding low-melting metals such as lead and tin, that at normal temperatures rather large speed ratios are necessary before important speed effects are observed.

Various investigators have reported that the ordinary form of static tension test in many cases does not detect certain properties which are disclosed by the notched beam impact test. For example, Riegel and Vaughn (13) have demonstrated that two mill heats of the same typical chemical composition and almost identical ordinary tension properties may possess very different notched beam impact values.

Experiments by Greaves and Jones (14) support the view that the difference in results obtained from the notched beam impact test and the slow-speed tension test are due mainly to the notch effect rather than to the difference in the speed of the testing machines. Impact tests made on ingot iron with and without notches showed that while the temperatures of hot brittleness for the unnotched bars in impact agreed well with those determined from static tension tests, the notched impact specimens gave temperatures of hot brittleness which were much in excess of those determined statically.

More recently, tests conducted by Jones (15) disclosed the fact that the total impact energies for notched tension and notched beam impact specimens were affected in a similar manner by changing the testing temperature. On the other hand, his experiments with unnotched tension impact specimens exhibited no correlation with the notched beam impact results.

The inability of the ordinary tensile properties to reveal the practical performance characteristics of certain heat-treated low-alloy steels has been brought out in a series of experiments by Sachs and Lubahn (16). They found that notched static tension tests were more valuable in this respect. In addition, a comparison was made between the total energies for notched beam impact specimens and the product of the ordinary tensile strength and the ordinary reduction of area at fracture obtained from static notched tension tests. The results disclosed that both quantities were similarly affected by the testing temperature. This provides additional evidence that the effects usually observed in standard notched-beam impact tests are due mainly to the presence of the notch and not so much to the speed of the testing machine.

The notched beam impact test has always been difficult to correlate with other forms of tests. It has been the authors' feeling, however, that if any correlation existed between the notched-beam impact test and the static-tension test, it might best be approached through the use of true stress-strain values (17, 18). Accordingly an experimental program was undertaken with the object of ascertaining if the static-tension test in its more rational form could be used to show essentially the same effects of certain mechanical and metallurgical conditions on energy values as were portrayed by the notched-beam impact test. If this were possible, the tension test would have the added advantage of supplying stress-strain values not determined in the other form of test.

The first part of the following discussion is devoted to a description of the general testing procedure together with some preliminary results obtained using uniform tension specimens. A comparison then is made of the effects of heat-treatment and testing temperature on the variation of the *energy per unit of deformed volume* from notched-beam tests (as originally suggested by Moser (19)), and from static tension tests of the true stress-strain type on notched specimens.

TABLE 1 MATERIALS AND HEAT-TREATMENTS

Material	Heat-treatment
S.A.E. 1020	Annealed for one hour at 1650 F and furnace cooled.
S.A.E. 1112	Annealed for one hour at 1650 F and furnace cooled.
S.A.E. 1045	Heated to 1550 F, quenched in water, and drawn at various temperatures. Tensile specimens held at drawing temperature for 45 min. Impact specimens held at drawing temperature for 20 min.
S.A.E. 3140	Annealed for one hour at 1550 F and furnace cooled.

NOTE: At least two impact and tension specimens were tested for each temperature condition.

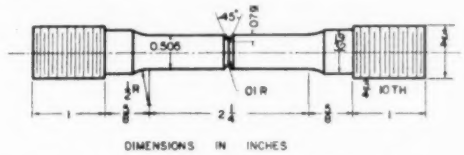

FIG. 1 NOTCHED TENSION SPECIMEN

TESTING PROCEDURE

The materials investigated together with their heat-treatments are listed in Table 1. They were received in the form of $^3/_4$-in. round bars and with the exception of the S.A.E. 1112 steel were in the hot-rolled condition. The S.A.E. 1112 was received as cold drawn.

Standard 0.505-in. diam uniform tension specimens were prepared from some materials, while notched-tension specimens were prepared from all materials. The dimensions of the notched-tension test pieces are given in Fig. 1. The 45-deg notch was produced by using as a lathe tool a tooth of the same milling cutter with which the notch in the notched beam specimens was formed. The S.A.E. 1045 specimens were notched after heat-treating.

Standard notched-beam impact specimens (Charpy impact specimens) were machined following the A.S.T.M. specifications. These specimens contained a single 45-deg notch 0.079 in. deep with a 0.01-in. radius at the base. Hence the notches in both tension and impact specimens were essentially the same.

The tension tests were performed on a 60,000-lb capacity Baldwin Southwark hydraulic testing machine having in addition both 2400- and 12,000-lb ranges. The procedure was to take simultaneous readings of load and minimum diameter throughout the tests. A special dial gage and clamp (17,18) was used to measure the diameter of the uniform specimens. For the notched bars, the minimum diameters were read with a measuring microscope. A special tank consisting of a metal tube 3 in. in diameter and 8 in. high surrounded the test pieces during the constant-temperature tests. The tank was fitted with two plastic windows which permitted observation of the specimen during the test, and measurement of the minimum diameter with the measuring microscope. For the higher temperatures the tank was filled with mineral oil which was electrically heated and circulated. The low temperatures were obtained by using alcohol with the addition of dry ice. The temperatures were held to plus or minus three degrees centigrade during each test. From the data so obtained the average true stress[4] $s = P/A$ was plotted versus the true strain $\epsilon = q' = \log_e A_0/A$ where P, A, A_0, ϵ, and q' are the instantaneous load, the instantaneous true area, the original area, the true strain and the true reduction of area respectively (17). A list of the symbols employed is given in Table 2. The values of energy absorbed per unit of volume up to fracture (E_s) were determined by computing

$$E_s = \int_0^{\epsilon_b} s \cdot d\epsilon$$

or the area under the true stress-strain curve where ϵ_b is the true fracture strain.[5]

TABLE 2 NOMENCLATURE

P = Axial load on tension test bar (Lb)
A_0 = Original area of cross section (In.)^2
A = Actual instantaneous area of cross section (In.)^2
L_0 = Original gage length (In.)
L = Actual gage length (In.)
A_u = Actual area of cross section at maximum load (In.)^2
A_b = Actual fracture area of cross section (In.)^2
ϵ = True strain = $\log_e A_0/A = \log_e L/L_0$
q' = True reduction of area = $\log_e \frac{A_0}{A} = \log_e L/L_0$
E_s = Energy per unit of volume = $\int_0^{\epsilon_b} s \cdot d\epsilon$ (Lb/In.^{2})
ϵ_b = True fracture strain = $\log_e A_0/A_b$
ϵ_u = True uniform strain = $\log_e A_0/A_u$
ϵ_n = True local necking strain = $\log_e A_u/A_b$
$\frac{\partial s}{\partial \epsilon}$ = Minimum modulus of strain hardening (Lb/In.^{2})

[4] For the notched specimens, the stress computed by dividing the load by the actual area represents an average of the true axial stresses. In order to save constant repetition, however, the word "average" will be omitted many places in the text.

[5] The value of the energy absorbed per unit of volume can be determined as follows: The total energy absorbed is equal to the work done on the specimen by the external forces. Let us first consider a uniform specimen. Then

$$\text{Total energy} = \int_{L_0}^{L} P \cdot dL = \int_{L_0}^{L} s \cdot A \cdot dL \quad \ldots\ldots [1]$$

where L and L_0 are the final and initial gage lengths and A and A_0 the final and initial areas of cross section. Since the volume remains constant

$$A \cdot L = A_0 \cdot L_0 \quad \ldots\ldots [2]$$

and hence

$$dL = -A_0 L_0 \frac{dA}{A^2} \quad \ldots\ldots [3]$$

Substituting Equation [3] in [1] gives

$$\text{Total energy} = A_0 L_0 \int_{A_0}^{A} s \left(-\frac{dA}{A}\right) = V_0 \int_{A_0}^{A} s \left(-\frac{dA}{A}\right) \quad [4]$$

where V_0 is the initial volume of material. But

$$V = A \cdot L = V_0 = \text{constant} \quad \ldots\ldots [5]$$

$$\text{Hence } dV = A dL + L da = 0 \quad \ldots\ldots [6]$$

$$\text{and } \frac{dL}{L} = -\frac{dA}{A} = d\epsilon \quad \ldots\ldots [7]$$

(From Equation [7] note that

$$\epsilon = \int_{L_0}^{L} \frac{dL}{L} = -\int_{A_0}^{A} \frac{dA}{A} = q' = \log_e \frac{L}{L_0} = \log_e \frac{A_0}{A}$$

which [17] are our definitions of true strain ϵ and true reduction of area q'.)

Substituting Equation [7] in [4] one obtains

$$\text{Total energy} = V \int_0^{\epsilon} s \cdot d\epsilon \quad \ldots\ldots [8]$$

The energy per unit of volume, or specific energy E_s corresponding to any strain value ϵ becomes

$$E_s = \int_0^{\epsilon} s \cdot d\epsilon \quad \ldots\ldots [9]$$

or the area under the true stress-strain curve.

When a uniform specimen begins to neck down (or for an initially notched test bar), the total energy calculated above refers only to an

The notched-beam impact specimens were tested in a standard Charpy impact machine having a striking velocity of 17.4 fps. For variation of testing temperature the specimens were immersed in oil at medium and higher temperatures, or in alcohol and dry ice at low temperatures, and were left in the bath until equilibrium was reached. They were then removed and tested as quickly as possible. The average time between removal from the bath and fracture was about four seconds.

In order to compare in a rational manner the static tension test results, where the energy per unit of volume was determined, with the results of the Charpy impact test, the energy absorbed per unit of deformed volume for the Charpy test was determined as originally suggested by Moser (19). After the notched beam impact specimens were machined, they were polished on one side and a fine network of lines 0.04 in. apart was marked on the surface with a diamond scriber. The network was measured before the test with a measuring microscope. After fracture the network was again carefully measured. The material which had a permanent strain of ± one per cent or greater was taken as the deformed volume. The limit of one per cent was chosen because

element in the most severely deformed region, and not to the over-all work done on the entire bar. In these cases such an element is subjected to both axial and radial stresses. Equation [9] represents then only that portion of the energy absorbed per unit of most severely deformed volume contributed by the axial stresses. Since the contribution by the radial stresses is neglected in Equation [9], the Equation must be taken as an approximation. While the effect of the radial stresses is probably not large for the uniform specimens, it is not negligible for severely notched bars. The value or distribution of the radial stresses in the plastic range for notched bars is not known at the present time. However, since the relative magnitude of the radial stress is determined mainly by the notch itself, it was felt that for a given notch and material the effect of various tempering and testing temperatures on the energy absorbed per unit volume might be adequately reflected by the value given in Equation [9]. The experiments described in this paper lend support to this view.

it was about the smallest value which could be reliably measured. The energy per unit of deformed volume then was obtained by dividing the total energy as read on the Charpy machine by the deformed volume determined in the manner described above.

Preliminary Results With Uniform Static Tension and Notched Beam Impact Specimens

Static true stress-strain tension tests were first made on uniform diameter specimens of S.A.E. 1045 steel which had been quenched from 1550 F and drawn at various temperatures. At least two specimens for each heat-treated condition were tested and Fig. 2 shows a typical set of curves obtained.[6] It will be noted that straight lines maintain from the maximum load to fracture. Figs. 3 and 4 show the variation of the true stress at maximum load (s_u), the true stress at fracture (s_b), the minimum modulus of strain hardening $\left(\frac{\partial s}{\partial \epsilon}\right)$, the true uniform strain (ϵ_u), the true local necking strain (ϵ_n), and the true fracture strain (ϵ_b) with the drawing temperature. Whenever the figure "2" appears on these curves, it indicates that two observed values are coincident. It is seen from Fig. 3 that the stress and modulus of strain hardening values decrease as the drawing temperature increases. As indicated in Fig. 4 the true fracture strain (ϵ_b) and the true local necking strain (ϵ_n) are affected in a very similar manner by the drawing temperature, while the true uniform strain (ϵ_u) behaves quite differently from these.

A series of notched beam impact tests were conducted on the S.A.E. 1045 steel in the manner previously described and for essentially the same heat-treated conditions used in the static tension tests. Fig. 5 includes the variation of the total impact energy and deformed volume as depending on the drawing temperature for this material. The notched-beam impact energies per unit of deformed volume are plotted versus the drawing temperature in Fig. 6. The areas under the curves of Fig. 2 for the uniform tension tests, i.e., the energy per unit of volume, were also plotted in Fig. 6 for comparison. These latter values form the lower curve in the figure. It can be seen that the uniform tension specimen values, while showing some variation with temperature, are not nearly as sensitive to this variable as the notched beam impact values, and do not reproduce the same type of variation.

Comparison of Energy Values Using Notched Specimens for Both Static Tension and Beam Impact Tests

Since the uniform tension tests did not correlate very well with the notched beam impact results, notched static-tension tests were performed as described above on specimens of the type shown in Fig. 1. Average true stress-strain curves were constructed and the areas under them determined. The energies per unit of volume obtained in this way are shown plotted versus the drawing temperature in Fig. 6, for the S.A.E. 1045 steel. It can be seen from this figure that the notched static tension tests correlate very closely with the notched beam impact tests. Since the energy per unit of deformed volume values for the notched beam impact tests represent an average over the deformed portion of the test piece, and the corresponding values for the notched tension specimens are measured at the most severely deformed portion only, it is natural that these curves should differ by a factor. It was found that the notched tensile specific energies agreed quantitatively with the notched beam specific energies when multiplied by the constant factor $^5/_8$. This result would

[6] After this paper was submitted to the A.S.M.E. it came to the authors' attention that similar true stress-strain curves for this material are contained in a paper presented at the National Metals Congress in Chicago on Oct. 19, 1943, by Lieutenant J. H. Hollomon of the Watertown Arsenal.

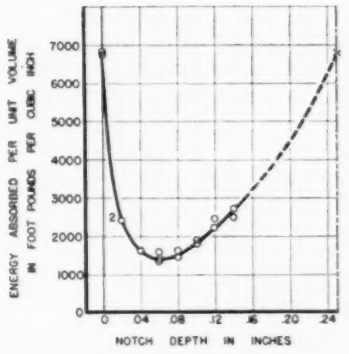

Fig. 7 Variation of Energy Absorbed per Unit of Volume With Notch Depth for Tension Tests on Annealed S.A.E. 1020 Steel

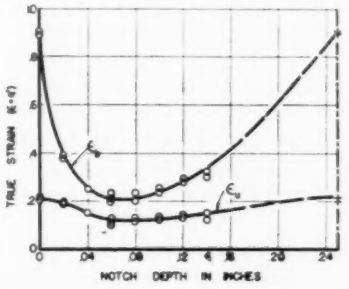

Fig. 8 True Fracture Strain (ϵ_b) and True Uniform Strain (ϵ_u) as a Function of Notch Depth for Tension Tests on Annealed S.A.E. 1020 Steel

seem to indicate that the notched static tension test performed in this way can yield the same information regarding the effect of heat treatment on specific energy values as the notched beam impact test, while at the same time providing additional strength and ductility data. It also indicates that the main effect is due to the notch rather than to the speed of the testing machine. This is in agreement with the results of other investigators. While quantitatively the energies per unit of volume for a given material differ by a constant factor in the two types of tests, this is not important since as pointed out by McAdam (1) and Clyne (1) it is not the actual numerical value of energy obtained from the notched beam impact test but its variation with different conditions that is the important feature of the test.

In order to investigate further the correlation of the static notched tension and the notched beam impact tests, additional experiments were carried out on other materials and under different conditions.

First, the variation of the energy per unit of volume with the depth of the notch in the tension test piece was determined for annealed S.A.E. 1020 steel as indicated in Fig. 7. Since the notch depth used in these experiments was 0.079 in., it can be seen that with a 45 deg angle and a radius of 0.01 in. at the base of the notch, this depth provided a minimum of energy per unit of volume. This is the same depth and shape of notch used in the notched beam impact specimen. Fig. 8 shows that the true uniform strain (ϵ_u) and true fracture strain (ϵ_b) are also a minimum near this depth of notch. It can be seen from this figure that the true uniform and fracture strains are affected somewhat differently by the notching procedure.

Since it is known that the testing temperature has an important effect on impact values, notched static tension and notched beam impact tests were conducted on S.A.E. 1020, 3140, and 1112 steels at various temperatures in order to compare further the results of these two forms of test.

The general effect of the testing temperature on the deformed volume and on the total energy absorbed in notched beam impact can be seen in Figs. 9, 10, and 11 for the three materials mentioned. From these curves it appears that the testing temperature affects the deformed volume in a manner similar to its influence on the total energy. An interesting result is shown in Fig. 11. The total absorbed energy curve has a discontinuity at 110 F. A similar discontinuity appears at this temperature in the deformed volume curve. The curve of energy per unit of deformed volume, however, is continuous throughout. Examina-

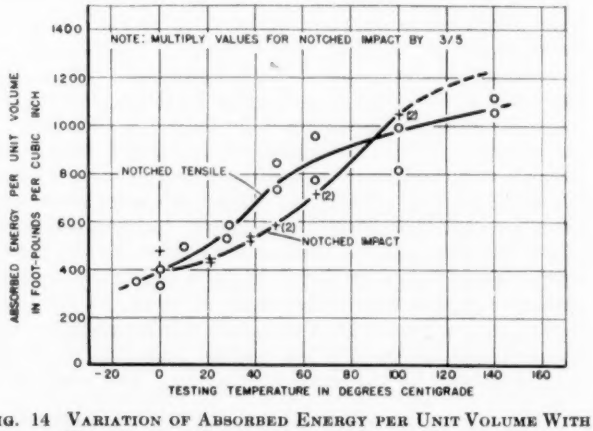

FIG. 14 VARIATION OF ABSORBED ENERGY PER UNIT VOLUME WITH TESTING TEMPERATURE DETERMINED BY RAPID NOTCHED TENSION TESTS AND NOTCHED BEAM IMPACT TESTS ON ANNEALED S.A.E. 1112 STEEL

tion of the test pieces showed that the specimen deforms only in a region near the notch below 110 F while above this temperature general plastic bending of the test piece results. The discontinuity then is not due to any change in the properties of the material at the notch but merely due to bending in a region removed from it. This provides added evidence that the energy per unit of volume is of more fundamental significance than total energy.

While the speed of testing was not found to be critical for the S.A.E. 1045 steel discussed earlier, or for the S.A.E. 3140 steel, the average testing time being 35 min for these materials, the onset of strain aging occurring during the tension tests at the higher temperatures for the low carbon steels necessitated for the S.A.E. 1020 and 1112 increased testing velocities if the results were to be compared with the notched beam impact tests. In fact the notched beam impact tests were completed before strain aging could be effective. Preliminary notched tension tests lasting 35 min on the two low-carbon steels showed that no correlation would be possible at the higher temperatures due to this aging effect. Consequently, the speeds of these tension tests were increased to 4 in. per min, providing a testing period of only a few seconds.

A comparison of the energies per unit of volume for the notched tension and the notched beam impact tests for these three steels, as affected by the testing temperature, can be made by referring to Figs. 12, 13, and 14. In Fig. 12 values from both slow and rapid tension tests are included. It can be seen that the testing velocity is not particularly important for the S.A.E. 3140. Further, the notched impact and the notched tensile specific energies show similar trends with the testing temperature. An examination of Figs. 13 and 14 for the S.A.E. 1020 and 1112 steels leads to a similar conclusion.

Although more experiments should be made with other materials and under other conditions of heat treatment, testing temperature, etc., in order to determine possible exceptions, these results seem to indicate that static notched tension tests of the true stress-strain type can be used to obtain essentially the same specific energy information as yielded by the notched beam impact test, while at the same time supplying useful stress-strain data not obtainable with the notched beam test.

Conclusion

The following conclusions may be drawn from these experiments:

1 For the same materials and conditions maintaining as in the present investigation, a reasonably good correlation exists between the notched beam impact test and the static notched tension test when true stress-strain values are employed. Both forms of test display essentially the same effects of drawing and testing temperatures on the specific energy for fracture.

2 While the main characteristics of the notched beam impact test in these experiments appear to be due to the notch rather than to the testing machine speed, the duration of the test is important where such effects as strain aging are pronounced. For a material subject to such changes in properties during the test, the duration of the tension test must approach that of the impact test in order for the correlation mentioned in (1) to hold. It is also apparent that when tests are conducted at temperatures considerably in excess of those employed in these experiments, or when low melting alloys are investigated at normal temperatures, the testing speed is of considerable importance.

3 Although the notched beam impact test appears to correlate with the notched static tension test better than with the uniform static tension test, this does not detract from the great value and significance of the tension test on uniform specimens. The latter are especially important where correlations are desired between tension values and results from other forms of tests such as torsion tests, combined stress tests of many kinds, metal forming operations such as drawing, rolling, etc. It is evident that no one form of tension test is the best for all purposes. The notched tension test seems to be particularly useful in those applications where the notched beam impact test has proved of value.

4 Attention should also be invited to the fact that while the notched static tension test takes longer to perform than the standard notched beam impact test where total energies only are determined, it has the added advantage of supplying stress-strain data not obtainable in the impact test. It appears that the energy per unit of deformed volume (specific energy) from the notched beam impact test is of more fundamental significance than total energy. If the former is determined in the impact test the time consumed is usually in excess of that required for the notched static tension test.

Acknowledgment

The experimental work described in this paper was performed in the laboratories of the Department of Mechanical Engineering at the Massachusetts Institute of Technology, and the authors wish to acknowledge the interest and support given the project by Dr. Compton and by Dr. Hunsaker. The careful machining of the test specimens was carried out by Mr. Herbert Johnson, and assistance in the experiments was given by Messrs. J. C. Crowley and H. J. Maier.

The Effects of Web Deformation on the Torsion of I-Beams

By J. N. GOODIER[1] and M. V. BARTON[2]

An analysis of the I-beam in nonuniform torsion, as for instance, when a built-in end or section of symmetry is prevented from warping, is made which includes not only the bending of the flanges in their own planes (as considered previously by Timoshenko) but also a deformation of the web cross section. This extends the theory to thinner webs and permits the satisfaction of more general end conditions. Numerical examples worked out for three sections, differing in web thickness only, show that the stress and deformation are significantly modified by the web flexibility when the web is sufficiently thin, and that there are then bending stresses in the web which may be larger than the bending stresses in the flanges. Only the unbuckled state of the web is considered.

WHEN I-beams are subject to a nonuniform torsional deformation, in which the angle of twist β at a section with axial co-ordinate z is not simply proportional to z (or linear in z), the center lines of the flanges become curves,[3] Fig. 1, and

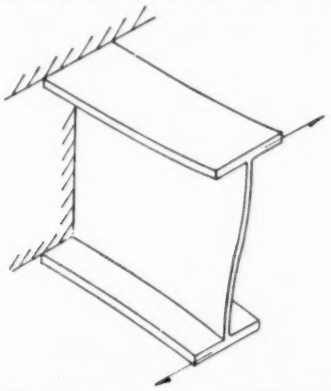

FIG. 1 FLANGE BENDING SHOWING SHEAR FORCES

each flange is in the condition of a beam with bending moments and shearing forces. The two shearing forces in the two flanges form an axial couple which combines with the ordinary Saint Venant couple of the torsional shearing stress to balance the axial couple, at the section, due to applied twisting moments. A theory of this behavior has been worked out by Timoshenko,[4] who applied it to the analysis of the twisted I-beam, and other sections, when warping of the cross section is prevented at one or both ends. Timoshenko's differential equation[5] may be written

$$\frac{1}{2}EI_f h^2 \beta''' - GC\beta' = -T$$

where EI_f is the flexural rigidity of one flange as a beam bent in its own plane, h is the distance between flanges, GC is the Saint Venant torsional rigidity of the whole section, and T is the twisting moment which must be balanced by the stresses on the section z. Primes denote differentiation with respect to z. The deflection of a flange as a beam is $\beta h/2$, Fig. 3*a*.

The solution for a beam built-in (warping prevented) at $z = 0$ and twisted by a moment T at the other end $z = l$ is such that

$$\beta' = \frac{T}{GC}\left\{1 - \frac{\cosh r(l-z)}{\cosh rl}\right\}$$

where $1/r^2 = EI_f h^2/2GC$. Thus (unless l is infinite) β''' is not zero at the end $z = l$, and the flange bending torque $EI_f(h^2/2)\beta'''$ is not zero. The moment T at $z = l$ must therefore, for the analysis, to be valid at both ends, be applied as a mixture of Saint Venant torque $GC\beta'$ and flange bending torque, in proportions which we are not free to assign. In fact, since the equation is of the third order, only three end conditions can be satisfied.

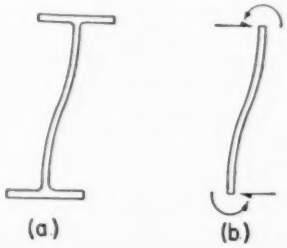

FIG. 2 WEB DEFORMATION

From the fact that the analysis treats the whole beam as twisted, and the flanges as beams bent in their planes, we should expect to be able to satisfy two conditions at each end of the flange, as for a beam, and one condition on the torsion of the beam as a whole for each end. At least we may expect to be able to assign the contributions to the total torque at each end of the Saint Venant torque and the torque of the flange shearing forces. The analysis of Timoshenko is not sufficiently general to permit this. The inference is therefore that it disregards some aspect of the problem which is significant in the bending of the flanges as beams and the torsion of the beam as a whole. It is shown in this paper that the desired generality may be obtained by considering a deformation of the web. At the same time it is shown that certain bending stresses exist in the web which become important when the web is thin. The analysis may also elucidate some problems in the deformation of "beams" formed of two flanges connected by a lattice "web," the latter being thought of as replaced by a thin continuous web. The

[5] Reference 4(*b*), p. 257.

lateral buckling of such beams is known to involve the type of deformation indicated in Fig. 2, rather than the simple rotation of cross sections assumed in the present theory of lateral buckling, and an analysis of lateral buckling taking this into account can be developed from the results which will be given.

The existence of web deformation, as indicated in Fig. 2, is to be expected from the consideration that the deflection of a flange in its own plane as a beam will in general have a nonzero fourth derivative, corresponding to some distributed load on the flange. This load (at least in part, when there is external distributed load on each flange) must be applied by the web. Correspondingly there are reactive lateral forces and accompanying moments on the web, as indicated in Fig. 2(*b*), and these cause the web cross section to become curved.

Again, if we consider the influence of web thickness on the behavior of an I-beam, it soon becomes apparent from examples that such deformation can be important. Consider a long I-beam built-in at one end, and twisted by two equal and opposite flange shears at the other end, Fig. 1. This couple is transformed more or less gradually as we proceed along the beam into the Saint Venant shearing stresses of torsion, the flange shears disappearing. This much follows from Saint Venant's principle. But the limiting case of the very thin web would be a web of negligible influence on the flanges. Then they are independent cantilevers, and the same shear force persists all along. The flanges are not twisted. When the web is very thin, therefore, it must have the deformation shown in Fig. 2, and its thickness must govern closely the manner in which the total torque at a section is shared between the Saint Venant torsional couple and the couple formed by the flange shear forces

Saint Venant's principle would indicate that simple (Saint Venant) torsion would be established in a distance from the end comparable with the "dimensions of the end." We find in this case, however, that the governing dimension is not the over-all size of the end, that is, the cross section, but something involving the thickness of the web in relation to the other cross-sectional measurements.

The Differential Equations

Fig. 3(*a*) indicates the rotation β of the section without deformation, which is assumed in Timoshenko's theory. Fig. 3(*b*) indicates how the web bending is specified by the angle α. Thus each flange is a beam bent in its own plane to a deflection $\beta h/2$, and twisted through an angle $\beta - \alpha$ at a section z. A distribution of lateral load q per unit length acts on it, as indicated in Fig. 4, and also a distribution of twisting couple m per unit length, both exerted by the web. The equations of bending and twisting may thus be written

$$\frac{1}{2} hEI_f\beta^{iv} = q \qquad [1]$$

$$GC_f(\beta' - \alpha') = -m \qquad [2]$$

where GC_f is the torsional rigidity of one flange alone, G being the shear modulus.

The web is a rectangular strip twisted to the angle β, but also deformed, as shown in Fig. 4, by the forces q and the couples m. These constitute a distribution of twisting moment $2m + qh$ per unit length, and the torsional equation is

$$GC_w\beta' = 2m + qh \qquad [3]$$

where GC_w is the torsional rigidity of the web alone. The angle α can be calculated in terms of the forces acting on a slice of the web between the sections z and $z + dz$. This strip may be regarded as bent (Fig. 5) by the end forces and couples qdz and mdz, and by the distributed bending couple formed by the difference in the Saint Venant shearing stresses on the two sections. The difference of torsional couple is $GC_w\beta'dz$ and this is distributed along the length h of the strip in Fig. 5, thus giving a distribution of couple $(GC_w/h)\beta'dz$ per unit length, which is a bending couple with reference to the bending indicated in Fig. 5. From the solution of this beam problem we find

$$m = \frac{6D_w}{h}\alpha \qquad [4]$$

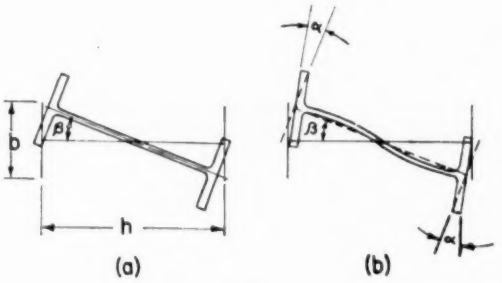

Fig. 3

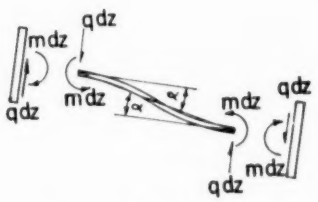

Fig. 4

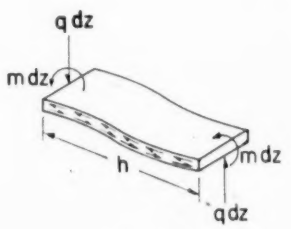

Fig. 5

where $D_w = Et_w^3/12(1 - \nu^2)$, t_w being the web thickness, and the factor $(1 - \nu^2)$ with ν as Poisson's ratio occurring in virtue of the prevention of anticlastic curvature in the strip by its attachment to the rest of the web.

Equations [1], [2], [3], and [4] are four equations for β, α, m, and q. On elimination of m and q we find the two equations

$$GC_f(\beta' - \alpha') + 6\frac{D_w}{h}\alpha = 0 \qquad [5]$$

$$\frac{1}{2}EI_fh^2\beta^{iv} - GC_w\beta' + 12\frac{D_w}{h}\alpha = 0 \qquad [6]$$

for α and β.

If T is the twisting moment produced by all forces beyond the section z, in the clockwise sense looking along the z axis, Fig. 6, this moment is balanced by the stress on the section, and

$$T = GC_w\beta' + 2GC_f(\beta' - \alpha') - \frac{1}{2}EI_fh^2\beta'''$$

or

$$T = GC\beta' - 2GC_f\alpha' - \frac{1}{2}EI_f h^2\beta''' \quad \ldots\ldots [7]$$

where GC is the torsional rigidity of the whole section. This follows at once from the fact that the web is twisted to the angle

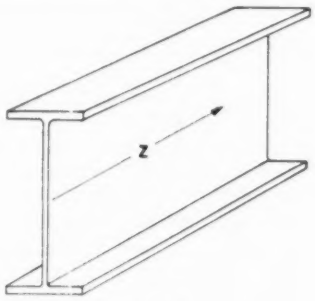

FIG. 6

β, each flange to the angle $\beta - \alpha$, and that there is a shearing force $\frac{1}{2}EI_f h\beta'''$ in each flange. Equation [7] may thus, when it is convenient, replace one of the Equations [1], [2], [3], or [4].

Using the dimensionless coefficients

$$\left.\begin{aligned} k_1 &= \frac{EI_f}{2GC} \\ k_2 &= \frac{C_w}{C} \\ k_3 &= \frac{C_f}{C} \\ k_4 &= \frac{6D_w h}{GC} \end{aligned}\right\} \quad \ldots\ldots [8]$$

Equations [5] and [6] may be written

$$k_3 h^2(\beta'' - \alpha'') + k_4\alpha = 0 \quad \ldots\ldots [9]$$

$$k_1 h^4\beta^{iv} - k_3 h^2\beta'' + 2k_4\alpha = 0 \quad \ldots\ldots [10]$$

SOLUTION OF THE DIFFERENTIAL EQUATIONS

The equations, being linear with constant coefficients, have solutions of the form $\beta = C_1 e^{\lambda z}$, $\alpha = C_2 e^{\lambda z}$, in addition to the obvious solution

$$\beta = A_1 + A_2 z, \quad \alpha = 0 \quad \ldots\ldots [11]$$

which corresponds to ordinary (Saint Venant) twisting. On substitution of the exponential forms we have

$$\left.\begin{aligned} (k_3\lambda^2 h^2 - k_4)C_1 - k_3\lambda^2 h^2 C_2 &= 0 \\ 2k_4 C_2 + (k_1\lambda^4 h^4 - k_3\lambda^2 h^2)C_1 &= 0 \end{aligned}\right\} \quad \ldots\ldots [12]$$

which can only be satisfied with C_1, C_2 different from zero if

$$\lambda^2 h^2(k_3\lambda^2 h^2 - k_4)(k_1\lambda^2 h^2 - k_3) + 2k_3 k_4\lambda^2 h^2 = 0 \quad \ldots\ldots [13]$$

The root $\lambda^2 h^2 = 0$ corresponds to the simple torsional solution previously mentioned. When the factor $\lambda^2 h^2$ is removed, Equation [13] becomes a quadratic in $\lambda^2 h^2$ with roots given by

$$\frac{2}{K_1}(\lambda h)^2 = 1 \pm \sqrt{1 - K_2} \quad \ldots\ldots [14]$$

where

$$K_1 = \frac{k_3}{k_1} + \frac{k_4}{k_3} = \frac{2GC_w}{EI_f} + \frac{6D_w h}{GC_f} \quad \ldots\ldots [15]$$

$$K_2 = \frac{4\frac{k_4}{k_1}\left(2 + \frac{k_3}{k_3}\right)}{\left(\frac{k_3}{k_1} + \frac{k_4}{k_3}\right)^2} = 48\frac{D_w h}{EI_f}\left(2 + \frac{C_w}{C_f}\right)\Big/\left(\frac{2GC_w}{EI_f} + \frac{6D_w h}{GC}\right)^2 \quad \ldots [16]$$

Thus the dimensionless group $(\lambda h)^2/K_1$ is a function of the group K_2 only. In any given case K_1 and K_2 can be calculated from the data and the two values of $(\lambda h)^2$ found. These are real or complex according as K_2 is less than or greater than 1. It appears from the calculations already made that they are complex if the web is sufficiently thin, being real for thick webs. The two cases are now discussed separately.

Real Roots. There are two real values of λ^2. Let these be denoted by λ_1^2, λ_2^2 where λ_1, λ_2 are positive. Then we have the four possible values of λ, $\pm\lambda_1$, $\pm\lambda_2$. The complete solution for β is

$$\beta = A_1 + A_2 z + A_3 e^{\lambda_1 z} + A_4 e^{-\lambda_1 z} + A_5 e^{\lambda_2 z} + A_6 e^{-\lambda_2 z} \quad \ldots [17]$$

where A_1, A_2, etc., are arbitrary constants. The corresponding constants in α are related to these as C_1 and C_2 are related by either of the Equations [12], and we have as the complete solution for α

$$\alpha = [k_5(\lambda_1 h)^2 - k_6(\lambda_1 h)^4][A_3 e^{\lambda_1 z} + A_4 e^{-\lambda_1 z}] + [k_5(\lambda_2 h)^2 - k_6(\lambda_1 h)^4][A_5 e^{\lambda_2 z} + A_6 e^{-\lambda_2 z}] \quad \ldots\ldots [18]$$

where $k_5 = k_2/2k_4$, $k_6 = k_1/2k_4$.

Complex Roots. When the two possible values of λ^2 are complex, they will yield four possible complex values δf λ in the form $\pm(\xi \pm i\eta)$. The solution for β becomes

$$\beta = B_1 + B_2 z + e^{\xi z}(B_3 \cos \eta z + B_4 \sin \eta z) + e^{-\xi z}(B_5 \cos \eta z + B_6 \sin \eta z)$$

where B_1, B_2, etc., are real constants. The solution for α in terms of these same constants then follows from Equation [10].

In the four values of λ, $\pm(\xi \pm i\eta)$, it is evident that whether ξ, η be positive or negative two of the values will have positive real parts, the other two negative. It is then permissible to take ξ (and η) as positive. Then with $\lambda_1 = \xi + i\eta$, $\lambda_2 = \xi - i\eta$ the four values are $\pm\lambda_1$, $\pm\lambda_2$, the values λ_1, λ_2 having positive, and $-\lambda_1$, $-\lambda_2$ negative, real parts. With this notation, the solution of Equations [17] and [18] covers both real and complex roots. In the latter case A_3, A_4, A_5, A_6 are complex. Then the real parts of β and α and the imaginary parts must satisfy Equations [9] and [10] separately, since these are linear equations with real coefficients. The imaginary parts may thus be discarded, but this may be done before or after β and α have, with the appropriate derivatives, been made to assume the required (real) end values of the particular problem.

End Conditions. If at a "fixed" end, the beam is rigidly attached by the flanges only (Fig. 7), the end of the web being free, each flange, as a beam in its plane, is built in with zero deflection. We have, therefore, $\beta = 0$ and $\beta' = 0$. Also, since there is no twisting rotation of the flange end, $\beta - \alpha = 0$. The web end is free from torsional shearing stress, requiring again $\beta' = 0$. The conditions are thus $\alpha = \beta = \beta' = 0$.

If the web is rigidly held, as well as the flanges, the condition

on the web is $\alpha = 0$ and the conditions are still the same. Fixing the web thus has no effect so long as the flanges are fixed.

If, however, the web is fixed but the flanges are free (Fig. 8), we have for the web

$$\alpha = 0, \quad \beta = 0$$

for the flange

$$\beta = 0, \quad \beta' - \alpha' = 0, \quad \beta'' = 0, \quad \beta''' = 0 \ldots\ldots [19]$$

the flange conditions corresponding, respectively, to zero deflection, zero torsional shearing stress, zero longitudinal (flange bending) stress, and zero transverse shear force. However, all these conditions cannot be satisfied by the present theory except of course in the trivial case of the completely unloaded condition. This is shown, and some explanation offered, in the next section.

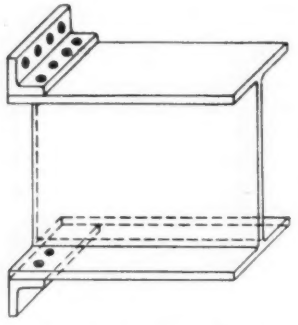

FIG. 7 FLANGES FIXED

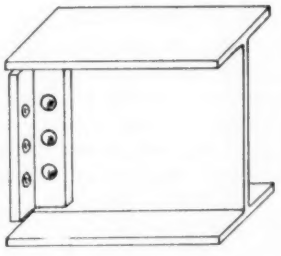

FIG. 8 WEB FIXED

THE LONG BEAM

Flanges Fixed at $z = 0$. If the beam is sufficiently long, the state of stress found at the fixed end will merge into that of ordinary torsion. Thus we may take besides the conditions

$$\alpha = \beta = \beta' = 0 \text{ at } z = 0$$

the condition that β approaches a linear function of z as z increases. We must then discard the positive exponentials in Equations [17] and [18], and take

$$\beta = A_1 + A_2 z + A_4 e^{-\lambda_1 z} + A_6 e^{-\lambda_2 z} \ldots\ldots [20]$$

$$\alpha = [k_5(\lambda_1 h)^2 - k_6(\lambda_1 h)^4] A_4 e^{-\lambda_1 z} + [k_5(\lambda_2 h)^2 - k_6(\lambda_2 h)^4] A_6 e^{-\lambda_2 z} \ldots\ldots [21]$$

This covers complex λ's as well as real, since in the former case λ_1 and λ_2 have been defined as having positive real parts; as

$$z \to \infty, \ \beta \to A_1 + A_2 z \text{ and } \beta' \to A_2$$

Thus the axial couple transmitted by the beam is $GCA_2 = T$. The conditions at $z = 0$ require

$$A_1 + A_4 + A_6 = 0, \qquad A_2 - \lambda_1 A_4 - \lambda_2 A_6 = 0$$

$$[k_5(\lambda_1 h)^2 - k_6(\lambda_1 h)^4] A_4 + [k_5(\lambda_2 h)^2 - k_6(\lambda_2 h)^4] A_6 = 0$$

whence

$$A_4 = \frac{A_2}{\lambda_2} \cdot \left[\frac{\lambda_1}{\lambda_2} - \frac{k_5(\lambda_1 h)^2 - k_6(\lambda_1 h)^4}{k_5(\lambda_2 h)^2 - k_6(\lambda_2 h)^4} \right]^{-1},$$

$$A_6 = \frac{A_2}{\lambda_1} \left[\frac{\lambda_2}{\lambda_1} - \frac{k_5(\lambda_2 h)^2 - k_6(\lambda_2 h)^4}{k_5(\lambda_1 h)^2 - k_6(\lambda_1 h)^4} \right]^{-1}$$

in which A_2 can be replaced by T/GC.

The quantity A_1, given by $-(A_4 + A_6)$ represents the effect on the angle of twist $(A_1 + A_2 z)$ of a long length, of the flange bending and web deformation near $z = 0$, since without this local condition there would be simple torsion $\beta = A_2 z$ with $GCA_2 = T$.

The results of such calculations for an I-beam with three different web thicknesses are given in the next section.

Web Fixed, Flanges Free. The end conditions (at $z = 0$) are given by Equation [19], and must be satisfied by Equations [20] and [21]. If we take only the conditions on the flange, the second line of Equation [19], we find at once from

$$\beta = \beta'' = \beta''' = 0 \quad \text{that} \quad A_1 = A_4 = A_6 = 0$$

and thus that $\alpha = 0$ all along the beam. Then the remaining flange condition $\beta' - \alpha' = 0$ reduces to $\beta' = 0$ and gives $A_2 = 0$. All the A's are now zero, and the beam is in the unloaded condition. The conclusion is that fixture of the web only involves a state of deformation which cannot be represented at all by the web twisting and bending, and flange twisting and bending, of the present theory. Some yet more highly localized and complex stress distribution is to be expected near the end, depending upon the details of the fixture.

THE FINITE BEAM

Flanges Rigidly Attached at Both Ends to Plates Which Remain Normal to Axis. The beam is twisted by moments applied to the plates to which the flange ends are fixed, Fig. 9. These plates rotate (by equal amounts β_1 in opposite directions) in their own planes. If we take the origin at the middle, β will be an odd function of z, and we may take

$$\beta = A_2 z + B_3 \sinh \lambda_1 z + B_5 \sinh \lambda_2 z$$

$$\alpha = [k_5(\lambda_1 h)^2 - k_6(\lambda_1 h)^4] B_3 \sinh \lambda_1 z + [k_5(\lambda_2 h)^2 - k_6(\lambda_2 h)^4] B_5 \sinh \lambda_2 z$$

with $\alpha = \beta' = 0, \quad \beta = \beta_1, \quad \text{at } z = l$

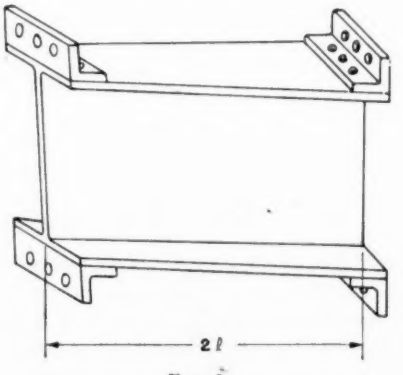

FIG. 9

These conditions yield three equations whence A_2, B_3, B_5 can be found in terms of β_1. The relation between β_1 and the applied twisting moment T can then be found from Equation [7].

NUMERICAL EVALUATIONS

Figs. 11 to 18 show the results of calculations for the section shown in Fig. 10, with three values of the web thickness, 0.35 in., 0.175 in., and 0.0875 in., respectively. Figs. 11, 12, 13 are for a beam of infinite length, built-in at the left end and twisted by a torque T at the other end, as discussed under the heading "The Long Beam: Flanges fixed at $z = 0$." Each figure is for a particular web thickness and shows the rotation of the cross section β, the bending moment (per unit axial length) m in the web, and the flange bending moment M. It will be observed that β and M show only small departures from the values found

from Timoshenko's analysis, the departures being most pronounced for the thinnest web.

There are radical differences however in m. The theory of this paper differs from the Timoshenko theory in the introduction of the angle α and reduces to it when α is taken as zero. Then Equation [2] gives $m = -GC_f\beta''$ for the calculation of m, according to the Timoshenko theory. This has its greatest value at the fixed end. On the other hand, the theory of the present paper gives m according to Equation [4], and since α vanishes at the fixed end, m does also.

The stress corresponding to m is called "web bending stress." It attains significant magnitudes, being greater for the thinner webs. Its ratio to the flange bending stress (using greatest values) is 0.19 for $t = 0.35$ in., but 1.02 for $t = 0.0875$ in. The ratio of flange bending stress to (Saint Venant) torsional shear stress is 1.85 for $t = 0.35$ in., and 1.35 for $t = 0.0875$ in.

It must be remarked, however, that Equation [4] is accurate only when m varies little in an axial length equal to the depth

T_w = Torque modification due to web deformation

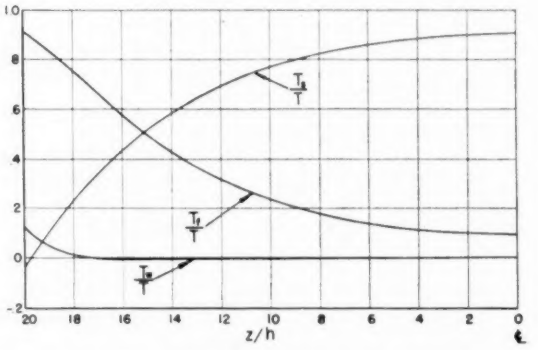

FIG. 18 TORQUE DIVISION FOR I-BEAM OF FINITE LENGTH
(Length = 20 h; web thickness = 0.35 in.)

h of the web. The variation found near the fixed end is rapid, and the results may therefore be subject to some correction on this account. The correction could be determined by more elaborate analysis.

Fig. 17 exhibits the relative magnitudes of the terms of Equation [7] for the total torque. The second term of course would be absent in the Timoshenko theory (and the value of β different). In Fig. 17, the first term of the right side of Equation [7] is denoted by T_s, the second by T_w, and the third by T_f. It will be observed that the second term, arising directly from the bending of the web, becomes important near the fixed end when the web is thin.

Another set of results is shown in Figs. 14, 15, 16, and 18 for the beam of finite length in the condition discussed under the heading "The Finite Beam: Flanges Rigidly Attached at Both Ends to Plates Which Remain Normal to Axis." In Figs. 14, 15, and 16, however, the web thickness is the same (0.35 in.) in each case. It is the length of the beam which is different. Again, there is little departure from the Timoshenko values in β and M, but pronounced departure in m near the end. In these three diagrams, the right end of the horizontal axis is the mid-section of the beam, the deformation being antisymmetrical about the plane of this section.

Pi-Tee Transformations in the Analysis of Mechanical Transmission Lines

By G. HORVAY[1] and S. PINES,[2] WASHINGTON, D. C.

A method is given which simplifies the analysis of mechanical transmission systems without making use of "electrical analogies." The method is applied to the problem of the viscous vibration damper.

1—Introduction

THE solution of the vibration problem of a shaft system is often facilitated by the replacement of certain portions of the system by simpler dynamical equivalents. For instance, the two shafts K_1, K_2, Fig. 1(*a*), connecting the masses M_1 and M_2 of a given system, can be replaced by a shaft of stiffness

$$K = K_1 + K_2 \quad [1]$$

Fig. 1(*b*), in all vibration calculations.* We shall refer to this replacement as "substitution I." Likewise, the two shafts K_α, K_β of the partial system shown in Fig. 2(*a*) can be replaced by the single equivalent shaft

$$K = \frac{1}{1/K_\alpha + 1/K_\beta} \quad [2]$$

as shown in Fig. 2(*b*). We shall call this "substitution II."

Other substitutions permit the simplification of geared systems. These substitutions are well known[3, 4, 5] and will not concern us. In this paper our main interest is centered on what we shall call "substitution III," the replacement of the partial system $[K_1, M_3, K_2]$ of Fig. 3(*a*) by the dynamically equivalent partial system $[M_1', K_3', M_2']$ of Fig. 3(*b*).

A given system, of which $[K_1, M_3, K_2]$ forms a part, transmits to shaft K_1 at point 1 a harmonic force $f_1(t) = F_1 e^{j\omega t}$ and a harmonic displacement

$$x_1(t) = X_1 e^{j\omega t} \quad [3a]$$

The partial system $[K_1, M_3, K_2]$ modifies the force and the motion, with the result that the force and the displacement delivered to the remainder of the system at point 2 assume the new values $f_2(t) = F_2 e^{j\omega t}$ and

Fig. 1 The System in Diagram (*b*) Is Equivalent to the System in Diagram (*a*) by Virtue of Equation [1]

Fig. 2 The System in Diagram (*b*) Is Equivalent to the System in Diagram (*a*) by Virtue of Equation [2]

Fig. 3 The System in Diagram (*b*) Is Equivalent to the System in Diagram [*a*] by Virtue of Equations [4]

$$x_2(t) = X_2 e^{j\omega t} \quad [3b]$$

If $[M_1', K_3', M_2']$ is the dynamical equivalent of $[K_1, M_3, K_2]$, then the application of the foregoing x_1 and f_1 at point 1′ results in the same x_2 and f_2 at point 2′ as resulted at point 2. Thus our problem is to determine the quantities M_1', K_3', M_2' which yield the correct x_2 and f_2.

The solution of the problem at any frequency ω is

$$M_1' = \frac{K_1 M_3}{K_1 + K_2 - M_3\omega^2}, \quad M_2' = \frac{K_2 M_3}{K_1 + K_2 - M_3\omega^2}$$

$$K_3' = \frac{K_1 K_2}{K_1 + K_2 - M_3\omega^2} \quad [4a]$$

We denote these equations more simply by

$$K_1' = K_1K_3/K, \quad K_2' = K_2K_3/K, \quad K_3' = K_1K_2/K \quad [5a]$$

where

$$K_1' = -M_1'\omega^2, \quad K_2' = -M_2'\omega^2, \quad K_3 = -M_3\omega^2,$$

$$K = K_1 + K_2 + K_3 \quad [5']$$

The inverse transformation, which leads from Fig. 3(*b*) to Fig. 3(*a*), is given by the formulas

$$\left.\begin{aligned} K_1 &= (1 + M_1'/M_2')K_3' - M_1'\omega^2 \\ K_2 &= (1 + M_2'/M_1')K_3' - M_2'\omega^2 \\ M_3 &= M_1' + M_2' - M_1'M_2'\omega^2/K_3' \end{aligned}\right\} \quad [4b]$$

In an abbreviated form these can be written as

$$K_1 = K'^2/K_2', \quad K_2 = K'^2/K_1', \quad K_3 = K'^2/K_3' \quad [5b]$$

where

$$K'^2 = K_1'K_2' + K_2'K_3' + K_3'K_1' \quad [5'']$$

The transformation [5*a*] is known in Electrical Engineering literature as a $\Pi - T$ (or $\Delta - Y$) transformation, the inverse

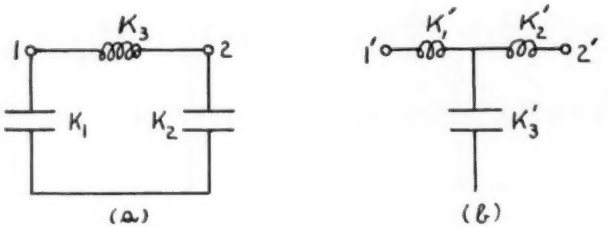

FIG. 4 PI AND TEE CIRCUITS

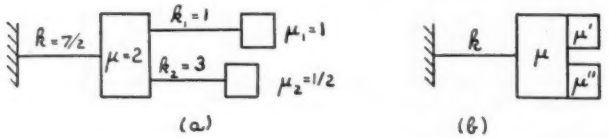

FIG. 5 REDUCTION OF A BRANCHED SYSTEM TO A SIMPLE SYSTEM

transformation [5b] is known as a $T - \Pi$ (or $Y - \Delta$) transformation. The Π and T circuits are illustrated in Figs. 4(*a*, *b*); the impedances are denoted by K_1, K_2, K_3, and by K_1', K_2', K_3', respectively. The equivalence of Figs. 3(*a*) and 4(*a*), and of Figs. 3(*b*) and 4(*b*) will become apparent in section 2. (Equations [7] and [8] apply both to the mechanical systems, Fig. 3, and to the electrical systems, Fig. 4. We shall not make use of this correspondence, as our aim is to analyze mechanical transmission systems without an appeal to "electrical analogies.")

As a simple illustration, we consider the problem of determining the natural frequencies of the branched system, Fig. 5(*a*). We replace the upper shaft k_1 and mass μ_1 by an equivalent mass μ' as follows: For the quantities $[K_1, M_2, K_2]$ of Fig. 3(*a*), we take $[k_1, \mu_1, 0]$ in Fig. 5(*a*). Equations [5*a*] then give $K_2' = K_3' = 0$, and

$$-\mu'\omega^2 = K_1' = \frac{K_1K_3}{K_1 + K_2 + K_3} = -\frac{k_1\mu_1\omega^2}{k_1 - \mu_1\omega^2}$$

from which

$$\mu' = \frac{k_1\mu_1}{k_1 - \mu_1\omega^2} \qquad [6]$$

In terms of the given numerical values $\mu' = 1/(1 - \omega^2)$.

Similarly, the lower shaft k_2 and mass μ_2 can be replaced by an equivalent mass μ''

$$\mu'' = \frac{k_2\mu_2}{k_2 - \mu_2\omega^2} = \frac{3/2}{3 - \omega^2/2}$$

Thus for the dynamically equivalent system, Fig. 5(*b*)

$$\omega^2 = \frac{k}{\mu + \mu' + \mu''} = \frac{3.5}{2 + 1/(1 - \omega^2) + 1.5/(3 - 0.5\,\omega^2)}$$

Clearing fractions and collecting terms, we get

$$\omega^6 - \frac{43}{4}\,\omega^4 + \frac{91}{4}\,\omega^2 - \frac{21}{2} = (\omega^2 - 2)\left(\omega^4 - \frac{35}{4}\,\omega^2 + \frac{21}{4}\right) = 0$$

from which $\omega = \sqrt{0.648},\ \sqrt{2},\ \sqrt{8.102}$ are obtained as the natural frequencies of the system.

Substitution III is one of the most powerful tools of electrical-circuit analysis. It also plays a fundamental role in shaft-vibration problems. An independent derivation of Equations [5*a*, *b*], using mechanical engineering terminology, seems therefore justified and is given in section 2. The method is applied to the problem of the viscous vibration damper in section 3. Two successive $\Pi - T$ transformations bring the system to a form which then can be treated by Holzer's method. For purposes of comparison Appendix 1 includes an outline of the solution of the same problem by means of the "electrical-analogy" method. This method appears artificial and lengthy compared to the direct approach.

2—THE $\Pi - T$ TRANSFORMATION

We begin with the inverse transformation. The equations of motion of the $[M_1', K_3', M_2']$ system, Fig. 3(*b*), are

$$M_1'\ddot{x}_1' + K_3'(x_1' - x_2') = \mathfrak{F}_1'e^{j\omega t}$$

$$K_3'(x_2' - x_1') + M_2'\ddot{x}_2' = \mathfrak{F}_2'e^{j\omega t} = -F_2'e^{j\omega t}$$

The force applied at point 1′ is denoted by $\mathfrak{F}_1'$. The force delivered at point 2′ is denoted by F_2'; the balancing force, $-F_2'$, is denoted by $\mathfrak{F}_2'$. In the notation of Equations [3*a*, *b*] and [5′], the foregoing equations can be written in the form

$$\left.\begin{aligned}(K_1' + K_3')X_1' - K_3'X_2' &= \mathfrak{F}_1' \\ -K_3'X_1' + (K_2' + K_3')X_2' &= \mathfrak{F}_2'\end{aligned}\right\} \qquad [7]$$

Let the quantities X_1' and $\mathfrak{F}_1'$ at terminal 1′ be given. Then the quantities X_2' and $\mathfrak{F}_2'$ at terminal 2′ are uniquely fixed in terms of X_1', $\mathfrak{F}_1'$ and the parameters K_1', K_2', K_3'.

The equations of motion of the system of Fig. 3(*a*) are

$$\begin{aligned}K_1(x_1 - x_3) &= \mathfrak{F}_1e^{j\omega t} \\ K_1(x_3 - x_1) + M_3\ddot{x}_3 + K_2(x_3 - x_2) &= 0 \\ K_2(x_2 - x_3) &= \mathfrak{F}_2e^{j\omega t}\end{aligned}$$

The motion of the mass M_3 is represented by $x_3(t) = X_3e^{j\omega t}$. We can rewrite these equations in the form

$$\left.\begin{aligned}K_1X_1 - K_1X_3 &= \mathfrak{F}_1 \\ -K_1X_1 + (K_3 + K_1 + K_2)X_3 - K_2X_2 &= 0 \\ -K_2X_3 + K_2X_2 &= \mathfrak{F}_2\end{aligned}\right\} \qquad [8]$$

By assumption $X_1 = X_1'$, $\mathfrak{F}_1 = \mathfrak{F}_1'$. The problem is to find the values K_1, K_2, K_3 which will result in $X_2 = X_2'$, $\mathfrak{F}_2 = \mathfrak{F}_2'$. Instead of fixing $X_1 = X_1'$, $\mathfrak{F}_1 = \mathfrak{F}_1'$, and solving the equations $X_2 = X_2'$, $\mathfrak{F}_2 = \mathfrak{F}_2'$ for K_1, K_2, K_3, we can prescribe more conveniently $\mathfrak{F}_1 = \mathfrak{F}_1'$, $\mathfrak{F}_2 = \mathfrak{F}_2'$, and solve for K_1, K_2, K_3 from $X_1 = X_1'$, $X_2 = X_2'$.

From Equations [7] we obtain

$$\left.\begin{aligned}X_1' &= \frac{K_2' + K_3'}{K'^2}\,\mathfrak{F}_1' + \frac{K_3'}{K'^2}\,\mathfrak{F}_2' \\ X_2' &= \frac{K_3'}{K'^2}\,\mathfrak{F}_1' + \frac{K_1' + K_3'}{K'^2}\,\mathfrak{F}_2'\end{aligned}\right\} \qquad [9]$$

From Equations [8], we obtain

$$\left.\begin{aligned}X_1 &= \left(\frac{1}{K_1} + \frac{1}{K_3}\right)\mathfrak{F}_1 + \frac{1}{K_3}\,\mathfrak{F}_2 \\ X_2 &= \frac{1}{K_3}\,\mathfrak{F}_1 + \left(\frac{1}{K_2} + \frac{1}{K_3}\right)\mathfrak{F}_2\end{aligned}\right\} \qquad [10]$$

The corresponding coefficients in Equations [9] and [10] must be equal. This leads to the relations, *independent* of $\mathfrak{F}_1$ and $\mathfrak{F}_2$

$$\frac{1}{K_3} = \frac{K_3'}{K'^2}, \qquad \frac{1}{K_1} + \frac{1}{K_3} = \frac{K_2' + K_3'}{K'^2}, \qquad \frac{1}{K_2} + \frac{1}{K_3} = \frac{K_1' + K_3'}{K'^2}$$

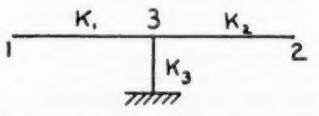

FIG. 6 REPLACEMENT OF MASS M_3 OF FIG. (3*a*) BY A SHEARED SHAFT K_3

These are Equations [5b] in a rearranged form. Equations [5a] are then obtained by solving Equations [5b] for K_1', K_2', K_3'. This completes the proof.

In Fig. 3(a), the motion x_3 of mass M_3 resulted from a force $K_3x_3 = -M_3\omega^2x_3$. In Fig. 6, the motion of the end point 3 of the (sheared) shaft K_3 is due to a force K_3x_3. Equations [5] apply also in this case. In general K_3x_3 stands for the force on any element which performs the absolute motion x_3, and the "stiffness" K_3 is merely an abbreviation for force per unit displacement. Similarly, $K_1(x_3 - x_1)$, in Fig. 3(a), represents the force on any circuit element which performs the relative motion $x_3 - x_1$. Thus, the "stiffness" terms K_i, K_i' of substitution III represent general mechanical impedances.

3—The Viscous Vibration Absorber[6,7]

The spring k_1 and the mass μ_1 constitute the main system. The absorber mass μ_2 is connected to μ_1 by the spring k_2, and by the damping device which consists of the two shafts k_α and k_β, of the two masses μ_α and μ_β, and of the damping fluid of damping constant ρ, see Fig. 7.

The springs k_1, k_2, k_α, k_β have distributed masses m_1, m_2, m_α, m_β. The mass μ_α is the effective plunger mass.[8] It is the sum of μ_α', the actual mass of the plunger, and of μ_α'', the mass of the fluid entrained by the plunger

$$\mu_\alpha = \mu_\alpha' + \mu_\alpha''$$

The mass μ_β is the effective dashpot mass. It is the sum of μ_β', the actual mass of the dashpot, and of μ_β'', the mass of the fluid which moves with the dashpot

$$\mu_\beta = \mu_\beta' + \mu_\beta''$$

The problem is to find the amplitude of motion of mass μ_1 under the action of an applied force $\mathfrak{F}e^{j\omega t}$. The (absolute) displacement of the masses μ_1, μ_2, μ_α, μ_β are denoted by x_1, x_2, x_α, x_β. As usual, $x_i(t) = X_ie^{j\omega t}$.

The problem is solved in two steps. First, the system, shown in Fig. 7, is reduced to that in Fig. 8, where $\mathfrak{K}_1$, $\mathfrak{K}_2$, $\mathfrak{M}_1$, $\mathfrak{M}_2$ denote certain effective spring constants and masses. Second, Holzer's method is applied to the system of Fig. 8, and the response $X_1e^{j\omega t}$ of mass μ_1 to the applied force is calculated.

We shall solve the problem in three successive approximations: (1) We shall assume that the shaft masses $m_1 = m_2 = m_\alpha = m_\beta = 0$, and that $\mu_\alpha = \mu_\beta = 0$, and $k_\alpha = k_\beta = \infty$. This is the usual procedure and is discussed by Den Hartog.[7] (2) We shall assume the correct values k_α, k_β for the damper springs, but leave the shaft masses $= 0$, and $\mu_\alpha = \mu_\beta = 0$, as in the preceding case. (3) We shall take all masses into account in an "appropriate approximation."

For numerical values we select $k_1 = 20$, $k_2 = 1$, $k_\alpha = 2$, $k_\beta = \infty$, $m_1 = 1.20$, $m_2 = 0.12$, $m_\alpha = m_\beta = 0.06$, $\mu_\alpha = \mu_\beta = 0.12$, $\rho = 0.2$, and finally, $\mathfrak{F} = 1$, $\omega = 0.9$.

First Approximation:

$$m_1 = m_2 = m_\alpha = m_\beta = \mu_\alpha = \mu_\beta = 0;\ k_\alpha = k_\beta = \infty$$

Since $k_\alpha = k_\beta = \infty$, the motions x_α and x_β are the same as x_1 and x_2. The damper is acted upon by the force

$$\rho(\dot{x}_\beta - \dot{x}_\alpha) = \rho(\dot{x}_2 - \dot{x}_1) = j\rho\omega(x_2 - x_1)$$

We denote this by $k_\gamma(x_2 - x_1)$. Using substitution I for the combination of springs k_γ and k_2, we obtain the system shown in Fig. 8, where

$$\begin{aligned}\overline{cb} &= \mathfrak{K}_2 = k_2 + k_\gamma = 1 + 0.18j\\ \overline{0a} &= \mathfrak{K}_1 = k_1 = 20\\ \overline{a1} &= \mathfrak{M}_1 = \mu_1 = 20\\ \overline{b2} &= \mathfrak{M}_2 = \mu_2 = 1\end{aligned}$$

The applied force is $\mathfrak{F}$ represented by $\overline{1c}$.

Holzer's method can be applied at once to the system of Fig. 8, as follows: We *assume* that $\mathfrak{M}_1$ vibrates with an amplitude $X_{au} = X_{1u} = 1$. (The subscript u stands for "unadjusted." See the schematic displacement-force diagram, Fig. 9; $P_{au} = [X_{au}, F_{au}]$.) The tension in the spring $\mathfrak{K}_1$ is $F_{au} = \mathfrak{K}_1X_{au} = \mathfrak{K}_1$. The mass $\mathfrak{M}_1$ takes up a force $\mathfrak{M}_1\ddot{x}_1 = -\mathfrak{M}_1\omega^2x_1$ and reduces the acting force from F_{au} at a to $F_{1u} = \mathfrak{K}_1 - \mathfrak{M}_1\omega^2$ at 1. This determines the dashed line $P_{0u}P_{au}P_{1u}$ of the diagram.

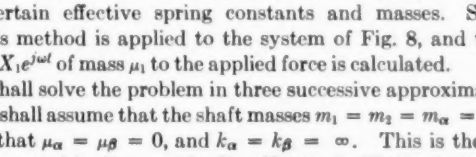

Fig. 7 Viscous Vibration Absorber

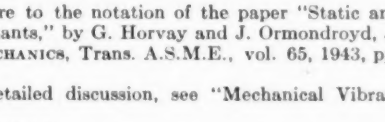

Fig. 8 The System in Fig. 8 Is Equivalent to the System in Fig. 7, by Virtue of Equations [14] and [15]

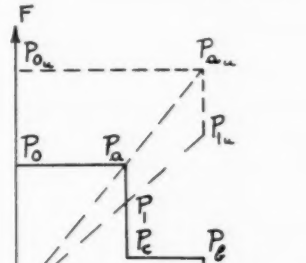

Fig. 9 Illustration of Holzer's Method

Next, we *assume* that $\mathfrak{M}_2$ vibrates with an amplitude $X_2 = X_b = 1$. Since the end 2 of the system is free, no force is acting on it. Thus, the amplitude of the force at point b is

$$F_b = \mathfrak{M}_2\omega^2X_b = \mathfrak{M}_2\omega^2$$

Under the action of this force the spring $\mathfrak{K}_2$ is extended by an amount

$$X_b - X_c = F_b/\mathfrak{K}_2 = \mathfrak{M}_2\omega^2/\mathfrak{K}_2$$

from which

$$X_c = X_b - \mathfrak{M}_2\omega^2/\mathfrak{K}_2 = 1 - \mathfrak{M}_2\omega^2/\mathfrak{K}_2$$

This fixes the full line $P_2P_bP_c$. (In Fig. 9 the complex quantity $X_b - X_c$ is represented by the real line P_cP_b.) But the points P_c and P_1 of Fig. 9 must have the same abscissa; the line P_cP_1 represents the applied force $\mathfrak{F} = F_1 - F_c$ and therefore must be vertical. We make it vertical by reducing the $P_{0u}P_{au}P_{1u}$ portion of the displacement-force diagram in the ratio

[6] We adhere to the notation of the paper "Static and Dynamic Spring Constants," by G. Horvay and J. Ormondroyd, Journal of Applied Mechanics, Trans. A.S.M.E., vol. 65, 1943, pp. A-213 to A-219.

[7] For a detailed discussion, see "Mechanical Vibrations,"[4] pp. 115–129.

[8] See Appendix 2.

$$\frac{X_c}{X_{1s}} = \frac{1 - \mathfrak{M}_2\omega^2/\mathfrak{C}_2}{1}$$

This leads to the adjusted points P_0, P_a, P_1. We now have

$$X_1 = X_c = 1 - \mathfrak{M}_2\omega^2/\mathfrak{C}_2 \quad [11a]$$

and

$$\mathfrak{F} = F_1 - F_c = (\mathfrak{C}_1 - \mathfrak{M}_1\omega^2)X_1 - \mathfrak{M}_2\omega^2 \quad [11b]$$

Since the force $\mathfrak{F}e^{j\omega t}$ causes a displacement of amplitude X_1, the force $1 \times e^{j\omega t}$ causes a displacement of amplitude

$$\overline{X} = X_1/\mathfrak{F} \quad [12]$$

This is the quantity we wish to evaluate.[9]

In our case

$$X_1 = 1 - \frac{1 \times 0.9^2}{1 + 0.18j} = 1 - \frac{0.81(1 - 0.18j)}{1.0324} = 0.2154 + 0.1413j = 0.2576 \angle 33.2 \text{ deg}$$

$$\mathfrak{F} = (20 - 20 \times 0.9^2)(0.2154 + 0.1413j) - 1 \times 0.9^2 = 0.0086 + 0.537j = 0.537 \angle 89.1 \text{ deg}$$

Thus $\overline{X} = X_1/\mathfrak{F} = 0.480 \angle -55.9$ deg. This compares with the static displacement $X_{stat} = 1/k_1 = 0.05$, giving $|\overline{X}/X_{stat}| = 9.60$. The reader will readily identify our example with the system $c/c_c = 0.10$ of Den Hartog, Fig. 79.[7] Mass μ_1 has maximum amplitude at the resonant frequency $\omega = 0.900$.

Second Approximation:

$$m_1 = m_2 = m_\alpha = m_\beta = \mu_\alpha = \mu_\beta = 0;\ k_\alpha = 2,\ k_\beta = \infty$$

Substitution II permits the replacement of shafts k_α, k_γ, k_β by an equivalent shaft

$$k_2' = (k_\alpha^{-1} + k_\gamma^{-1} + k_\beta^{-1})^{-1} = \left(\frac{1}{2} + \frac{1}{0.18j} + 0\right)^{-1} = \frac{0.18j}{1 + 0.09j} = 0.0161 + 0.1786j$$

which in combination with k_2 gives

$$\mathfrak{C}_2 = k_2 + k_2' = 1.0161 + 0.1786j$$

The constants $\mathfrak{C}_1$, $\mathfrak{M}_1$, $\mathfrak{M}_2$ are as in the preceding approximation. We find

$$X_1 = 1 - \frac{0.81}{1.0161 + 0.1786\,j} = 0.2267 + 0.1359\,j = 0.2643 \angle 30.9 \text{ deg}$$

$$\mathfrak{F} = 3.8(0.2267 + 0.1359\,j) - 0.81 = 0.0514 + 0.516\,j = 0.519 \angle 84.3 \text{ deg}$$

and

$$\overline{X} = X_1/\mathfrak{F} = 0.509 \angle -53.4 \text{ deg}$$

In this case, $|\overline{X}/X_{stat}| = 10.19$. The result is close to the previous value, 9.60.

[9] Equation [12] can be obtained more readily by applying a $\Pi - T$ transformation to the $[\mathfrak{C}_2, \mathfrak{M}_2, 0]$ end of the system of Fig. 8. This leads to a one-degree-of-freedom system, consisting of a shaft $\mathfrak{C}_1$, and of an end mass $\mathfrak{M}_1' = \mathfrak{M}_1 + \mathfrak{C}_2\mathfrak{M}_2/(\mathfrak{C}_2 - \mathfrak{M}_2\omega^2)$, cf. Fig. 5. The amplitude of motion of mass $\mathfrak{M}_1'$ (and also of mass $\mathfrak{M}_1$) under the action of a force $1.e^{j\omega t}$ is then given by $\overline{X}_1 = 1/(\mathfrak{C}_1 - \mathfrak{M}_1'\omega^2)$. This is Equation [12]. The vibration problem of any arrangement, involving a sequence of masses and elasticities, can thus be solved by successive $\Pi - T$ transformations, but ordinarily such a process is more laborious than Holzer's method.

Appropriate Approximation. The appropriate approximation consists in replacing a shaft k with distributed inertia m by a weightless shaft of stiffness $K = k + m\omega^2/6$ which carries masses $m/2$ at each end.[6, 10] This leads to the dynamic spring constants

$$K_1 = 20 + 0.2\,\omega^2 = 20.162,\quad K_2 = 1 + 0.02\,\omega^2 = 1.0162,$$

$$K_\alpha = 2 + 0.01\,\omega^2 = 2.0081,\quad K_\beta = \infty$$

The masses μ_1, μ_2, μ_α, μ_β are now replaced by the dynamic masses

$$M_1 = \mu_1 + \frac{1}{2}m_1 + \frac{1}{2}m_2 + \frac{1}{2}m_\alpha = 20 + 0.6 + 0.06 + 0.03 = 20.69,\quad M_2 = \mu_2 + \frac{1}{2}m_2 + \frac{1}{2}m_\beta = 1.09,$$

$$M_\alpha = \mu_\alpha + \frac{1}{2}m_\alpha = 0.15,\quad M_\beta = \mu_\beta + \frac{1}{2}m_\beta = 0.15$$

The mass

$$M_\gamma = -j\rho/\omega = -0.2\,j/0.9 = -0.2222\,j$$

is the effective "damper" mass of the fluid.[8]

We apply a $\Pi - T$ transformation to the partial system of damping fluid $K_\gamma = -M_\gamma\omega^2$, dashpot M_β, and dashpot shaft K_β, which now play the role of $[K_1, M_3, K_2]$ of Fig. 3(*a*). Then we obtain an $[M_1', K_2', M_2']$ system which we denote by the letters M', K', μ'. By Equations [5*a*]

$$-M'\omega^2 = \frac{M_\beta M_\gamma\omega^4}{K_\beta - (M_\beta + M_\gamma)\omega^2},\quad K' = \frac{-K_\beta M_\gamma\omega^2}{K_\beta - (M_\beta + M_\gamma)\omega^2},$$

$$-\mu'\omega^2 = \frac{-K_\beta M_\beta\omega^2}{K_\beta - (M_\beta + M_\gamma)\omega^2} \quad [13]$$

A second $\Pi - T$ transformation, applied to $[K_\alpha, M_\alpha + M', K']$, leads to auxiliary quantities μ_1', K_2', μ'', where

$$-\mu_1'\omega^2 = -\frac{K_\alpha(M_\alpha + M')\omega^2}{K_\alpha + K' - (M_\alpha + M')\omega^2},$$

$$K_2 = \frac{K_\alpha K'}{K_\alpha + K' - (M_\alpha + M')\omega^2},$$

$$-\mu''\omega^2 = -\frac{K'(M_\alpha + M')\omega^2}{K_\alpha + K' - (M_\alpha + M')\omega^2}$$

In view of Equations [13] we can write

$$\mu_1' = K_\alpha(K_\beta M_\alpha - M^2\omega^2)/D \quad [14a]$$

$$K_2' = -K_\alpha K_\beta M_\gamma\omega^2/D \quad [14b]$$

$$\mu'' + \mu' = \mu_2' = K_\beta(K_\alpha M_\beta - M^2\omega^2)/D \quad [14c]$$

where M^2 and D are the abbreviations.

$$M^2 = M_\alpha M_\beta + M_\beta M_\gamma + M_\gamma M_\alpha$$

$$D = K_\alpha K_\beta - K_\alpha(M_\beta + M_\gamma)\omega^2 - K_\beta(M_\alpha + M_\gamma)\omega^2 + M^2\omega^4 \quad [14']$$

The system of Fig. 7 is now reduced to the system of Fig. 10, and the final reduction to Fig. 8 consists in taking

$$\mathfrak{C}_1 = K_1,\ \mathfrak{M}_1 = M_1 + \mu_1',\ \mathfrak{M}_2 = M_2 + \mu_2',\ \mathfrak{C}_2 = K_2 + K_2' \quad [15]$$

The numerical substitutions give

$$M^2 = 0.15^2 - 2 \times 0.15 \times 0.2222\,j = 0.0225 - 0.06667\,j$$

$$D = [K_\alpha - (M_\alpha + M_\gamma)\omega^2]K_\beta = (1.8866 + 0.18\,j)K_\beta$$

[10] "The Appropriate Lumped Constants of Vibrating Shaft Systems," by G. Horvay and J. Ormondroyd, JOURNAL OF APPLIED MECHANICS, Trans. A.S.M.E., vol. 65, 1943, pp. A-220 to A-224.

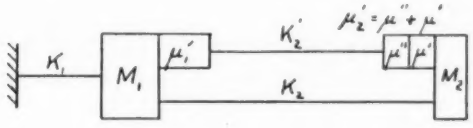

FIG. 10 INTERMEDIATE STEP IN REDUCTION OF SYSTEM OF FIG. 7 TO SYSTEM OF FIG. 8

$$\mathfrak{M}_1 = M_1 + K_\alpha K_\beta M_\alpha/D = 20.69 + \frac{2.0081 \times 0.15\,K_\beta}{(1.8866 + 0.18\,j)K_\beta} =$$

$$20.69 + \frac{0.30121\,(1.8866 - 0.18\,j)}{3.5917} = 20.848 - 0.01510\,j$$

$$\mathfrak{M}_2 = 1.09 + \frac{0.3012 - 0.01822 + 0.054\,j}{1.8866 + 0.18\,j} = 1.2414 + 0.01418\,j$$

$$\mathfrak{K}_2 = 1.0162 + \frac{2.0081 \times 0.18\,j}{1.8866 + 0.18\,j} = 1.0343 + 0.1899\,j, \mathfrak{K}_1 = 20.162$$

The constants of Fig. 8 are now determined, and Equations [11*a*,*b*] apply. We find

$$X_1 = 1 - \mathfrak{M}_2\omega^2/\mathfrak{K}_2 = 0.0576 + 0.1619\,j = 0.1718 \angle 70.4 \text{ deg}$$

$$\mathfrak{F} = (\mathfrak{K}_1 - \mathfrak{M}_1\omega^2)X_1 - \mathfrak{M}_2\omega^2 = -0.819 + 0.519\,j = 0.970 \angle 147.6 \text{ deg}$$

By Equation [12]

$$\overline{X} = X_1/\mathfrak{F} = 0.1771 \angle -77.2 \text{ deg}$$

Finally

$$|X/X_{\text{stat}}| = 3.54$$

This result differs considerably from the two previous approximations and shows the importance of accounting appropriately for all distributed and concentrated masses.

ACKNOWLEDGMENT

The authors are indebted to Commander J. P. Den Hartog, for suggesting the problem. They are also indebted to the referee, Prof. F. M. Lewis, for several improvements, particularly for the shortcut in footnote 9, and for an improved interpretation of the expression for fluid energy, Appendix 2.

Appendix 1

THE "ELECTRICAL-ANALOGY" METHOD

We assign a length $l_1 = L_1$ to shaft k_1 of Fig. 7; a length $l_2 = L_2 - L_1$ to shaft k_2; a length $l_\alpha = L_\alpha - L_1$ to shaft k_α; a length $l_\beta = L_2 - L_\beta$ to shaft k_β. We use $x_l(\xi, t) = X_l(\xi)e^{j\omega t}$ to denote the instantaneous displacement along the lower shaft k_2; we use $x_u(\xi, t) = X_u(\xi)e^{j\omega t}$ to denote the displacement along the upper shafts k_α, k_β. The abscissa ξ is the running co-ordinate. Then the kinetic energy of the system is given by [8,10]

$$T = \frac{1}{2}\mu_1\dot{x}_1^2 + \frac{1}{2}\mu_2\dot{x}_2^2 + \frac{1}{2}\mu_\alpha\dot{x}_\alpha^2 + \frac{1}{2}\mu_\beta\dot{x}_\beta^2 - \frac{1}{2}\frac{j\rho}{\omega}(\dot{x}_\beta - \dot{x}_\alpha)^2 + \frac{1}{2}\frac{m_1}{l_1}\int_0^{L_1}\dot{x}^2d\xi + \frac{1}{2}\frac{m_2}{l_2}\int_{L_1}^{L_2}\dot{x}_l^2d\xi + \frac{1}{2}\frac{m_\alpha}{l_\alpha}\int_{L_1}^{L_\alpha}\dot{x}_u^2d\xi + \frac{1}{2}\frac{m_\beta}{l_\beta}\int_{L_\beta}^{L_2}\dot{x}_u^2d\xi \quad [16a]$$

and the potential energy is given by

$$V = \frac{1}{2}k_1l_1\int_0^{L_1}x'^2d\xi + \frac{1}{2}k_2l_2\int_{L_1}^{L_2}x_l'^2d\xi + \frac{1}{2}k_\alpha l_\alpha\int_{L_1}^{L_\alpha}x_u'^2d\xi + \frac{1}{2}k_\beta l_\beta\int_{L_\beta}^{L_2}x_u'^2d\xi \quad [16b]$$

Assuming a linear variation for $X(\xi)$, the energy expressions become[10]

$$T = \frac{1}{2}\mu_1\dot{x}_1^2 + \frac{1}{2}\mu_2\dot{x}_2^2 + \frac{1}{2}\mu_\alpha\dot{x}_\alpha^2 + \frac{1}{2}\mu_\beta\dot{x}_\beta^2 - \frac{1}{2}\frac{j\rho}{\omega}\cdot(\dot{x}_\beta - \dot{x}_\alpha)^2 + \frac{1}{6}m_1\dot{x}_1^2 + \frac{1}{6}m_2(\dot{x}_1^2 + \dot{x}_1\dot{x}_2 + \dot{x}_2^2) + \frac{1}{6}m_\alpha(\dot{x}_1^2 + \dot{x}_1\dot{x}_\alpha + \dot{x}_\alpha^2) + \frac{1}{6}m_\beta(\dot{x}_2^2 + \dot{x}_2\dot{x}_\beta + \dot{x}_\beta^2) \quad [17a]$$

$$V = \frac{1}{2}k_1x_1^2 + \frac{1}{2}k_2(x_2 - x_1)^2 + \frac{1}{2}k_\alpha(x_\alpha - x_1)^2 + \frac{1}{2}k_\beta(x_2 - x_\beta)^2 \quad [17b]$$

We form the Lagrangian equations of motion

$$\frac{d}{dt}\frac{\partial T}{\partial \dot{x}_i} + \frac{\partial V}{\partial x_i} = \mathfrak{F}_ie^{j\omega t} \quad [18]$$

associated with the approximate energy expressions [17], and obtain

$$\left.\begin{aligned} x_1&: M_1\ddot{x}_1 + K_1x_1 + K_2(x_1 - x_2) + K_\alpha(x_1 - x_\alpha) = \mathfrak{F}e^{j\omega t}\\ x_2&: M_2\ddot{x}_2 + K_2(x_2 - x_1) + K_\beta(x_2 - x_\beta) = 0\\ x_\alpha&: M_\alpha\ddot{x}_\alpha + M_\gamma(\ddot{x}_\alpha - \ddot{x}_\beta) + K_\alpha(x_\alpha - x_1) = 0\\ x_\beta&: M_\beta\ddot{x}_\beta + M_\gamma(\ddot{x}_\beta - \ddot{x}_\alpha) + K_\beta(x_\beta - x_2) = 0 \end{aligned}\right\} \quad [19]$$

We used the abbreviations

$$M_1 = \mu_1 + \frac{1}{2}(m_1 + m_2 + m_\alpha), \qquad M_2 = \mu_2 + \frac{1}{2}(m_2 + m_\beta),$$

$$M_\alpha = \mu_\alpha + \frac{1}{2}m_\alpha, \qquad M_\beta = \mu_\beta + \frac{1}{2}m_\beta, \qquad M_\gamma = -j\rho/\omega,$$

$$K_1 = k_1 + \frac{1}{6}m_1\omega^2, \qquad K_2 = k_2 + \frac{1}{6}m_2\omega^2,$$

$$K_\alpha = k_\alpha + \frac{1}{6}m_\alpha\omega^2, \qquad K_\beta = k_\beta + \frac{1}{6}m_\beta\omega^2$$

Equations [19] are recognized as the equations of charge displacement in the loops (1), (2), (α), (β), of Fig. 11, where K_i denotes reciprocal capacities, M_i denotes inductances.

Two successive $\Pi - T$ transformations, applied to the α, β loops, reduce Fig. 11 to Fig. 12, which corresponds to Fig. 10 of the mechanical system. Finally, the combinations $\mathfrak{K}_2 = K_2 + K_2'$, $\mathfrak{M}_1 = M_1 + \mu_1'$, $\mathfrak{M}_2 = M_2 + \mu_2'$ reduce Fig. 12 to an electrical system equivalent to Fig. 8. Whereas in the "electrical-analogy" method the calculations are carried out in connection with the electrical system, and the results are retranslated into mechanical engineering terminology, the direct method of section 3 eliminates all intermediate steps.

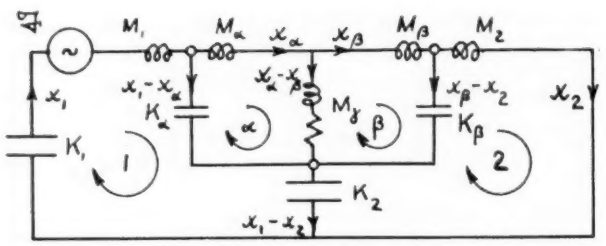

FIG. 11 ELECTRICAL ANALOGUE OF SYSTEM IN FIG. 7

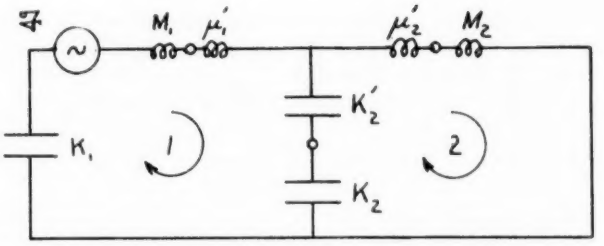

FIG. 12 ELECTRICAL ANALOGUE OF SYSTEM IN FIG. 10

Appendix 2

THE ENERGY EXPRESSION OF THE FLUID

Since some fluid particles move with the velocity $\dot{x}_\alpha$ of the plunger, others with the velocity $\dot{x}_\beta$ of the dashpot, the kinetic energy of the fluid is to a good approximation a quadratic form in $\dot{x}_\alpha$ and $\dot{x}_\beta$

$$T_{fl} = \alpha\dot{x}_\alpha^2 + \beta\dot{x}_\beta^2 + \gamma\dot{x}_\alpha\dot{x}_\beta$$

A more convenient way of writing this is[11]

$$T_{fl} = \mu_\alpha''\dot{x}_\alpha^2/2 + \mu_\beta''\dot{x}_\beta^2/2 + M_\gamma(\dot{x}_\beta - \dot{x}_\alpha)^2/2$$

Here μ_α'' denotes the mass of the fluid which moves with the plunger. We incorporate it into μ_α, the effective plunger mass. The mass μ_β'' moves with the dashpot. We incorporate it into μ_β, the effective dashpot mass. The mass $M_\gamma = \mu_\gamma - j\rho/\omega$ is the effective "damper" mass of the fluid. Whereas the μ_α'' and μ_β'' energy terms change periodically into potential energy, the M_γ term, which depends upon the relative motion of plunger and dashpot, converts almost immediately into heat. Thus the nondissipative term $\mu_\gamma(\dot{x}_\beta - \dot{x}_\alpha)^2/2$ can be considered as negligibly small, and $\mu_\gamma = 0$ can be used. This we did throughout the text.

[11] The corresponding expressions for shaft k_2 (see Equation [17a]) are

$$T_{\text{shaft}_2} = \frac{1}{6}\, m_2(\dot{x}_1^2 + \dot{x}_2^2 + \dot{x}_1\dot{x}_2)$$

$$= \frac{1}{2}\left[\frac{1}{2}\, m_2\dot{x}_1^2 + \frac{1}{2}\, m_2\dot{x}_2^2 - \frac{1}{6}\; m_2\,(\dot{x}_2 - \dot{x}_1)^2\right]$$

The term $\frac{1}{6}\, m_2\omega^2\,(x_2 - x_1)^2$ manifests itself in an increase in the stiffness of the shaft.

Design Data

It is important that the data contained in technical papers be made readily available to designing engineers. In order to satisfy these needs of industry, this section of the Journal includes a concise presentation of data and information drawn chiefly from papers previously published by the Applied Mechanics Division of The American Society of Mechanical Engineers.

The data have been prepared by a subcommittee of the Applied Mechanics Division—S. Timoshenko, R. E. Peterson, J. Ormondroyd, J. N. Goodier, and J. M. Lessells.

Balancing of Rotating Apparatus—II*

By R. P. KROON,[7] PHILADELPHIA, PA.

Shop Balance Methods

IT is customary to balance rotors at relatively low speed in balancing machines in the shop. These detect the unbalances by the vibration produced in the balancing machine. Fig. 16 shows the principles of such a machine. The bearings are supported on thin strips g, flexible in the lateral direction. The vibration can be measured at A and B by dial indicators or by other instruments.

Balancing in its most primitive form, popular in shops where it is not a mass-production operation, consists in principle of the following:

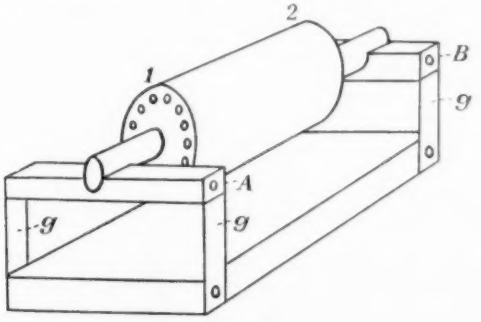

Fig. 16

One bearing, say B, is locked so that it cannot move laterally and the rotor is brought up through the critical speed (of the rotor on the flexible bearing A). The rotor can be speeded up by an air jet or by a motor-driven belt passing over the rotor. While coasting down through the critical speed, the horizontal motion at A is measured. Corrections are now made (usually by cut-and-try methods) in plane 1 until this amplitude is reduced to zero. This can be facilitated by holding a pencil against the rotor, scribing the high spot.

Now the other bearing is locked and the motion at B is reduced to zero by placing corrective weight in plane 2.

Some machines are built with a frame which allows the locking of a fulcrum exactly in the balance plane (say, 2). Then the corrective weight put in plane 1 is indeed final. Where this is not the case one can scuttle back and forth, locking first one bearing, then the other, then going back to the first, etc., until a satisfactory balance is obtained; which can be checked by running with both bearings unlocked, or the correct weight can be immediately determined by means of the following consideration:

Let the original unbalance be such that it can be represented by a weight W_I in plane 1 and another weight W_{II} in plane 2, Fig. 17 (*a*). Now when bearing B is locked, the correction weight w_1, in plane 1, which reduces the motion at A to zero can

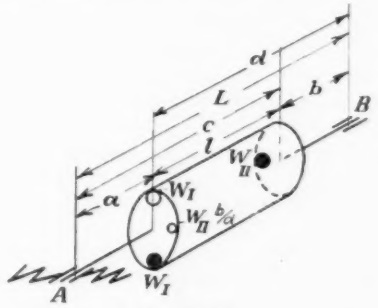

Fig. 17 (*a*)
(Bearing B locked; motion at A reduced to zero.)

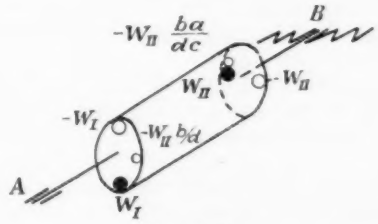

Fig. 17 (*b*)
(Bearing A locked; motion at B reduced to zero.)

be thought of as consisting of two parts. One component ($-W_I$) corrects the unbalance W_I in plane 1. The second part ($-W_{II}\,b/d$) is necessary to offset the moment about B caused by W_{II}. Now when bearing A is locked (with w_1 left in place) and bearing B is left free to float, the weight w_2, in plane 2, which cuts down all vibration of B, must compensate not only for W_{II}, but also for the moment from the portion $-W_{II}\,b/d$ of weight w_1, Fig.

* Part I of this paper was published in the Journal of Applied Mechanics, Trans. A.S.M.E., vol. 65, December, 1943, p. A-225.

[7] Manager, Development Division, South Philadelphia Works, Westinghouse Electric & Manufacturing Co. Mem. A.S.M.E.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until April 10, 1944. Discussion received after the closing date will be returned.

17 (*b*). Therefore, weight w_2 can again be resolved into two components, one weight $-W_{II}$ and another, $W_{II}\frac{ba}{dc}$ diametrically opposite.

Since
$$w_2 = -W_{II} + W_{II}\frac{ba}{dc}$$

$$W_{II} = \frac{-w_2}{1 - \frac{ab}{cd}} = -w_2\frac{cd}{lL}$$

Therefore, after the location and amount of w_2 in plane 2 has been found with bearing A locked, the amount is increased in the ratio cd/lL. Then, in plane 1, one adds a weight $-W_{II}\frac{b}{d} = w_2\frac{bc}{lL}$ exactly on the opposite side of the rotor. These weights and w_1 which was left in the rotor, will provide complete balance.

More Elaborate Shop Balancing; Field Balancing

The more efficient shop-balancing methods (in which both bearings are left unlocked) and the procedures used in field balancing are not fundamentally different. Shop balancing is simpler in so far as the vibratory system can be so designed that the angle of lag is known ($\varphi = 90$ deg for operation at resonance of the rotor on its flexible supports, $\varphi = 180$ deg for operating far above resonance, now preferred, because of greater independence of variations in speed and damping). There exist a great many methods relying either on using amplitudes alone, or phase angles and amplitudes on one side at a time, etc., but the most efficient methods use as much information as can be gathered during a run; i.e., both amplitude and phase measured in as many places as is necessary. This presupposes that instruments are available to measure both amplitude and phase accurately.

The term "angle of lag" (sometimes called "phase angle") has so far been used to designate the angle φ between the direction of the eccentricity and the direction of the center of gravity S, Fig. 5. While balancing, the position of S is unknown. The phase angle ϕ is measured between the high spot T and an arbitrary reference point R on the shaft, Fig. 18.

The high spot T may be the physical point on the shaft touched by a marking pencil. But generally, and this applies to shaft as well as to bearing vibration, the high spot T can be defined as the point on the rotor which passes some arbitrary reference mark C when the vibratory motion reaches its maximum positive value. The phase angle ϕ is the angle between the high spot T and a given reference point R on the rotor.

It is customary always to show the diagram, Fig. 18, with the reference point R (say, No. 1 balance hole) on top and to draw the arrow OA to represent the amplitude to a certain scale, Fig. 19.

The vibration of a two-bearing unit, Fig. 20, which we shall suppose vibrates in one direction only (say, vertically) can thus be represented by two of these vector diagrams, one for bearing A and one for B. Notice that the direction of rotation is the same in both diagrams. Here A_0 and B_0 are the amplitudes measured at A and B, and ϕ_A and ϕ_B are phase angles between the vibration and a common reference point R.

Weights should be applied in the balance planes 1 and 2 in such a fashion as to eliminate the vibration of both bearings. A trial weight w_1 is now put in plane 1. This affects the vibration. For example, the vibration at bearing A has now changed from A_0 to A_{01}, Fig. 21; there is a different amplitude and a different

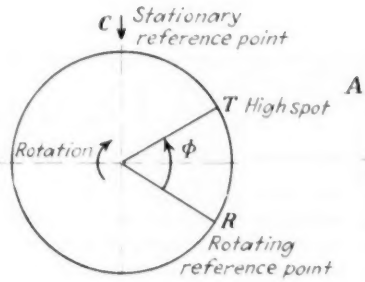

Fig. 18

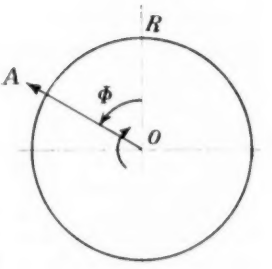

Fig. 19

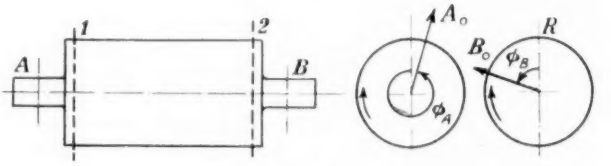

Fig. 20

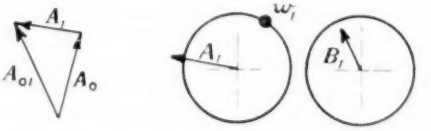

Fig. 21

Fig. 22

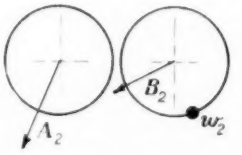

Fig. 23

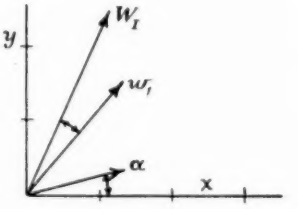

Fig. 24

high spot. The difference in vibration is expressed vectorially by A_1.

Thus Fig. 22 may represent the changes in vibration (the increment) caused by the trial weight w_1. A trial weight w_2 in the other balance plane 2 again produces changes in vibration, shown in Fig. 23. The original vibration measurements and the two trial runs yield all the necessary information to find the amount and location of the final balance weights.

A speedy solution (6, 7)[8] hinges around a convenient method to describe the vibration from any balance weight. The theory of complex numbers has provided an operation which does just this thing; namely, if the vector w_1 (Fig. 24) represents the weight w_1, both in magnitude and direction (location), multiplication with another vector α gives, by definition, another vector having a magnitude equal to the product of the magnitudes of w_1 and α and enclosing an angle with the x axis equal to the sum of the angles between the x axis and w_1 and α, respectively. Therefore, varying α both in magnitude and direction, any unbalance weight $W_1 = \alpha w_1$ in plane 1 can be described.

In all analytical balance methods, a linear system is assumed. The vibration due to a weight in a certain plane is taken to be proportional to the amount of weight. The phase angle between weight and vibration is assumed to stay constant.

[8] Numbers in parentheses refer to the Bibliography, at the end of this section of the design data.

FIG. 25

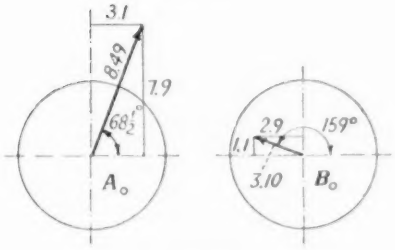

FIG. 26

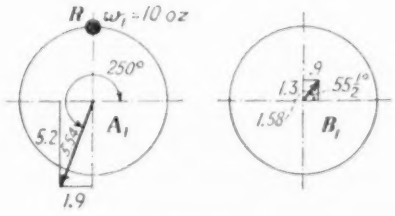

FIG. 27

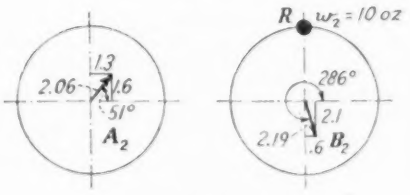

FIG. 28

Then the vibratory effect of W_I in plane 1 can be obtained by multiplying the vectors A_1 and B_1 (due to the trial weight w_1) with the vector α (Fig. 25).

Similarly, the vibration produced by weight $W_{II} = \beta w_2$ will be βA_2 in plane A and βB_2 in plane B.

Let W_I and W_{II} now be defined as those weights which together, on an initially balanced rotor, would produce the vibrations A_0 and B_0; then

$$\left.\begin{aligned} \alpha A_1 + \beta A_2 &= A_0 \\ \alpha B_1 + \beta B_2 &= B_0 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [11]$$

Note that all symbols in the equations represent complex numbers. The solutions

$$\left.\begin{aligned} \alpha = \frac{W_I}{w_1} &= \frac{A_0B_2 - A_2B_0}{A_1B_2 - A_2B_1} \\ \beta = \frac{W_{II}}{w_2} &= \frac{A_1B_0 - A_0B_1}{A_1B_2 - A_2B_1} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [12]$$

determine the weights W_I and W_{II} in terms of the trial weights w_1 and w_2. The corrections to be made are $-W_I$ in plane 1 and $-W_{II}$ in plane 2.

Equations [12] can be solved either graphically or analytically by means of the complex number notation $a + bj$ for any of the vectors.

To illustrate the vector algebra method, a simple example is treated here. The initial conditions are shown in Fig. 26. They might be written as follows:

$$A_0 = 3.1 + 7.9\,j$$

$$B_0 = -2.9 + 1.1\,j$$

A trial weight of 10 oz is inserted at balance hole 1, point R, in balance plane 1. Its effect (the vectorial change in vibration it produces) is shown in Fig. 27.

The same unbalance weight, removed and inserted at R in balance plane 2, produces the changes given in Fig. 28.

Applying Equation [12]

$$\alpha = \frac{W_I}{w_1}$$

$$= \frac{(3.1 + 7.9j)\,(0.6 - 2.1\,j) - (1.3 + 1.6\,j)\,(-2.9 + 1.1\,j)}{(-1.9 - 5.2\,j)\,(0.6 - 2.1\,j) - (1.3 + 1.6\,j)\,(0.9 + 1.3\,j)}$$

$$= \frac{23.96 + 1.44\,j}{-11.15 - 2.26\,j}$$

$$\beta = \frac{(-1.9 - 5.2\,j)\,(-2.9 + 1.1\,j) - (3.1 + 7.9\,j)\,(0.9 + 1.3\,j)}{(-1.9 - 5.2\,j)\,(0.6 - 2.1\,j) - (1.3 + 1.6\,j)\,(0.9 + 1.3\,j)}$$

$$= \frac{18.71 + 1.85\,j}{-11.15 - 2.26\,j}$$

Carrying out the division

$$\alpha = -2.09 + 0.295\,j, \qquad \beta = -1.64 + 0.167\,j$$

The 10-oz trial weight at point R can be described by

$$w_1 = w_2 = 10\,j$$

Then

$$W_I = \alpha\, w_1 = -2.95 - 20.9\,j$$

$$W_{II} = \beta\, w_2 = -1.67 - 16.4\,j$$

and the corrective weights are $-W_I = 2.95 + 20.9\,j$ in plane 1, and $-W_{II} = 1.67 + 16.4\,j$ in plane 2.

The amount of $-W_I$ is $\sqrt{2.95^2 + 20.9^2} = 21.1$ oz. This corrective weight should be put at an angle arc $tg \frac{20.9}{2.95} = 82$ deg from the positive horizontal axis, that is, 8 deg clockwise from R. The size of weight $-W_{II}$ is $\sqrt{1.67^2 + 16.4^2} = 16.5$ oz, and it should be located at an angle of arc $tg \frac{16.4}{1.67} = 84$ deg from the real positive axis, or 6 deg to the right of R.

Another way of finding the corrective weight for the same example is shown in Fig. 29. Here are plotted the vector products A_0B_2, A_2B_0, A_1B_0, A_0B_1, A_1B_2, A_2B_1. With A_0 being 8.49 units long and enclosing an angle of $68\frac{1}{2}$ deg with the positive horizontal axis; B_1 being a vector 1.58 units making an angle $55\frac{1}{2}$ deg with the horizontal axis; A_0B_1 is a vector $8.49 \times 1.58 = 13.40$ units long at an angle $68\frac{1}{2}$ deg + $55\frac{1}{2}$ deg = 124 deg with the horizontal.

The vector subtractions $A_1B_0 - A_0B_1$, etc., are done graphically.

The values α, β in Equations [12] are determined arithmetically. When $A_1B_0 - A_0B_1$ is found to be 18.8 units long at an angle of $5\frac{1}{2}$ deg and $A_1B_2 - A_2B_1$ comes out 11.4 units long, with an angle of $191\frac{1}{2}$ deg, β is $\frac{18.8}{11.4} = 1.65$ and includes an angle $365\frac{1}{2} - 191\frac{1}{2} = 174$ deg with the positive x axis. Thus $-W_{II}$ is

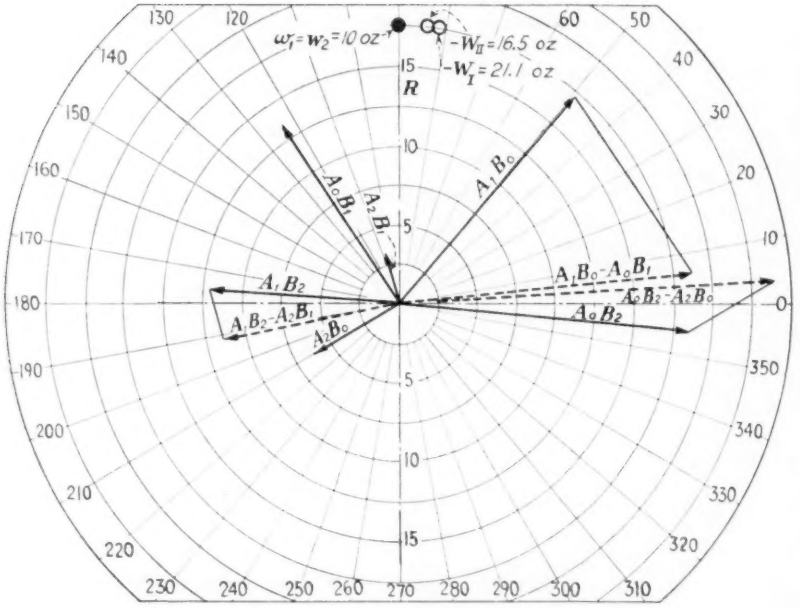

FIG. 29

$1.65 \times 10 = 16.5$ oz, it should be put at an angle (174 deg + 90 deg) —180 deg = 84 deg away from the positive axis (6 deg from R).

Trial-and-Error Solution. The analytical method just described can be applied to units with more than two bearings. However, in such cases it is usually more convenient to find the corrective weights by trial and error rather than by solving complicated determinants. This is done by manipulating the vectors from the trial weights, changing both amount and location of the weights and noticing their combined effect on the initial vibration.

General Discussion of Field Balancing

Because of the complexity of the vibratory systems on large machines, several points require special consideration.

Nonlinearity. Many machines are found to be nonlinear, that is, the vectorial changes produced by a certain amount of weight, vary. On rough-running units, correction weights made up according to Equations [12] may not altogether eliminate the vibration. One can then make a second approximation, using the old effects (A_1, B_1, A_2, B_2) on the new "initial condition." In cases of bad nonlinearity, it may be necessary to find new effects after reasonably smooth running has been obtained.

Operating Conditions. Machines operating under widely varying conditions may show a variation in vibration. To insure that this variation does not result in false readings for the effects of the trial weights, runs must be made under the same operating conditions and after making sure that steady conditions prevail.

New Balance Planes. In balancing flexible shafts such as long generator rotors (8), the balance planes can be so situated that no satisfactory balance can be obtained. For example, a balance weight in the center of the shaft (the node) of Fig. 12, would have to be infinite to counteract an unbalance in any other place.

A different but equally unsatisfactory condition exists when the denominator $A_1B_2 - A_2B_1$ equals zero. This again would require infinite weights according to Equation [12]. In this condition $\frac{A_1}{B_1} = \frac{A_2}{B_2}$; in other words, no matter whether we put the corrective weight in plane 1 or in plane 2, the change in vibration at bearing A always bears a certain relation to that at B, and it is impossible to neutralize any arbitrary initial vibration at A and B. In such cases the selection of a new balance plane is indicated.

On machines such as turbogenerators, it is customary to take vibration measurements in three directions (vertical, lateral, and axial) on all bearings and at whatever other locations (shaft, bedplate, columns, floors, etc.) as are of interest. It can happen that the corrective weight decreases all these vibrations simultaneously. But it also can happen on complicated dynamic systems where moments as well as forces on the bearings may be important that one can eliminate, say, the vertical vibration only by making the horizontal vibration worse. In the latter cases there are two choices; (*a*) to achieve a compromise, (*b*) to select additional balance planes.

Local Resonance. Occasionally local resonances can exist (of floor plates, columns, etc.). To eliminate vibration at such points may require such smooth running as would be impossible or impractical to maintain. When this is the case, one should detune the part in question by changing its mass or its rigidity (3).

Vibration Spells. Where variable vibration of running frequency occurs, the balancing operation can be expected only to eliminate a certain average "steady component." Where the variation is pronounced, the only remedy lies in abolishing the cause of the variation (9, 10). For permissible amplitudes refer to a paper by Rathbone (12).

Circular Beams Loaded Normal to the Plane of Curvature—2

By MERVIN B. HOGAN,[1] SALT LAKE CITY, UTAH

Expressions are presented in this paper for the deflection, angle of slope, and angle of twist of the free end of a circular cantilever beam with a bending moment applied at the free end. Like expressions are also given for the same beam with a twisting moment acting at the free end. The values of the reaction and the angles of slope and twist at the simple support are given for a circular beam built in at one end, simply supported at the other, and loaded as in each of the foregoing cases. Also, equations are included for the three internal reactions, i.e., bending moment, twisting moment, and shear existing at the plane of symmetry of a cantilever arc beam, built in at both ends, with an arbitrarily placed concentrated load acting perpendicular to the plane of the beam, and at its center line. Corresponding expressions for the same element with a uniformly distributed load covering the half of the beam to one side of the axis of symmetry, and an expression for the bending moment at the plane of symmetry of the same beam when its entire length is uniformly loaded, are also stated.

Introduction

THIS paper is supplementary to a previous one by the author.[2] The curves here presented are for the same three cross sections, with steel as the chosen material, as those used in that paper. The nomenclature is the same except for the two additional items j and k. These two ratios are clearly

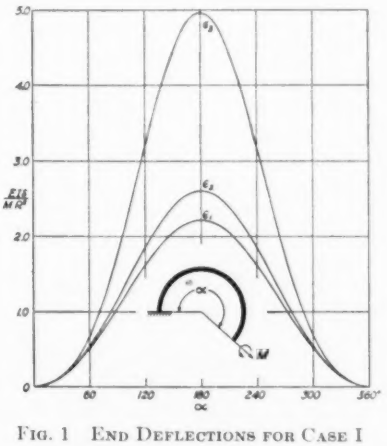

FIG. 1 END DEFLECTIONS FOR CASE I

defined in Fig. 5. The same method of derivation was employed as in the former case, and the same remarks concerning the use of the principle of superposition are applicable here.

All the expressions for the different beams and loadings are given in Table 1.

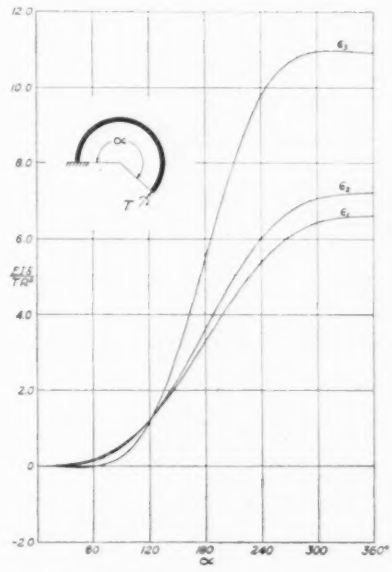

FIG. 2 END DEFLECTIONS FOR CASE II

TABLE 1 EXPRESSIONS FOR THE VARIOUS BEAMS AND LOADINGS

Case I	$\delta_1 = \frac{MR^2}{EI}\left[\frac{(1-\epsilon)}{2}(1+\cos\alpha)+\epsilon\right](1-\cos\alpha)$ $\theta_1 = \frac{MR}{EI}\left[\frac{(1+\epsilon)}{2}(\alpha+\sin\alpha\cos\alpha)-\epsilon\sin\alpha\cos\alpha\right]$ $\beta_1 = \frac{MR}{EI}\left[\frac{(1-\epsilon)}{2}\sin^2\alpha\right]$
Case II	$\delta_2 = \frac{TR^2}{EI}\left[\frac{(1+\epsilon)}{2}(\alpha-\sin\alpha\cos\alpha)-\epsilon\sin\alpha(1-\cos\alpha)\right]$ $\theta_2 = \frac{TR}{EI}\left[\frac{(1-\epsilon)}{2}\sin^2\alpha\right]$ $\beta_2 = \frac{TR}{EI}\left[\frac{(1+\epsilon)}{2}(\alpha-\sin\alpha\cos\alpha)+\epsilon\sin\alpha\cos\alpha\right]$
Case III	$F_3 = \frac{EI}{R^3D_1}\frac{k}{j}$; $\delta_3 = \delta_1 - \frac{F_3R^3}{EI}N_1$; $\beta_3 = \beta_1 - \frac{F_3R^2}{EI}N_1$ — WHERE: $D_1 = \frac{(1+3\epsilon)}{2}(\alpha-\sin\alpha\cos\alpha)-2\epsilon\sin\alpha(1-\cos\alpha)$
Case IV	$F_4 = \frac{EI}{R^3D_1}\frac{k}{j}$; $\theta_4 = \theta_2 - \frac{F_4R^2}{EI}N_1$; $\beta_4 = \beta_2 - \frac{F_4R^2}{EI}N_1$ — $N_1 = \left[(1+\epsilon+(1-\epsilon)\cos\alpha)\frac{(1-\cos\alpha)}{2}\right]$; $N_2 = \left(\frac{1+\epsilon}{2}\right)(\alpha-\sin\alpha\cos\alpha)-\epsilon\sin\alpha(1-\cos\alpha)$
Case Va	$M_5 = \frac{PR}{2}\left[\frac{(1+\epsilon)\{\sin\alpha\sin(\alpha-\Sigma)-(\alpha-\Sigma)\sin\Sigma\}-2\epsilon\{\sin\alpha\sin(\alpha-\Sigma)+\cos\alpha-\cos\Sigma\}+2K\{\frac{k}{2}\cos\alpha+(1-\epsilon)\cos\alpha\sin(\alpha-\Sigma)+\epsilon(\sin\alpha-\sin\Sigma)\}}{(1+\epsilon)(\alpha+\sin\alpha\cos\alpha)-2\epsilon\sin\alpha\cos\alpha+2K\{(1-\epsilon)\sin^2\alpha+\epsilon\}}\right]$ $T_5 = \frac{PR}{2}\left[\frac{AF-BE}{AC-BD}\right]$; $V_5 = \frac{P}{2}\left[\frac{CE-DF}{AC-BD}\right]$ — WHERE: $A = K^2\left\{\frac{3\sin\alpha}{2}+\frac{k^2}{8}\right\}+\epsilon\{\alpha\cos\alpha+K(1-\cos\alpha)\}$; $B = \frac{(1+\epsilon)}{2}(\alpha-\sin\alpha\cos\alpha)-\epsilon\sin\alpha(1-\cos\alpha)+K\{(1-\epsilon)\sin^2\alpha+\epsilon(1-\cos\alpha)\}+\frac{k^2}{2}\sin\alpha$; $C = \frac{(1+\epsilon)}{2}(\alpha-\sin\alpha\cos\alpha)+\epsilon\sin\alpha\cos\alpha+K\{(1-\epsilon)\sin^2\alpha+\epsilon\}$; $D = \frac{k^2}{2}\sin\alpha-\epsilon(\sin\alpha+K\cos\alpha)$; $E = K^2\left\{\frac{3\sin(\alpha-\Sigma)}{2}+\frac{k^2}{8}\right\}+\epsilon\{\alpha-\Sigma-\sin\alpha(\alpha-\Sigma)+K\{1-\cos\alpha(\alpha-\Sigma)\}\}$; $F = \frac{(1+\epsilon)}{2}\{\alpha-\Sigma\}\cos\Sigma-\sin\alpha\cos\{\alpha-\Sigma+\sin\Sigma\}-\epsilon\sin\alpha\{1-\cos(\alpha-\Sigma)\}+K\{(1-\epsilon)\sin\alpha\sin(\alpha-\Sigma)+\epsilon\{\sin\Sigma-\cos\alpha\}+\frac{k^2}{2}\sin\alpha$
Case Vb	$M_6 = \frac{PR}{2\Sigma_6}K^2(1-j)^2\cos\alpha$; $T_6 = \frac{PR}{4}K^2(1-j)^2\left[\frac{A\sin\alpha-B\frac{k^2}{8}(2+j)}{AC-BD}\right]$; $V_6 = \frac{P}{4}K^2(1-j)^2\left[\frac{C\frac{k^2}{8}(2+j)-D\sin\alpha}{AC-BD}\right]$ — WHERE: $\Sigma_6 = (1+\epsilon)(\alpha+\sin\alpha\cos\alpha)-2\epsilon\sin\alpha\cos\alpha+2K\{(1-\epsilon)\cos^2\alpha+\epsilon\}$; SYMBOLS SAME AS ABOVE
Case VI	$M_7 = \frac{WR}{2(\alpha+K)\Sigma_7}\left[(2-\cos\alpha)\sin\alpha-\alpha+\epsilon\left\{\sin\alpha-\alpha\cos\alpha-(1+\cos\alpha)(\alpha-\sin\alpha)\right\}+2K\left\{\sin\alpha\left(\frac{k^2}{8}+\frac{3}{2}\alpha+\frac{1}{2}\alpha\cos\alpha\right)+\epsilon\sin\alpha(\alpha-\sin\alpha)\right\}\right]$
Case VII	$M_8 = \frac{WR}{2(\alpha+K)\Sigma_8}\left[(2-\cos\alpha)\sin\alpha-\alpha+\epsilon\left\{\sin\alpha-\alpha\cos\alpha-(1+\cos\alpha)(\alpha-\sin\alpha)\right\}+2K\left\{\sin\alpha\left(\frac{k^2}{8}+\frac{3}{2}\alpha+\frac{1}{2}\alpha\cos\alpha\right)+\epsilon\sin\alpha(\alpha-\sin\alpha)\right\}\right]$ $T_8 = \frac{WR}{2(\alpha+K)}\left[\frac{A\left\{F+\frac{K^2\sin\alpha}{8}\right\}-B\left\{E+\frac{k^2}{8}\right\}}{AC-BD}\right]$; $V_8 = \frac{W}{2(\alpha+K)}\left[\frac{C\left\{E+\frac{k^2}{8}\right\}-D\left\{F+\frac{K^2\sin\alpha}{8}\right\}}{AC-BD}\right]$ — NOTATION SAME AS ABOVE

Statically Determinate Cases

The circular cantilever beam of arc α with a bending moment M acting at the free end is shown in Fig. 1. The curves are presented for three different cross sections showing the variation in the end deflection as α increases from 0 to 360 deg. The expressions for δ, β, and θ are given in Table 1 for this beam under the heading of Case I.

The same beam with a twisting moment T acting at the free

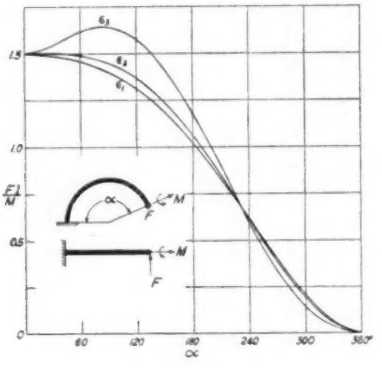

Fig. 3

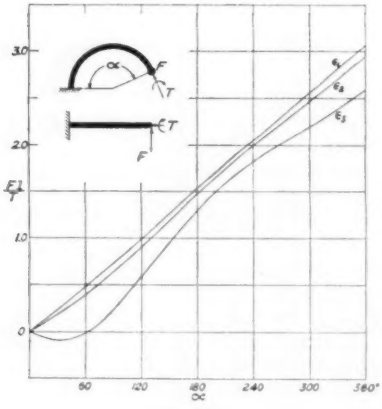

Fig. 4

end is denoted Case II and is shown in Fig. 2. There also is visualized the variation in the end deflection for the three cross sections, as α varies from 0 to 360 deg. Case II of Table 1 gives the expressions for δ, β, and θ for this loading.

Statically Indeterminate Cases

Cases I and II become statically indeterminate when a simple support is placed at the free end. Case I then becomes that denoted as Case III, and Case II that entitled Case IV.

The ratio of the product of the reaction F and the length l of the curved beam to the moment M is graphically shown in Fig. 3, for the angle of arc α from 0 to 360 deg. In Fig. 4, the ratio of the product Fl to the twisting moment T is likewise presented as a function of the arc angle α through the same range. In both figures, the curves are drawn for the three indicated cross sections.

The cantilever arc beam is shown in Fig. 5. It consists of a circular arc of angle 2α with two equal tangential legs of length l. Due to the discontinuity of the structure, two sets of expressions are necessary for the reactions M_0, T_0, and V_0 at the plane of symmetry of the beam. One group of expressions is valid for the load P at any position on the arc, denoted by the angle γ, as shown in Fig. 5(a). The second set of equations holds for the load P at any position on the leg, as indicated by the distance a in Fig. 5(b). For the loading presented in Fig. 5(a) the designation Case Va is used, while for the loading of Fig. 5(b) the notation is Case Vb.

The positive sense of the three reactions, i.e., bending moment M_0, twisting moment T_0, and shear V_0 at the plane of symmetry of the beam is indicated in Fig. 5. As shown, P is a concentrated load acting downward and perpendicular to the plane of the beam on the left-hand side of the axis of symmetry of the beam. The shear reaction V_0 acts in the same direction as P on the right-hand half and in the opposite direction (upward) on the left-hand half.

The variation in the ratio of M_0 to PR is shown in Fig. 6 for

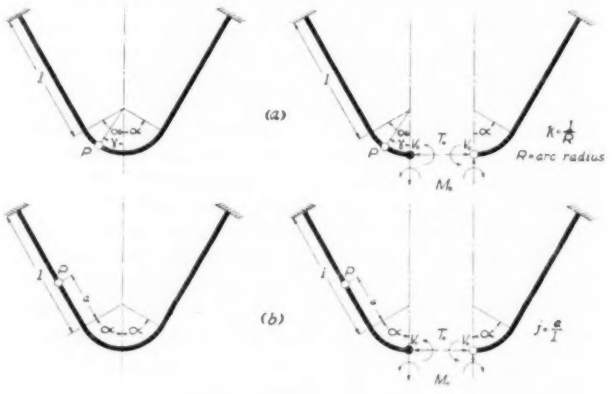

Fig. 5

various positions of the load P on the arc α, as denoted by the ratio γ/α. Curves are there plotted for values of $k = 0.5$, 1.0, and 2.0, and of α from 0 to 90 deg for the three cross sections. Like results are given in Fig. 7 for any position of P on the leg l of the beam. This position is indicated by the ratio j.

The ratio of T_0 to PR as a function of α is shown in Fig. 8 for the three cross sections and values of $k = 0.5$, 1.0, and 2.0. Curves are plotted for various positions along both the arc and the leg of the beam. Fig. 10 presents the ratio of T_0 to PR as a function of the position of the load, i.e., γ/α and j, for the steel circular cross section, $\epsilon = 1.3$, and values of $k = 0.5$, 1.0, and 2.0. These curves clearly show the variation in T_0 from zero with the load P at the axis of symmetry of the beam, to a maximum and then to zero again at the built-in support.

In Fig. 9 is plotted the variation in the ratio of V_0 to P as a function of α for values of α from 0 to 90 deg. The results for the three cross sections, and $k = 0.5$, 1.0, and 2.0, are given for various values of γ/α and j.

The substitution of a differential load $wRd\gamma$ for P in the expressions of Case Va, followed by an integration between the limits of 0 and α, gives results for M_0, T_0, and V_0 due to a uniformly distributed load of intensity w over the left-hand arc α. A similar substitution of a differential load wdx for P in the expressions for Case Vb, followed by an integration between the limits of 0 and l, gives corresponding results due to a uniformly distributed load of intensity w over the left-hand leg l. The sum of these two results for the bending moment gives an expression for the bending moment M_0 at the plane of symmetry of the beam due to a uniformly distributed load of intensity w over the left-hand side of the beam. Similarly, the expressions for the twisting moment T_0 and the shear V_0 at the same point are obtained. These results are tabulated in Table 1 as Case VII.

The use of the results of Case VII and the principle of super-

position immediately give the corresponding results for the cantilever arc beam in Fig. 11, subjected to a uniformly distributed load of intensity w over its entire length. Then $T_0 = 0$, $V_0 = 0$, and M_0 is given under the heading of Case VI in Table 1. It should be observed that the total transverse load W in Case VI is just twice the value of W in Case VII.

The ratio of M_0 to WR for the uniformly loaded cantilever arc beam is presented in Fig. 11, for values of $k = 0$, 0.5, 1.0, and 2.0, and arc angle α from 0 to 90 deg. Curves are presented in each case for the three cross sections. The same curves for the case of $k = 0$, the built-in circular beam of arc angle 2α, are plotted in Fig. 12 for values of α from 0 to 180 deg.

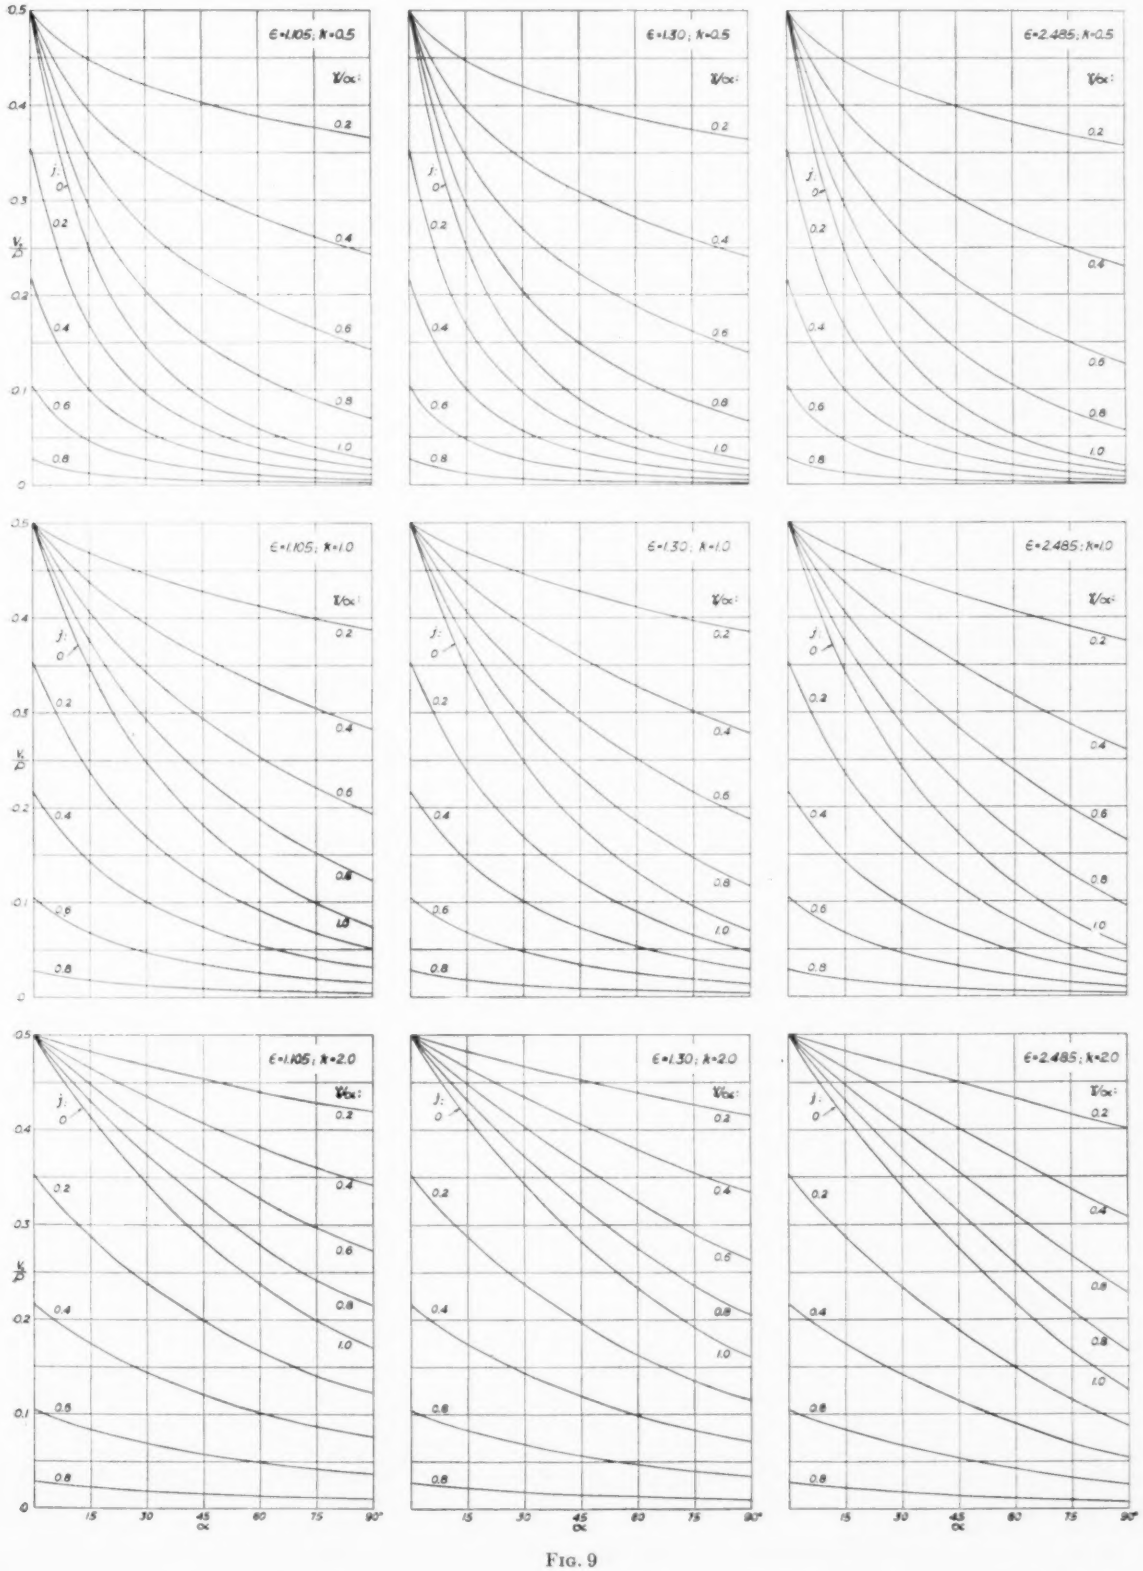

FIG. 9

LIMITING VALUES

For the statically determinate Cases I and II there are two possibilities as α approaches zero. The first is that the radius R remains constant as α approaches zero. Then the result is simply that of the curved beam of zero length. If, however, as α approaches zero, the length of the beam remains finite, the radius R approaches infinity, and the product αR approaches the length l of a straight beam. This leads to the results for straight

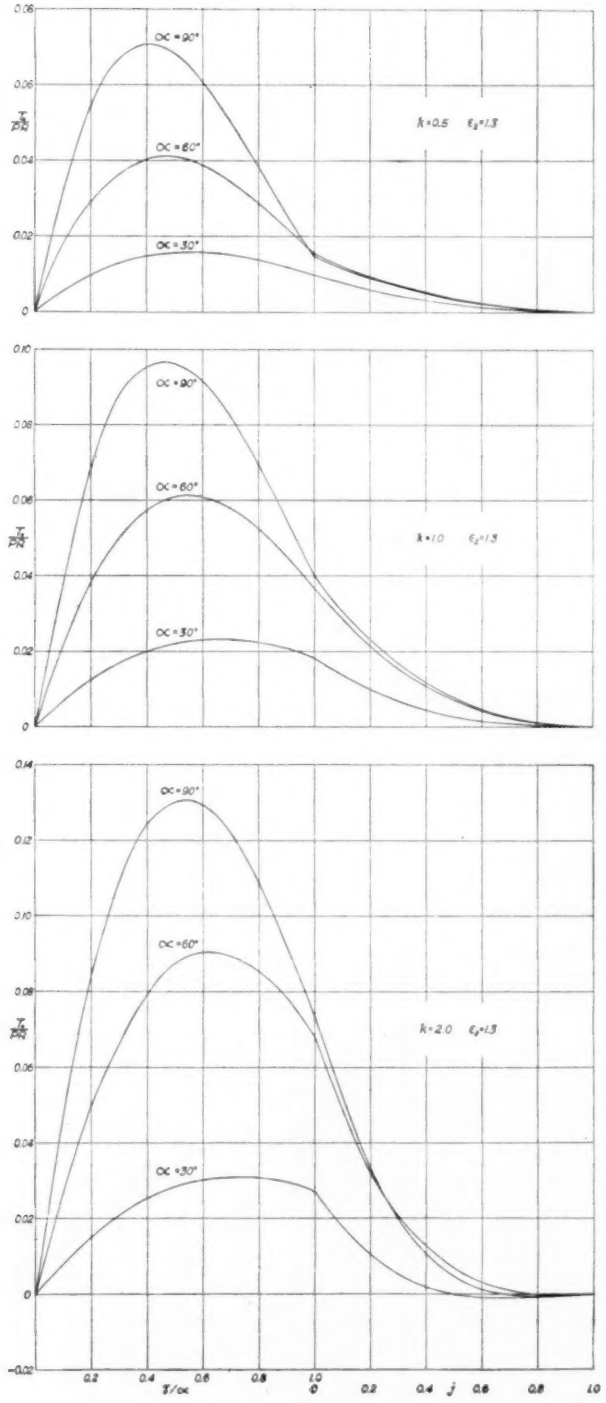

FIG. 10

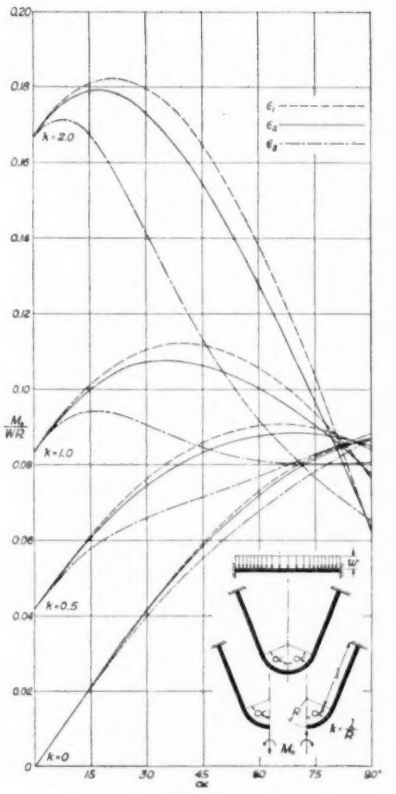

FIG. 11

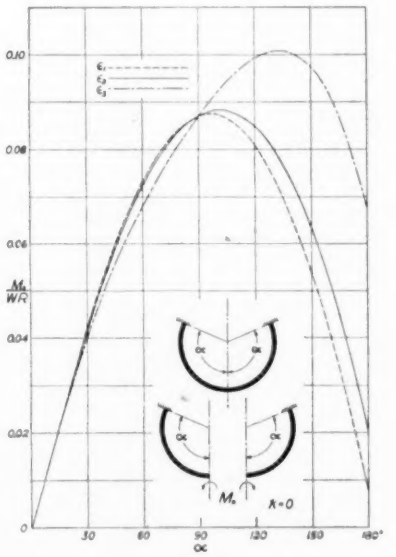

FIG. 12

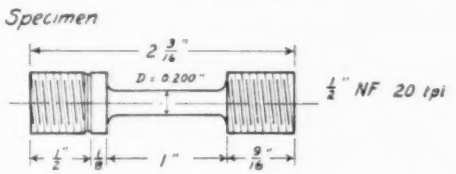
beams with the same loadings. For Cases III and IV the values of the reactions F approach those of straight beams with corresponding loads as α approaches zero.

As α approaches zero Case V*a* degenerates into a straight beam of length $2l$ with the load P at mid-span while Case V*b* becomes that of a straight beam of length $2l$ with the load P at the distance a to the left of mid-span. Similarly, Case VII degenerates into a straight beam of length $2l$ with a uniformly distributed load over the left half and Case VI into the same beam with the distributed load extending over the entire length $2l$.

Discussion



Measurement of Dynamic Strain[1]

LEVAN GRIFFIS.[2] The writer participated in developing bonded "metalectric" strain gages for recording complete stress-strain curves during tensile impact tests.[3] Specimens of 1 in. gage and 1/8 in. diam were tested at velocities of 10 to 250 fps.[4]

The authors' Fig. 11, referring to elastic longitudinal impact stresses, recorded and compared to theoretical values is of particular interest. Electric strain gages are also used to record plastic stresses, e.g., tensile impact stress-strain curves. This requires a wire resistor bonded to a dynamometer bar holding the specimen (Fig. 1 of this discussion). This bar is alloy steel, longitudinally wound with resistance wire, of sufficient section to insure that all stresses applied to it are in the elastic range, although the specimen is tested to failure. An early criticism of such gages was that, calibrated statically, they are used dynamically, with no proof that dynamic and static behavior should coincide. On the basis of elementary wave mechanics, one can predict the dynamic response of such a gage to any force-time function and show that it is reliable. A simplified form of such analysis was made by G. Datwyler and L. Griffis in June, 1938, as part of the research program.[3]

The analysis is generalized from a paper by L. H. Donnell,[5] a section of which deals with waves in materials which do not obey Hooke's law. The speed of an elastic stress wave front in a material is $c_0 = \sqrt{\frac{E_0}{\rho}}$ in which E_0 is the elastic modulus, ρ is density. For a material with curves stress-strain (σ-δ) diagram (Fig. 2 of this discussion), the speed of an inelastic stress increment ($\Delta\sigma$) at σ_1 is $c_1 = \sqrt{\frac{E_1}{\rho}}$ where the E_1 is the slope of the (σ-δ) curve at σ_1. A wave of intensity σ_1 will travel with a changing curved wave front whose shape depends upon $d\sigma/d\delta$, since each increment travels with slower speed than a lower increment. As a wave-front increment $\Delta\sigma$ passes a section Δx of a bar, that section will acquire a change in velocity due to the impulse applied; force-time $= A \cdot \Delta\sigma \cdot \frac{\Delta x}{c} = \rho \cdot A \cdot \Delta x \Delta V$. Therefore a velocity of impact V at a section will produce a succession of stress increments from zero to σ_a, depending upon ρ and the (σ-δ) curve. Velocity V determines σ_a, since from the preceding equation $V = \frac{1}{\rho} F(\sigma)$, where $F(\sigma)$ is a function only of the stress-strain curve and may be plotted graphically: $\sum_{\sigma_a}^{n} \left(\frac{\Delta\sigma}{c}\right)$.

When a wave front strikes a section of increased or decreased area, or when opposing wave fronts meet, the transmitted (σ_t) and reflected (σ_r) stresses (waves) are determined by the facts that, on each side of that section, (1) final particle velocities must be equal and, (2) total forces must be equal. A fixed end is equivalent to infinite increase in section; a free end to a decrease in section to zero. Equating impulse to momentum change for particles on each side of the discontinuity determines

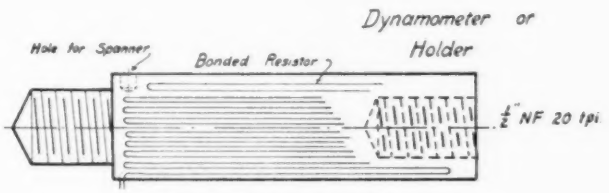


FIG. 1 SPECIMEN AND HOLDER

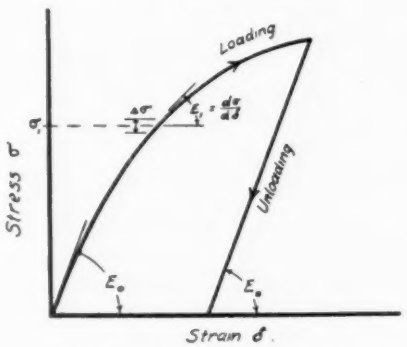

FIG. 2 STRESS-STRAIN CURVE

the magnitude of σ_r and σ_t. A discontinuity in material of a bar may be reduced to an equivalent change in sectional area. At increases in section, $\sigma_r > \sigma_a$ and $\sigma_t < \sigma_a$; at decreases in section, $\sigma_r < \sigma_a$ and $\sigma_t > \sigma_a$.

The shapes of the transmitted and reflected wave fronts are obtained by dividing the original waves into steps, each with its own speed $c_n = \sqrt{\frac{E_n}{\rho}}$. The time-position picture of these increments, and of all reflected and transmitted increments, can be constructed if these characteristic speeds are known. By carrying out a simultaneous computation of transmitted and reflected stress magnitudes for all increments, during meetings of waves or at discontinuities in section, the speeds are found from the (σ-δ) curve, using $c = \sqrt{\frac{E}{\rho}}$. The time-position of any stress is indicated by a ray whose slope with the time axis equals the speed. This determines the complete time-space-stress function for the bar up to necking, for any case of longitudinal impact. From the stress, the strain distribution may be found. If a

material unloads along an elastic line from any stress, Fig. 2 of this discussion, an elastic unloading wave may be added to the picture under certain conditions, permitting analysis of stress conditions in the dynamometer after the specimen fails.

To illustrate, assume a specimen and holder as in Fig. 3, herewith. An instantaneous impact velocity V applied at A at time t_0 will set up a continuous tensile-stress wave front of intensity σ_a traveling toward B. This will strike B, beginning at time t_1, then be partially transmitted to the holder as an elastic tensile wave front σ_t, and also be reflected as a tensile wave front σ_r superimposed upon σ_a. The elastic wave σ_t proceeds to the rigid end C where, beginning at time t_2, it reflects as an elastic wave of intensity $2\,\sigma_t$. Simultaneously σ_r returns toward A where it reflects at t_3

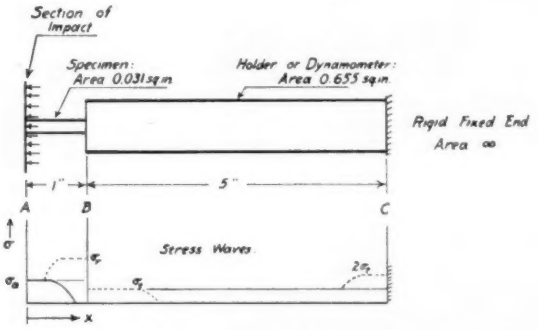

FIG. 3 WAVE PROPAGATION IN SPECIMEN AND HOLDER

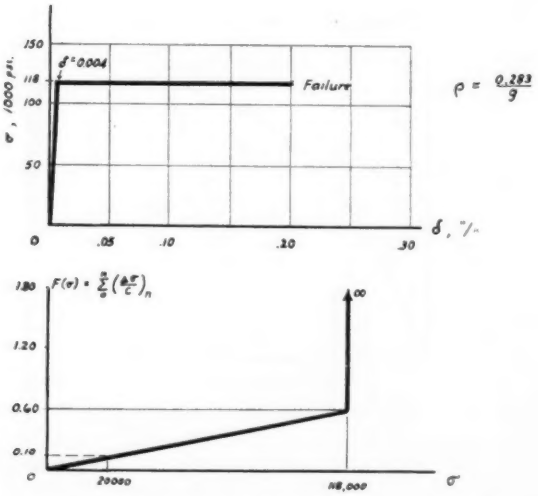

FIG. 4 ASSUMED STRESS-STRAIN CURVE FOR STEEL, AND COMPUTED CURVE OF $F(\sigma)$

as another tensile wave front σ_a', as if A were a rigid end. The wave $2\,\sigma_t$ will reach B at t_4 where, at this decrease in section, it is partially reflected as a wave front of less intensity than $2\,\sigma_t$, and partially transmitted to the specimen as a tensile wave of increased intensity. (Imagine a large mass striking a small mass inelastically.) This might cause necking in the specimen near C, simultaneously with necking near A, if stress intensities were of proper amounts. Or, such transmissions and reflections at A, B, and C may continue if the specimen stress has not built up to the ultimate, until at some point (which might be predicted) necking and failure result. The response of the strain gage at any instant depends upon the intensity and distribution of the elastic waves in the holder.

As an example, assume specimen and holder to be steel, the specimen having simple (σ-δ) and $F(\sigma)$ curves as in the writer's Fig. 4. For an impact velocity of 11.3 fps, one finds that $F(\sigma_a) = 0.10$ lb-sec per cu in., $\sigma_a = 20{,}000$ psi, and $c_0 = 196{,}000$ in per sec. In this simple case, all waves in the specimen have velocities c_0 up to the instant of yield, then have zero velocity; $6\cdot\sigma_a$ is required to produce yield. In this case it is simpler to use forces f instead of stresses σ, since a force wave intensity distributed along the entire holder, and equal to the specimen force at the same instant, corresponds to 100 per cent response. At section B (time t_1), $f_t = 1.91\cdot f_a$ and $f_r = 0.91\cdot f_a$. Also, the required $6\cdot f_a$ will develop in the specimen before $2\cdot f_t$ returns to B, after which B becomes in effect a free end.

Fig. 5 of this discussion shows the stress-time-space picture, with each ray indicating a force intensity moving at speed c_0. Polygons in the diagram indicate at any time the distribution of constant force in the specimen or holder, of intensity as noted in small print.

Fig. 6 (dotted) shows the curve of holder response, based upon 100 per cent response equal to yield force in the specimen. No damping of stress intensity is assumed in specimen or holder.

Assuming for metals that the damping of waves or vibrations is proportional to intensity, and to distance which the wave has traveled, Fig. 6 shows (dashed) the curve of holder response calculated as before, but assuming that in one holder length, a wave intensity f damps to intensity $^3/_4 f$ (25 per cent damping). Similar results are shown (solid curve) in Fig. 6 for 50 per cent damping in one holder length. In each case, perfect holder response would be indicated by the heavy line rising directly to 118,000 psi and then becoming horizontal. The mean line through the gage response vibrations is then the correct and reliable response. The gage does not respond at all until time t_1 ($0.5\cdot10^{-5}$ sec after impact). Clearly, a dynamometer should have a high natural frequency compared to the phenomenon being recorded. For

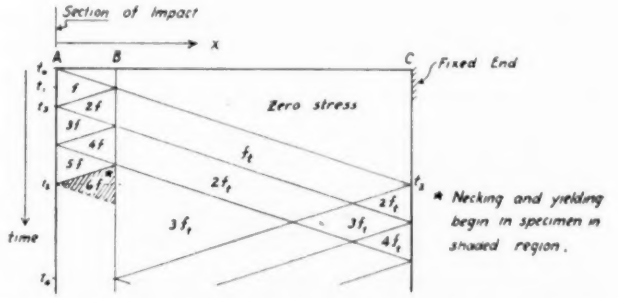

FIG. 5 BEGINNING OF FORCE-SPACE-TIME DIAGRAM FOR SPECIMEN AND HOLDER

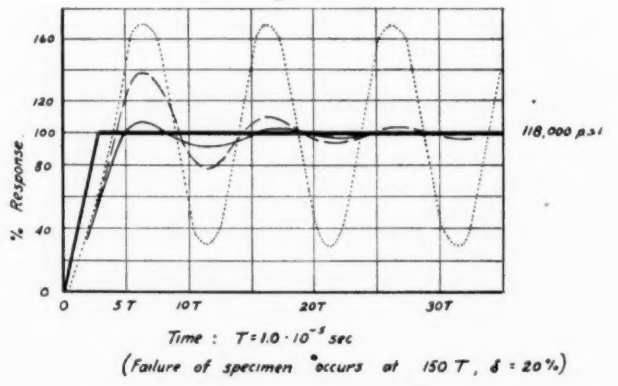

FIG. 6 DYNAMOMETER RESPONSE, IN PER CENT OF YIELD STRESSES

higher velocity impact tests, a shorter dynamometer would be desirable.

Fig. 7 herewith shows a force-time elongation diagram for an aluminum specimen tested at 20 fps. The force calibration (2590 lb) is made by introducing a known resistance into the oscillograph circuit, corresponding to a definite force required to produce an equal resistance change in the strain gage. A modulated timing wave (5000 kc) is shown, the time for tensile fracture being 0.0028 sec. Modulations on the force-time

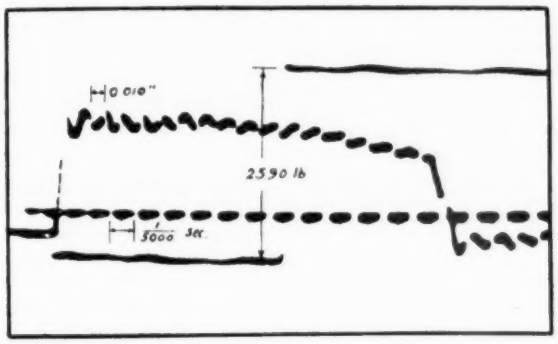

FIG. 7

curve are produced by recording the forward motion of the section of impact using a scratch gage. This device alternately makes and breaks a contact at each 0.01 in. of forward motion.

J. H. MEIER.[6] The Bucyrus-Erie Company's Research Department has developed a somewhat similar unit for field measurement of strains on large excavators.[7] The amplitude modulation scheme was chosen as it is well capable of covering the range of mechanical frequencies encountered on heavy machines. Carrier frequencies up to 3000 cycles per sec have been used successfully; thus mechanical vibrations up to 500 cycles per sec can be recorded without appreciable loss in accuracy of peak values.

The bridge circuit employed is shown in Fig. 8 of this discussion. Like the authors' arrangement it is symmetrical. Phase balancing is identical; however, resistance balancing is considerably simpler. It is achieved by means of a large fixed resistor across one arm of the bridge and a variable resistor across the adjoining arm, the common point being ground. A decade box is used as variable resistor; contact resistance is not critical because of the high shunt resistance. With this arrangement the balance point is found easily and rapidly, thus the disadvantage of hunting for the correct setting as described by the authors is overcome. Also, sensitivity adjustment and calibration are greatly simplified. From the gage factor and the balance setting the resistance offset causing the same signal as a convenient strain, for instance 0.001, can be computed easily. The decade box is offset by this amount, and after proper adjustment of amplifier gain, the oscillograph deflection is photographed and serves as calibration for the record. Proper functioning of the setup can be checked readily by offsetting the decade box 500 or 1000 ohms.

All four arms of the bridge are arranged near the active strain gage. This requires four leads between gages and recording equipment, while the authors' arrangement requires only three. The inconvenience is small, however, since three leads in a shield can be handled easily. Two leads feed the bridge, while one lead and the shield carry the signal. The great advantage of this scheme is that relatively large changes in lead resistance affect the signal but slightly. This is particularly important when using trailing cables from moving objects, since these cables are apt to be stressed and act as undesirable strain gages of their own. Furthermore, the effect of lead resistance on calibration is much smaller than in the authors' scheme. Also, the undesirable influence of the distributed capacity of the leads is substantially reduced.

Electrical-resistance gages have linear response within the range of strains covered by the authors' investigation.[8] The authors' nonlinear calibration curve is therefore a characteristic of the circuits described. Linearity of response is desirable in several respects, as follows:

1 It greatly facilitates the checking of equipment and performance, and it is of importance in detecting pickup and other disturbances affecting the accuracy of the results.

2 It renders calibration easy and reliable.

3 It permits making full use of the available oscillograph screen width; thus greatest possible accuracy can be expected.

With equipment of sufficient sensitivity available to measure very small strains, an initial offset corresponding to a multiple of the strains to be observed is a certain disadvantage. When the sign of strain is known (as for instance when rope pulls are measured by means of calibrated links), the drawback of the initial offset to eliminate the nonlinear portion is particularly apparent.

The cathode-ray oscillograph will be of great help in determining the cause of nonlinearity. Although the authors claim that the plot represents the unbalanced voltage, it appears from their diagram, Fig. 4, that at least part of the nonlinearity may

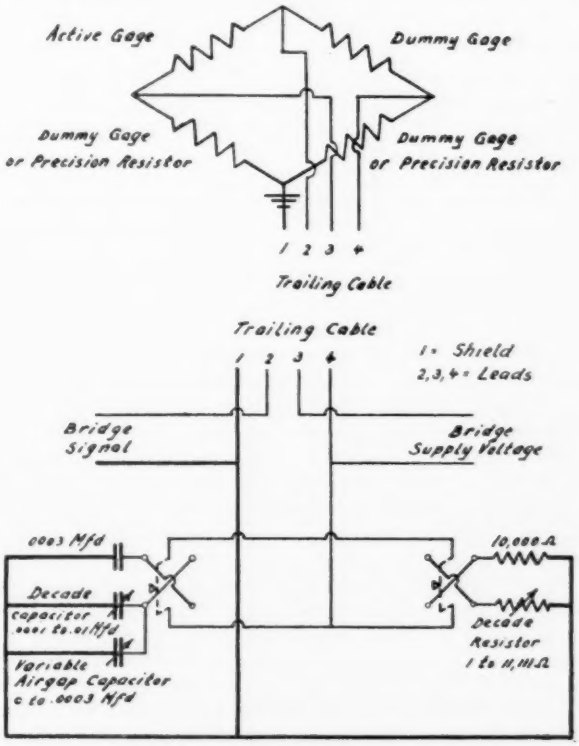

FIG. 8 BRIDGE ARRANGEMENT AND CONTROL

be the characteristic of the rectifier-meter system. It could be greatly improved by using higher amplification, an electronic-tube rectifier, and a high series resistance in the meter circuit. The nonlinearity observed in the rectifier-meter system of the writer's company is less than 2 per cent of that shown by the authors. The meter is used primarily for observation while photographic records are being taken.

If the bridge is working properly, the response of the cathode-ray oscillograph is perfectly linear and the deflection for zero strain is zero. It is important that this be verified for each setup, in order to secure proper phase balancing. If phase balance is not obtained the bridge signal is not proportional to the strain and considerable errors may result. As phase balance is different for each installation, it cannot be accounted for by calibration.

Readings and records should not be taken before zero deflection on the oscillograph screen can be obtained. Phase balancing should then not be disturbed for the entire test period. Failure of the signal to become zero reveals a potential source of error. It is usually due to pickup or to harmonics in the carrier wave which cannot be balanced simultaneously.

H. C. Roberts.[9] Although for several years there has been available excellent commercial equipment for recording mechanical strains and movements, there is still a shortage of usable published material dealing with methods and instruments. For this reason, such papers as do appear are likely to be studied with great interest by test engineers. This writer feels that with regard to the authors' present paper several omissions of some importance should be pointed out.

The authors have in no manner indicated the differences in the nature of the technical problem which appear when a measuring circuit is transferred from a single-channel setup under well-controlled conditions to a multichannel apparatus which will simultaneously record dynamic phenomena from a number of gages under conditions of field or factory operation. For industrial measurements, in general a ten-channel apparatus is much more than 10 times as useful as a single-channel apparatus. The experimental difficulties are likewise greater, but by proper selection of equipment the operating difficulties connected with a ten-channel apparatus may be made little greater than with a two-channel apparatus.

For multichannel recording, the electromagnetic oscillograph, recording a number of traces on the same strip of photographic film, together with a time indication, and with sequence or operation indications, is unexcelled within its frequency range. Such an oscillograph can be made to record satisfactorily as high as 10,000 cycles per sec, and at film speed as high as 50 ips for continuous drive; much higher speeds are available in the drum-type drive. These data refer to standard-model commercially available instruments. With such an oscillograph, all data as recorded are correlated against time, and thus a correlation also exists between all the traces. The magnetic oscillograph is a robust self-contained instrument, extremely efficient and flexible in operation. Its only serious handicap is a loss of response at extremely low operating temperatures; many commercial instruments have thermostatic control of temperature, thus eliminating this defect.

The writer feels also that the carbon-type resistance strip strain gage is being unjustifiably neglected. Admittedly it has its faults; at the same time it has some very appreciable advantages. There are now available some half-dozen commercial gages of this type, with a wide range of characteristics. A degree of stability is easily attainable which is satisfactory for practically all dynamic measurements; for tests involving weeks or months of elapsed time no gage now available can be used without rather elaborate precautions. For work which requires the use of many gages simultaneously, the ability to remove and re-use the same gage is worth while; this is not because of the cost of the gages, but because a gage can be calibrated experimentally and re-used many times. The principal disadvantage of the carbon-type gage is its relatively high cross-sensitivity; however, the wire-type resistance strip gage is not free from this fault.

The higher sensitivity of the carbon-type resistance strip gage permits the design of direct-coupled amplifiers having a high degree of stability. Such amplifiers are at this time giving satisfactory service; they have been in use for several years.

No mention is made of that most useful device, the carrier-type amplifier. With such an amplifier, the response may be maintained from static conditions (zero frequency) up to the highest frequencies normally encountered, and far above those which can be recorded with the magnetic galvanometer. Amplifiers of this type have been used to record phenomena well up into the tens of thousands of cycles per second. At the same time the gage circuit is excited with direct current and is thus freed from many operating difficulties which appear with alternating-current bridge circuits. The accuracy and stability of such an amplifier are comparable to that of an alternating-current amplifier. Such apparatus is sometimes deranged by extreme conditions of humidity, unless constructed with suitable precautions; the same is true of the cathode-ray oscillograph and of any other instrument utilizing high voltages or high-impedance circuits.

By means of either the direct-coupled amplifier or the carrier-type amplifier, operating into the magnetic oscillograph, it is possible to record phenomena at frequencies ranging from static conditions up to several thousand cycles per second. At the same time the records appear as single-line traces, which are easier to read and somewhat more accurate than the amplitude-modulated trace; this is especially true when several traces are recorded upon the same film.

It is of course true that the magnetic strain gage is limited in its applications; for example, its frequency response is necessarily limited by the frequency of the exciting current, and by other factors. Excitation frequencies as high as 50,000 cycles per sec have been used; there is, however, considerable doubt if even with this frequency of excitation the recording ability extended as high as the 9000 to 10,000 cycles per sec that such a frequency of excitation would indicate. At frequencies higher than perhaps 2500 cycles per sec, a magnetic gage is likely, because of its mechanical inertia, to act as an accelerometer.

Within its range of frequencies, and upon specimens to which it can be satisfactorily attached, the modern magnetic strain gage is the most reliable, the most stable, and the least difficult of operation of all the electrical strain gages. The push-pull type of gage, attached by clamping with its knife-edge feet, is least disturbed by time and temperature changes of all such equipment. The magnetic gage is normally a low-impedance device and is not disturbed by random fields or by changes in length of connecting cable; this because, although its total impedance is low, still the largest component of that impedance is inductance, and the effect of ohmic resistance, and of changes in ohmic resistance, can be made small. The magnetic gage does not normally require an amplifier and can be made to provide sufficient output to operate a recording galvanometer. It is of course necessary to provide an excitation current, which must be well regulated, so that changes in the amount of power absorbed by the gage, and changes in the voltage of the power-line supply, will not produce changes in the voltage applied to the gage. This equipment is also well developed and is commercially available.

With some types of magnetic gages, the effective level of measurement is above the surface of the specimen, and bending stresses will therefore introduce inaccuracy; with other types this is not the case. Few of the commercial magnetic strain gages now available are so constructed that the specimen is made part of the magnetic circuit; they may therefore be used on specimens of nonmetallic materials and may be attached by clamps, by screws, or by any other convenient method. In the

[9] Special Research Associate, Engineering Experiment Station, University of Illinois, Urbana, Ill.

'Progress Reports of the Stresses in Track Investigation" of the Association of American Railroads, several very informative discussions of such gages have appeared; the work of this organization with this equipment extends back to about 1930.

The magnetic strain gage has one advantage shared only by the capacity type among the electrical gages, that is, its ability to operate at different gage sensitivities and over wide ranges of strain. There are types of magnetic gages available for measuring movements of several inches, or even several feet, if necessary. All of these gages employ the same auxiliary equipment, thus increasing the flexibility of the entire group. Accelerometers are also available, operating from conditions of constant acceleration up to frequencies of change of acceleration as high as several hundred sinusoidal cycles per second.

The capacity type of strain gage is not especially well suited for use except under very closely controlled conditions, if it is to be calibrated quantitatively. Yet, since the early announcement of the Whiddington ultramicrometer in 1919, many capacity gages have been used. They are capable of an extremely high sensitivity, but their disadvantage is that it is very difficult to so construct them that there will be no change of capacity excepting that due to the strain. They are especially susceptible to humidity changes. Transducer circuits having an exceptionally high electrical stability have been developed, but this electrical stability does not compensate for errors coming from without the instrument. In the laboratory, or in applications in which the shape and variation in magnitude of a wave form are more important than its absolute magnitude, the capacity gage is often quite suitable.

Both the capacity gage and the magnetic gage are superior to the resistance types in that they impose no restraint upon the specimen other than that due to the weight of the gage itself. Most types of resistance gage impose quite a considerable restraint upon the specimen; this restraint appears as a shear in the adhesive by which the gage is attached, and there is thus usually a reasonable doubt in the mind of the worker as to whether or not there is creepage in the adhesive. With most of the available adhesives, this doubt is well founded. It is also true that with the magnetic and the capacity gages, there is no cross sensitivity.

The writer does not wish to criticize any type of gage unduly, but experience has convinced him that few electrical strain gages are at the present time in such form that their application and operation can be considered an exact science. For this reason, the type of gage selected should be affected by the character of the personnel which is to operate the equipment as well as by the type of measurement to be made.

A. V. de Forest[10] and A. C. Ruge.[11] This paper is timely in adding pertinent information on the many uses of the wire resistance strain gage. As the authors point out, the associated equipment for measuring the gage response is the all-important part of successful operation.

A few additional types of equipment which may be useful in certain instances might well be added to the list described by the authors of the paper. We have found many instances where the rate of application of load is reasonably slow, as in stresses in moving vehicles and landing stresses in airplanes, and where a pen-and-ink recorder, operating on a modulated 60- or 120-cycle alternating bridge, is more convenient and lighter in weight than an oscillograph. The Brush crystal recorder has been used very successfully in this field.

For high-speed work, particularly in preliminary investigations of transients, we have had good success in photographing a 5-in. cathode-ray tube with a still camera using a recurrent sweep. This process normally gives some distortion of the time scale but the system is so simple that where a transient may conveniently be repeated the records have proved to be valuable.

For high-speed work, where accurate timing is necessary, we have found the Dumont 208 cathode-ray oscillograph to have excellent frequency response and sufficient sensitivity to operate on large stresses without any additional amplification. Two, three, or four oscillographs may be photographed simultaneously with a drum camera. In using this equipment, it is frequently desirable to introduce a pulser circuit so that the oscillograph spot only remains on the screen for 1 revolution of the drum.

In all cases involving amplification and oscillograph measurements, we have found it desirable to calibrate the deflection directly in terms of a change in resistance. This is most easily accomplished by shunting the measuring gage through a resistance which changes the total to an amount corresponding to the approximate range of stress for which the oscillograph is set up. The calibration and the record are both photographed on the same film. There is then no question of interpreting the record later on. This method of procedure is applicable because the sensitivity of the original gage is highly dependable. The calibrating equipment mentioned by the authors is well suited for determining this strain sensitivity in the case of unknown gages.

Where the frequency response of amplifiers and oscillographs is in question, we have found it convenient to measure the response of this portion of the measuring device by the normal means of a variable-frequency oscillator rather than by means of the tuning fork described in the paper. The tuning-fork method is, of course, an extremely simple method of generating a fixed frequency. Where this is sufficient, it becomes a most practical solution to the problem. Additional points regarding the use of the strain gages are covered in a paper by one of the writers.[12]

C. W. Gadd.[13] The writer considers this paper a very worthwhile contribution to the literature available to the mechanical engineer interested in strain measurements, particularly because it sets down in concrete and immediately applicable form the essential information required to apply the wire-gage technique to dynamic studies. Since wire gages were made available there has been considerable duplication of effort in the development of equipment for dynamic-strain measurement with the gages, and much should be gained from this paper, particularly by organizations who either are not equipped or do not have the time to develop their own instrumentation.

In regard to static versus dynamic strain measurements, the writer believes that either or both are necessary, depending upon the problem at hand. It is often best to determine, first, with dynamic gages, the service loads and distortions of the part in question and then to analyze by means of a laboratory test, using one of the static-strain-measuring methods, for the effects of design changes. This procedure will often be advantageous from the standpoint of economy of time, control over the variables affecting the test results, and ease of measurements in fillets and other points difficult of access with dynamic gages.

As for the electrical circuits themselves, the writer believes that the usefulness of the potentiometer type could be empha-

[12] "Characteristics and Aircraft Applications of Wire Resistance Strain Gages," by A. V. de Forest, *Instruments*, vol. 15, April, 1942, p. 112.

[13] Research Engineer in Mechanical Engineering, No. 6, Research Laboratories Division, General Motors Corporation, Detroit, Mich.

sized somewhat. In many practical problems, where variables of the order of 5 per cent or more will exist, the practical low limit of the alternating-current amplifier frequency response should be considered as only a few cycles per second. In regard to the degree of amplification required, general-purpose equipment should include amplifiers such as those described in the paper, particularly if low-resistance gages are to be employed; however, the use of gages of several hundred ohms with no amplifier other than that with which the oscilloscope is equipped might be kept in mind as the simplest practical method of making dynamic measurements.

Authors' Closure

The application of the wire gage, as explained by Le Van Griffis, is extremely interesting, especially since the gage was used to record plastic strains. It might be well to point out that for large strains, such as are obtained in the plastic regions, the creep of the binding material may become a major factor and care must be exercised in making such applications. The authors have found the information concerning the shapes of wave fronts, as explained by this discussion, very interesting. The work on longitudinal impact as mentioned in the original paper, however, was presented only to show the characteristic of the amplifier used.

Mr. Meier's comments relating to the curvature of the calibration curve of the auxiliary meter for static work with the amplitude modulation unit are of interest. In any case both the vacuum-tube and copper-oxide rectifiers have an appreciable internal impedance and if curvature of the calibration curve is to be eliminated, extremely high series resistances must be used in the rectifier circuit. This high resistance will limit the current to a very small value and therefore a sensitive spotlight galvanometer must be used. If the designer is willing to accept a small amount of curvature in the calibration curve a rugged 1-ma meter can be used and this is more suitable for field use than a delicate galvanometer.

It should also be pointed out that the effect of curvature at the origin is negligible if the operating point is selected at mid-scale by unbalancing the bridge as suggested in the paper.

The amplifier and oscilloscope used with the amplitude-modulation unit are linear so there is no curvature of the oscilloscope calibration curve.

In the three-wire system, as described in the paper, one wire of the cable is a part of the standard arm of the bridge and a second wire is part of the variable arm of the bridge; normally both wires are subject to the same temperature and strain conditions. Therefore both temperature and strain effects on the cables will tend to cancel leaving only changes due to strain in the measuring gage. If the cables are allowed to hang, the swaying due to wind will be a bending condition, and therefore the wires will be subject to different strain conditions. An error due to strain may result.

The four-wire system has a complete bridge circuit located at the measuring point. Therefore the effect of strain and temperature on the resistance of the cables is eliminated, but since the four-wire cable includes both leads to the amplifier input and oscillator leads for power to the bridge, some trouble may be encountered with direct pickup of oscillator output by the amplifier. This will limit the degree of amplification so that only large strains can be measured.

The four-wire arrangement is very useful in applications in which slip rings must be used to take off a signal from a rotating member. The effect of contact resistance of clean slip rings is negligible with this system.

In applications in which many measuring points are used the three-wire system is more convenient as simpler switching systems and fewer gages are required.

Mr. Roberts' remarks concerning the usefulness of a multichannel set as compared to a single channel is well taken. However, difficulties of multichannel units are not serious and the danger of cross talk and oscillation is well known to amplifier designers. The string type of oscilloscope can give good results in laboratory practice; however, in the field it proves a bulky piece of equipment quite sensitive to mechanical shock. There are, however, many applications where pen-and-ink or chemical recorders can be used to good advantage.

The fault of cross sensitivity of the wire gage as pointed out by Mr. Roberts is present, but its magnitude is less than the accuracy of the auxiliary equipment used with the gage and is therefore of little consequence. Mr. Roberts is not too clear in his remarks concerning the carrier type of amplifier, which appears to be, from his description, quite similar to the type labeled amplitude modulation by the authors. For direct-current amplifiers the gain required for good results is so high as to require very high amplification leading to instability.

The suggestion of Mr. Roberts that it would be simple to detect the amplitude-modulated wave and obtain the envelope by filtering off the carrier-frequency wires was tried originally and gave good results, but since the choice of time constants is critical in order to respond to peak values, we feel it is safer to record the amplitude-modulated carrier. One advantage is that the carrier provides a good time axis.

In the authors' opinion the magnetic type of gage is quite useful when large displacements are to be measured. For dynamic-strain measurements, or normal-strain measurements, the application is too complicated to make it a good device for strain analysis, especially since magnetic shielding is essential; also the application requires holes, or attachments of some variety, and the action of these disturbances is indeterminate.

There is no doubt that this type of gage is excellent for certain purposes; high-speed dynamic strain is not one of them. Mr. Roberts is of the opinion that the application of the electrical strain gage cannot be considered an exact science. The authors would like to point out that even though this be the case, one must learn to creep before he walks and walk before he runs. The electrical gage, especially the wire type, has allowed measurements by the mechanical engineer never before possible. In dynamic measurement, the type of personnel cannot at present control the type of gage required. The personnel must of necessity be more elastic than the laws of nature they are trying to interpret.

The authors agree with Messrs. deForest and Ruge in their statement that the sensitivity of the original gages is highly dependable and the electrical method of calibration good for such gages.

The remarks of Mr. Gadd, stating that the dynamic gage can be of use to determine service loads or distortions and to make the analysis in the laboratory by use of static-strain-measuring methods, is well taken.

In summary, the authors wish to express their appreciation to the discussers for the time they have given and feel that each has added much to help in the understanding of the limitation of the measurements of dynamic strain. It may also be well to point out that the applications of electrical measurements in mechanics are undergoing rapid development and all the instrumentation is in a state of continual change.

There is one error in the original paper: In Fig. 2 the condenser C_2 was marked 0.01 mfd and it should be marked 10 mfd.

Book Reviews

Vector and Tensor Analysis

VECTOR AND TENSOR ANALYSIS. By Homer Craig, professor of applied mathematics and astronomy, University of Texas. McGraw-Hill Book Company, Inc., New York, N. Y., 1943. Cloth, 6 × 9 in., xiv and 434 pp., $3.50.

REVIEWED BY ALBERT E. HEINS[1]

VECTOR and Tensor Analysis" by Homer Craig was written with a threefold purpose in mind. Briefly the aims are the following: (*a*) To supply the necessary material to bridge the gap between the elementary calculus and the study of vector and tensor analysis; (*b*) to give a treatment of vector and tensor analysis; and finally, (*c*) to emphasize the concept of the invariant. The book is accordingly divided into four parts. Part *A* deals with the additional mathematical background mentioned in (*a*). In this section we find a discussion of such topics as the real number system, infinite sequences, the calculus of functions of two variables, parameterization of arcs and co-ordinate transformations including some remarks on Jacobians. This background is certainly adequate to orient the reader into what is to follow.

Parts *B* and *C* are concerned with a treatment of vector and tensor analysis. In these sections there is a discussion of the algebra and calculus of vectors and tensors. Some applications of vector analysis to the differential geometry of curves and surfaces are given. The section on the calculus of vectors also includes line, surface, and volume integrals, and the theorems of Gauss, Stokes, and Green which play such a prominent role in certain developments in the dynamics of continuous media. The last part of the book gives a discussion of the applications of Parts *B* and *C* to classical dynamics, special and general relativity.

A study of this book will reward the student of mathematics, engineering, or physics with a good working knowledge of vector and tensor analysis. The indicated applications to geometry and dynamics serve to illustrate the use of vector and tensor analysis in pure and applied mathematics. A useful bibliography is appended to each part.

Proceedings of the Society for Experimental Stress Analysis

PROCEEDINGS OF THE SOCIETY FOR EXPERIMENTAL STRESS ANALYSIS. Volume 1, No. 1. Papers presented at the Seventeenth Eastern Photoelasticity Conference and Experimental Stress Symposium. Held Under the Auspices of the Chrysler Institute of Engineering, Detroit, Michigan, May 13, 14, and 15, 1943. Published by Addison-Wesley Press, Inc., Cambridge, Mass. Cloth, 8½ × 11 in., xvi and 156 pp., figs., tables, $3.

REVIEWED BY A. M. WAHL[2]

THIS volume, edited by Dr. C. Lipson and Prof. W. M. Murray, consists of a collection of papers presented at the seventeenth Eastern Photoelasticity Conference and Experimental Stress Symposium held at Detroit during May, 1943. It also represents the first volume of the proceedings of the newly formed Society for Experimental Stress Analysis.

Although the S.E.S.A. is an outgrowth of the Photoelastic Conference which, at first, was devoted largely to papers on photoelastic-stress analysis, the wartime trend in emphasis toward strain measurements on actual structures or machine parts is exemplified in this volume by the predominant number of papers discussing uses and applications of electric gages or brittle coating methods. Thus out of the seventeen papers in this volume, about one half are concerned with the description, use, or application of electric strain gages and associated instrumentation. This reflects the increasing importance of electrical strain measurements, particularly in aircraft and automotive design problems.

Those engineers who are interested in the technique of using the resistance-wire type of gage together with the associated instrumentation will find much data of interest in the papers by Gibbons, Hathaway, Grover, and Dohrenwend. The paper by Gibbons discusses many technical problems arising in the use of the resistance-wire gage while that by Hathaway treats not only resistance-type gages but also electromagnetic types together with associated control, power supply, and recording equipment. The use and application of resistance-type gages to the measurement of dynamic strains, particularly in fatigue testing, is described in the paper by Grover. A paper of considerable interest to spring designers is that by Dohrenwend,who investigated the stress distribution and eccentricity of loading in volute springs.

A considerable number of papers in this volume treat applications of strain measurements to aircraft and automotive design problems. There is an interesting paper by Tucker which discusses the use of resistance gages in aircraft-engine parts where elevated temperatures (up to around 500 F) are involved. Results of strain measurements thus obtained on aircraft cylinder-barrel flanges and cylinder studs are given. The increase in dynamic stress due to insufficient tightening of the cylinder studs is shown by the test results. This paper also emphasizes the obvious truth that it is not enough to merely measure stresses; they must also be evaluated by the designer in terms of fatigue life or margin of safety. This latter phase of the problem is often the more difficult one. Other papers involving strain measurements include that by Lipson on stresses in connecting-rod bearings and by Ellis which treats of an analysis of an aircraft-engine-cylinder failure using the brittle-lacquer method. This latter paper should be of considerable interest to engineers interested in the technique involved in such measurements and the application of brittle coating methods to dynamic- and static-strain measurements. A paper by Gadd discusses the results of strain measurement with a short-gage-length extensometer on an engine crankshaft together with other stress-analysis problems in engine design.

An interesting discussion of the determination of aircraft-engine-piston operating temperatures by means of hardness changes during operation is given by R. G. Anderson. This paper also records the results of brittle-lacquer measurements on actual pistons. These data are correlated with fatigue-test results on pistons, using a hydraulic type of machine in which operating temperature gradients are simulated.

An investigation of the stress distribution around an elliptical hole in a plate under biaxial stress using photoelastic and brittle-lacquer methods is reported by Durelli and Murray. The usefulness of the brittle-lacquer method in order to determine the

[1] Assistant Professor of Mathematics, Purdue University, Lafayette, Ind. (Pro tem on leave of absence.)

[2] Research Engineer, Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa. Mem. A.S.M.E.

principal stress directions is brought out very well in this paper.

A paper of direct practical interest to machine designers is that by Hetényi which treats of the stress distribution in threaded connections using both plane and three-dimensional photoelastic methods. It is shown that approximately 40 per cent reduction in peak stress for elastic conditions may be obtained by using a nut with a tapered thread or a tapered lip. The results of comparative photoelastic tests on U. S. Standard, Whitworth, and Aero-Thread forms are also presented.

A mechanical device for evaluating strain rosette readings in terms of principal stresses and stress directions forms the subject of a paper by Murray. Such a device should be quite useful where a large amount of test data must be worked up. In discussions of this paper, three graphical solutions of this problem are presented by Meier, Hansen, and Baumberger. The latter presents a particularly simple solution for the 45-deg rosette gage with three components.

Two papers involving fatigue studies are included. The first by Horger, Neifert, and Regen describes residual stress measurements on $2^3/_{16}$-in. round bars of heat-treated S.A.E. 1045 steel, electric strain gages being used. Of interest is the nonsymmetrical stress distribution found. The results of fatigue tests on 2-in. alloy-steel bars with very small transverse holes are also given to show the improvement produced by surface rolling. The second paper by Peterson shows how the results of photoelastic tests or strain measurements may be correlated with strength-reduction factors obtained by means of fatigue tests on specimens with notches or grooves. This paper represents further progress on the general problem of evaluating the results of strain measurements of photoelastic tests in terms of danger of failure, particularly where fatigue is involved.

In general, it may be said that this first volume of the newly formed S.E.S.A. contains a great deal of information of interest not only to engineers directly concerned with the experimental determination of stress in machines or structures but also to design engineers and stress analysts in general.

Dynamical Analogies

DYNAMICAL ANALOGIES. By Harry F. Olson, acoustical research director, RCA Laboratories, Princeton, N. J. D. Van Nostrand Company, Inc., New York, N. Y., 1943. Cloth, $5^1/_2 \times 8^1/_2$ in., xi and 196 pp., $2.75.

REVIEWED BY J. P. DEN HARTOG[3]

THIS is a small and extremely useful book by a well-known engineer in the acoustic field. In a previous book by the same author, "Elements of Acoustical Engineering," D. Van Nostrand, 1940, which incidentally is also highly recommended, there appears a chapter on "Electrical, Mechanical, and Acoustical Analogies," which forms the basis of the work now under review.

It gives in a concise and clear form, without derivations, but with adequate definitions, the principal formulas and pictures showing four equivalent systems: linear mechanical, rotational mechanical, electrical, and acoustical. The author confines the analogy to the usual one where mechanical velocity corresponds to electric current. Other proposals, the best known of which is due to Firestone, are mentioned in a footnote, but since they are not widely used they are not discussed further in the book. The "acoustical" system differs from the "linear mechanical" mainly by the substitution of pressure in lb per sq in. for force in lb. The book is nicely illustrated by groups of five figures showing sketches of the four different systems and a small diagram with their common characteristics.

The detailed contents of the various chapters follow:

Chapter 1 gives definitions, clear and concise, of all the quantities discussed, some hundred of them.

Chapter 2, entitled "Elements," gives pictures and tables showing the correspondence between "mass" and "inductance," etc., as well as between the various kinds of impedance with their dimensions.

Chapter 3 deals with single-degree-of-freedom systems, and chapter 4 with systems of two and three degrees of freedom, giving pictures and listing the principal differential equations and formulas for the natural frequencies, impedances, and other characteristics.

Chapter 5 is entitled "Corrective Networks" and could also appropriately be called "Compounding of Elements." It shows various series and parallel connections of elements, usually not involving more than three such elements. Again, comparative figures with little diagrams showing transmissibility vs. frequency are the main contribution.

Chapter 6, "Wave Filters," extends the subject of the previous chapter to more than three elements and presents the matter in the same form with a good collection of formulas showing cutoff frequencies.

Chapter 7, "Transients," gives a statement of Heaviside's unit function and the response of the four kinds of systems to it and also a short exposition of how the response of such a system to an arbitrary exciting force can be found by integration of the response to the unit function.

Chapter 8 deals with "Driving Systems" or "Transducers," being devices for converting electric currents into mechanical vibrations, mainly for loudspeakers and phonograph recorders It discusses the electrodynamic, electromagnetic, electrostatic, magnetostrictive and piezoelectric systems and gives the electric circuit diagrams and the pertinent formulas both for the electrical and the mechanical parts of the system.

In chapter 9 "Generating Systems" are treated, which are devices operating on the same principle but opposite to those of the previous chapter in that they convert mechanical vibrations into electric currents, with applications mainly to microphones and phonographs.

Chapters 10 and 11 state some theorems and give a few applications to mechanical engineering, such as vibration and shock-mounting of engines and instruments, mufflers, and automobile suspensions.

All in all, a very readable book which will be useful to engineers dealing with vibration—mechanical, as well as electrical or acoustical.

Measurement of Dynamic Stress and Strain in Tensile Test Specimens

By R. O. FEHR,[1] E. R. PARKER,[2] AND D. J. DEMICHEAL[1]

In the investigation detailed in this paper, the tensile strength, the yield strength, and the breakage energy of test specimens (cold-rolled steel and dural) were measured while the specimens were being broken by a force applied at a high rate of speed in a commercial high-velocity impact-testing machine. The dynamic tensile strength, the dynamic yield strength and the dynamic breakage energy were found to be higher than the static values up to the maximum impact velocities of these tests (100 fps). The paper contains: (1) A presentation of some results of these tests. (2) A description of the technique used. (3) A description of the analysis used.

Introduction

FOR rational design, the dynamic characteristics, such as strength and breakage energy, of materials used in apparatus subjected to impact need to be known. However, at the present time, designs of apparatus are mostly based upon the static characteristics of the different materials even when the apparatus is subjected to impacts. When the dynamic breakage strength is lower than the static breakage strength, the apparatus may not withstand the impact, and when the dynamic breakage strength is above the static value, the weight of the apparatus may be unnecessarily high. Design of apparatus subjected to dynamic loads can, therefore, be improved when the design is based upon the dynamic characteristics of materials.

The determination of the relative dynamic characteristics of different materials is of special importance when materials which are now scarce have to be replaced by substitute materials.

In the tests reported in this paper, measurements of stress and strain have been made on test samples of cold-rolled steel (S.A.E-X-1112), and of dural (17-ST), while specimens made from these materials were being broken by a force applied at a high rate of speed in a commerical high-velocity impact-testing machine,[3] shown in Fig. 1.

The object of this paper is to present some results of these tests, to explain the technique and the analysis used, and to demonstrate the adequacy of this technique and analysis.

Summary of Test Results

The dynamic tensile strength, the dynamic yield strength, the dynamic breakage energy, and the dynamic elongation of the tested materials were found to be higher than the corresponding values obtained in the static tensile test.

The values for these four material characteristics increased with increasing striking velocity. The increase of the strength value above the static-strength value was in most cases less than 50 per cent up to a striking velocity of 100 fps, which was the highest test velocity.

The dynamic tensile strength and the dynamic yield strength versus the striking velocity are shown in Fig. 2 (*a*) for cold-rolled steel and in Fig. 2 (*b*) for dural; the dynamic breakage energy versus the striking velocity is shown in Fig. 3; and the dynamic elongation versus the striking velocity is shown in Fig. 4.

Limitations of High-Velocity Impact-Testing Machine

Only the dynamic breakage energy and the dynamic elongation, not the dynamic strength values, are obtainable from the conventional high-velocity impact-testing machine in the absence of special strain-gage equipment. It is, therefore, important to consider to what extent the dynamic strength values are indicated by the values for dynamic breakage energy and dynamic elongation.

The test results here presented indicate that, for the materials tested, the strength values vary only qualitatively, not in quantitative proportion, with the energy and elongation values. No definite relationship between the strength values and the energy or elongation values is evident.

The conventional high-velocity impact-testing machine will, therefore, require addition of strength-measurement equipment, such as the strain gages here discussed, when quantitative results on dynamic-strength characteristics are desired.

Recommendations for Use of Strain Gages

Results of the present investigation seem to warrant the follow-

ing recommendations in future applications of strain gages to measurements of dynamic strength in the high-velocity impact-testing machine:

1 The strain gage should be attached to the pendulum end, not the tup end, of the specimen.

2 The strain gage should be attached as close to the small cross section of the test specimen as practicable.

3 The length of the strain gage should be as short as practicable.

DESCRIPTION OF EQUIPMENT

The measurements were made while test specimens were being fractured in a high-velocity impact-testing machine. This machine consisted essentially of a flywheel, from which two striking horns could be thrust, and a heavy pendulum which supported the specimen. These are shown schematically in Fig. 5. The striking horns were thrust out after the circumferential speed of the wheel had attained the desired velocity. The specimen was fractured when the striking horns engaged a tup attached to the front end of the specimen. The holding force was the very high inertia force of the pendulum. The breakage energy could be calculated from the swing of the pendulum after the impact.

The shape of the test specimens, which were used for the dynamic tensile tests, was similar to a specimen shape which is in common use for static tensile tests. The specimens used are shown in Fig. 6.

The stress in the tensile test specimen was measured with a resistance-type electric strain gage,[4] in most cases attached to a large-diameter section adjacent to the test section of the speci-

men (Fig. 7), or in some cases attached to a cylindrical specimen holder.

The elongation of the specimen was measured with a thin nichrome wire stretched between the two ends of the specimen, Fig. 7. The elongation of this wire equaled the elongation of the specimen, and the resistance change in this wire due to this elongation was recorded.

The acceleration of the tup was measured by recording the stress produced solely by the acceleration force in a hollow cylinder attached to the tup, Fig. 8. This stress was measured with a resistance-type electric strain gage.

The resistance change in these gages was recorded on photographic film by means of a cathode-ray oscillograph and a high-speed camera. A record was obtained which showed the stress, strain, and, in some cases, the acceleration as a function of time. Two typical records are shown in Figs. 9 (*a*) and 9 (*b*).

This equipment is described in greater detail in Appendix 1.

EVALUATION OF TEST RESULTS

The object of the tests was to determine the values of the dynamic tensile strength, of the dynamic yield strength, and of the breakage energy of test specimens as a function of the striking velocity. The following procedure was used:

Stress versus time curves were obtained from measurements with strain gages which measured the stress in the large diameter section adjacent to the smaller diameter test section in which the break occurred. The stress in the test section was usually obtained by a simple multiplication of the stress in the larger diameter section, provided the measurements were made near the pendulum end. When the measurements were made near the tup end, the stress due to the inertia forces was first deducted from the recorded stress values before applying the multiplication factor. These curves were replotted as stress versus strain curves using the strain versus time records, which were obtained from oscillographic records, such as shown in Fig. 9. This analysis is discussed at greater length in Appendix 2.

The dynamic tensile strength is the stress in the test section corresponding to the highest point of the average line in the stress-strain curve in Fig. 10. The dynamic yield strength is that value of stress at which the rate of change of elongation for a constant increment of stress begins to increase.

Values for the dynamic tensile strength were also obtained from measurements with strain gages cemented, not to the specimen itself, but to a strain-sensitive specimen holder which was attached to the pendulum end. This arrangement was used when a large number of specimens was to be tested, since it made it unnecessary to attach strain gages to the individual specimens. The stress versus time records obtained by this arrangement showed large peaks, in contrast to the rather smooth stress versus time record obtained by a gage attached to the large-diameter section of the specimen, and placed in an identical location.

The energy values were obtained by integration of the stress-strain curves. The values obtained checked closely those energy values which had been obtained by the measurement of the pendulum swing[5] (see graph in Fig. 3).

ADEQUACY OF TEST TECHNIQUE

To establish the adequacy of the technique, it has to be demonstrated that measurements with a strain gage in the chosen location yield the proper results.

Stress measurements were made on the specimen at two locations, i.e., one between the point of rupture and the fixed specimen holder, and the other between the point of rupture and the point

[5] "The Effect of Strain Rate Upon the Tensile Impact Strength of Some Metals," by E. R. Parker and C. Ferguson, Trans. American Society for Metals, vol. 30, 1942, pp. 68–85.

of impact. Analysis in Appendix 2 indicates that for the specimen shape used the stress measurements at the first of these locations should give directly an approximate value for the stresses in the test section. The analysis shows, moreover, that the stresses in the test section could be determined approximately also from records taken at the other location, provided inertia effects were taken into consideration. The values obtained both ways were found to be in good agreement; this fact provides a confirmation of the analysis as well as of the validity of the strength values obtained.

Inadequacy of Reference Velocity

The true impact velocity at the critical region of fracture was decidedly not equal to the striking velocity (velocity of the striking horns) at the characteristic moment of the beginning of plastic flow. The value of this important true impact velocity could not be obtained offhand from the records, or from readings of the instruments on the machine. The answer to the question

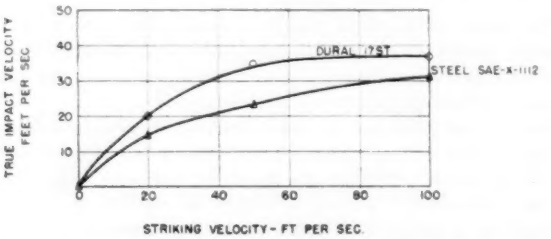

Fig. 11 True Impact Velocity, at Which Yield Strength Is Reached, Versus Striking Velocity

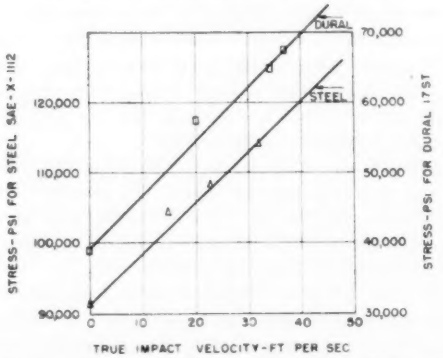

Fig. 12 Dynamic Yield Strength Versus True Impact Velocity

as to what the true value of this impact velocity is, was obtained from the analysis by stress waves discussed in Appendix 2. It was found from this analysis that the true impact velocity was generally far below the striking velocity at the critical instant at which the yield strength was reached (see Fig. 11). The true impact velocity was found to give a simpler correlation of yield strength than the striking velocity gave.

When the yield strength was plotted as a function of the true impact velocity, it was found to approximate a straight line while the conventional plot of the same value versus the striking velocity gave a curve which apparently approached a finite value, as illustrated by comparison of Fig. 12 with Fig. 2 (*a*) and (*b*).

The striking velocity was, nevertheless, chosen as the velocity of reference in correlating the effect of velocity on the strength and energy results. This choice seemed advisable for practical reasons. The striking velocity could be obtained directly from the speedometer on the testing machine, whereas the true impact velocity could be obtained only by cumbersome calculations impractical for general use. Moreover, the plot of the strength and energy values as a function of the true impact velocity would not be of much greater practical significance than the plot of these values as a function of the striking velocity, since in most practical cases the impact is transmitted to the place of failure through some sort of structure as is also the case for specimens tested in the high-velocity machine.

Acknowledgment

The authors are indebted for helpful comments to Prof. A. V. deForest of the Massachusetts Institute of Technology, and also for suggestions and advice to a number of individuals in the General Electric Company organization. Appendix 1

Detailed Description of Equipment

Strain Gages

For stress measurements, two wire gages[4] were cemented 180 deg apart (see Fig. 7) to the large-diameter section of the specimen. The two gages were connected in series so that the total resistance change was produced by compression or by tension, and so that no resistance change was produced by bending.

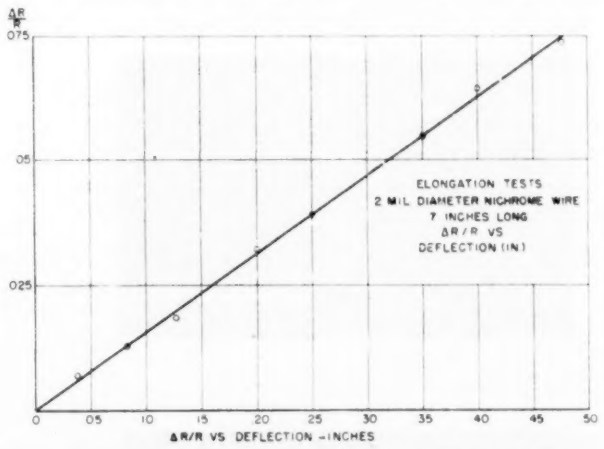

Fig. 13 Single-Wire Strain-Gage Resistance Change Versus Elongation

For acceleration measurements, the same type of wire gages was applied. A pair of these gages was cemented to a hollow cylinder which was used as acceleration-sensitive element (see Fig. 8). The gages were connected in series so that no resistance change was caused by bending. It was assumed that the strain in the cylinder was caused by the force necessary to accelerate the mass of that section which was located between the center of the strain gage, and the free end.

For strain measurements, a 2-mil-diam nichrome wire, 7 in. long, was stretched between two anchor points, one of them on the tup, and the other one on an arm attached to the pendulum, Fig. 7. This anchor point for the wire was isolated from the arm, and provisions were made for putting the wire under tension after it had been soldered.

This arrangement made the stress in the wire near the soldered joint very small even when the impact occurred. This provision was necessary as experience has shown that thin wires break near soldered junctions when relatively small stresses occur.

The gage factor[6] was determined by elongating the wire stati-

[6] "The Development of Electrical Strain Gages," by A. V. deForest and H. Lederman, National Advisory Committee for Aeronautics, Technical Notes No. 744.

cally, and by simultaneous measurement of the relative resistance and of the relative elongation. To make these measurements, the wire was cemented to a rubber strip, suspended vertically. The lower end of the rubber strip carried a platform on which weights could be placed. The elongation was measured by a scale observed with a magnifying glass. The resistance change was measured by a standard bridge. The relative resistance change is plotted as a function of relative elongation in Fig. 13, and it should be noted that this function is a straight line which extends well into the plastic range of the wire. This is not necessarily true, however, when the stress is reduced after the yield strength has been exceeded.

Attention was given to the attachment of the leads to the gages near the tup to prevent breakage due to the high acceleration, and due to the approximate 2-ft travel of the tup end after the fracture of the specimen. The terminals of the gages were soldered to cotton-covered insulated copper wire of 10 mils diam. The terminals and the wire were tied to the specimen and to the tup by friction tape and by transparent Scotch tape, as can be seen in Fig. 7.

Electrical Circuit

The electrical circuits associated with the strain gages for the measurement of stress, strain, and acceleration were identical. A schematic diagram of this circuit is shown in Fig. 14.

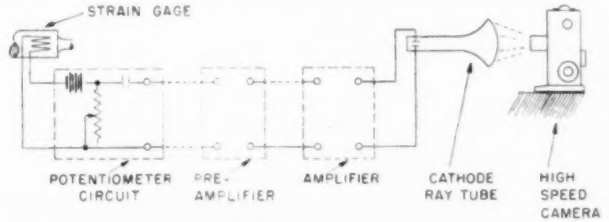

Fig. 14 Electrical Equipment and Recording Equipment Associated With Strain Gages

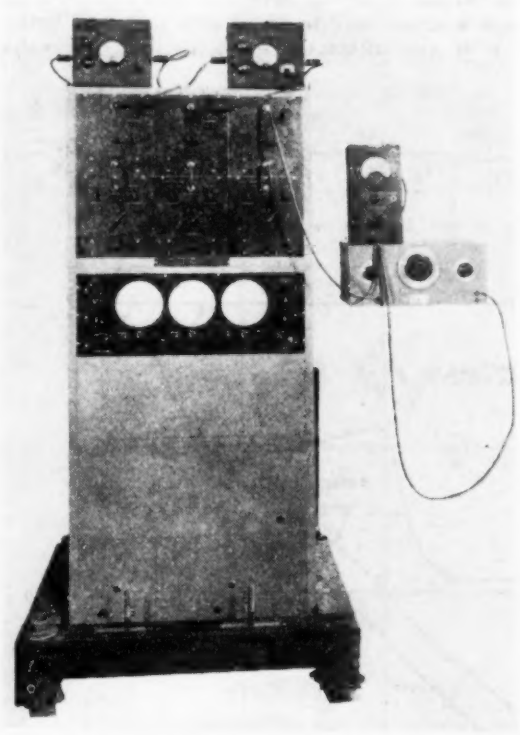

Fig. 15 Cathode-Ray Oscillograph for Simultaneous Recording of Three Signals

The changing resistance of the gage wire due to the elongation or compression of the specimen was converted to an alternating voltage in the potentiometer circuit. The output of the potentiometer circuit was supplied to the low-level amplifiers of a commercial three-tube cathode-ray oscillograph, which is shown in Fig. 15. In this illustration, the cabinets containing the potentiometer circuits are placed on top of the oscillograph. The oscillator and the vacuum-tube voltmeter seen at the right are used to calibrate the circuit, and to put a 2000-cps timing wave on the record. The gain of the electrical circuit was constant within 5 per cent for sinusoidal input voltages from 10 to 100,000 cps. An input voltage having a square wave shape did not excite any oscillations which would be noticeable on the records. The available gain of the amplifiers was 1,000,000. A gain of approximately 100,000, however, was sufficient for most tests.

Appendix 2

Effect of Location of Strain Gage

Forces in Test Section and in Large-Diameter Sections

The force distribution in the specimen was analyzed. The stress in the test section in which fracture took place was determined from measurements of the strain in one or both of the adjacent sections of larger diameter, since strain measurements by wire-type strain gages could not, of course, be made in the test section itself. The relations between the forces in the test section and the forces in each of the large-diameter sections were found by analysis and confirmed by the consistency of results, as mentioned elsewhere.

The following equation was used to calculate the stresses in the test section from the strain measurements in either one of the large-diameter sections

$$\sigma_{TS} = \left(\epsilon_{LS} E_{LS} \pm \frac{ma}{A_{LS}}\right) \frac{A_{LS}}{A_{TS}} \quad \ldots\ldots\ldots\ldots [1]$$

where σ = stress
ϵ = strain
E = modulus of elasticity
A = area
m = mass between center line of strain gage in large-diameter section and line of rupture
a = acceleration of mass m
Subscript (LS) indicates the large-diameter section, and subscript (TS) indicates the test section.

The plus sign was used in Equation [1], when the strain measurements were made near the tup end and the minus sign was used when strain measurements were made near the pendulum end, although for this latter case the term for the stress due to the inertia effect $\frac{ma}{A_{LS}}$ was in general very small (less than 5 per cent of the total stress). The stress was obtained with sufficient accuracy for most practical purposes for measurement made near the pendulum end from the simplified equation

$$\sigma_{TS} = \epsilon_{LS} E_{LS} \frac{A_{LS}}{A_{TS}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

Equations [1] and [2] were derived from the analysis of the equivalent "mass-and-spring" system. The same Equation [2] was obtained by an additional analysis by "stress waves." This latter analysis is independent of the previously mentioned analysis. Both methods of analysis will be discussed in detail.

The strain value ϵ_{LS} and the acceleration values a, were ob-

tained as a function of time from oscillograms, such as shown in Fig. 9 (*b*).

Analysis as "Mass-and-Spring" System

In this analysis the specimen was considered as a system split up into one mass and two springs. (The justification and limitations are discussed later.) The "mass-and-spring" system for that case in which the strain gage was attached near the tup end is shown in Fig. 16. The spring k_1 represents that portion of the large-diameter section covered by the strain gage, and the spring k_2 represents that portion of the small-diameter section in which yielding occurred. The mass represents the mass of the specimen between the center of the strain gage and the point of rupture. The strain gage attached to the large-diameter section measured the force F_1 through the spring k_1, while the force F_2 through the spring k_2 ruptured the specimen. The relation between those two forces is then

$$F_1 = ma + F_2$$

where a = acceleration of the mass.

Equation [1] is obtained from this equation by substitution of corresponding stresses in place of the forces.

The stress in the large-diameter section was, therefore, mainly produced by a force which was equal to the tensile force on the specimen at the point of rupture, the value of which was desired to be known, plus the force required to accelerate that section of the specimen which was between the gage and the point of rupture.

When the strain gage was attached near the pendulum end, the "mass-and-spring" system in Fig. 16 was applicable except that the tup and the pendulum are now interchanged in the sketch in Fig. 16, and that the force F cuts in the opposite direction.

The foregoing analysis can be justified as providing a reasonable approximation for the period of plastic deformation which is the greater part of the time interval of the total rupture period, and which lasts from 250 to 1000 μ sec, depending upon the striking velocity. This "mass-and-spring" system analysis, however, should preferably not be used for the short time interval of elastic deformation, lasting only 30 to 60 μ sec, since it does not furnish information on the details of the force fluctuations during certain small time intervals. This interval is the time it takes a stress wave to travel once back and forth. This time is 40 μ sec within the specimens used. To analyze the

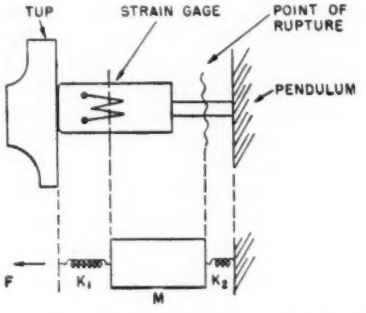

Fig. 16 Equivalent "Mass-and-Spring" System of Specimen

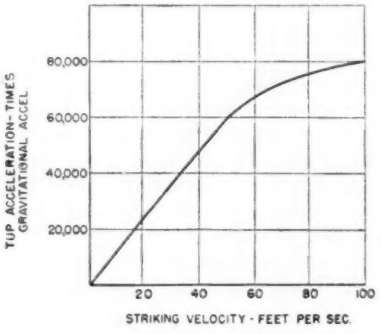

Fig. 17 High-Velocity Impact-Testing Machine; Tup Acceleration Versus Striking Velocity

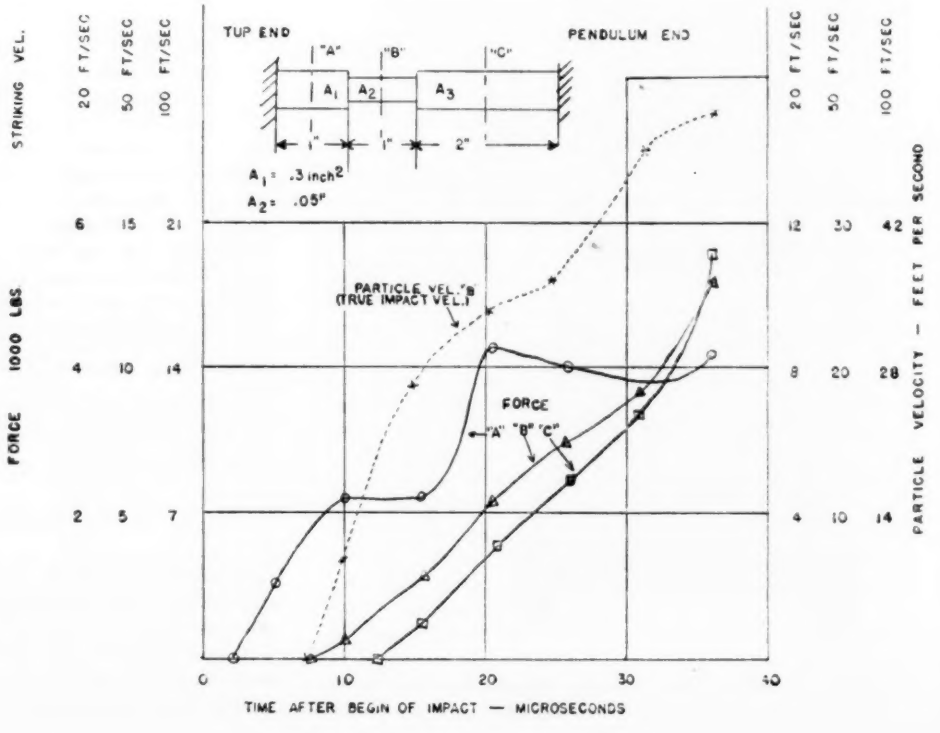

Fig. 18 Constructed Forces and Particle-Velocity Curves (*a*, Specimen for stress wave analysis. *b*, Force versus time curves. *c*, Particle velocity versus time curves.)

stresses during this time interval, the analysis by stress waves was used.

Analysis by Stress Waves

For the analysis by means of stress waves, certain assumptions seemed necessary. The acceleration of the tup end of the specimen was assumed to be constant from the instant of the impact to that instant at which the front end of the specimen attained the velocity of the striking horns, and for the succeeding time intervals the acceleration was assumed to be zero. The value of this initial constant acceleration was chosen as the maximum acceleration measured, Fig. 17. It was further assumed that both the pendulum end of the specimen and also the tup end were attached to masses which were very large compared with the mass of the specimen. The specimen for which this analysis was made is shown in Fig. 18(*a*).

The process of this analysis has been described by Donnell.[7]

[7] "Longitudinal Wave Transmission and Impact," part 1, by L. H. Donnell, Trans. A.S.M.E., vol. 52, 1930, p. 153.

The magnitude of force in each section of the specimen during the time intervals after the impact was obtained from the analysis, and these forces were plotted as a function of time in Fig. 18(*b*). A similar analysis and curves of somewhat similar shape were obtained for the magnitudes of the particle velocity to obtain the actual impact velocities when the yield strength was reached, Fig. 18(*c*).

The analysis was carried out only for the range of elastic deformation, i.e., up to that instant at which the yield strength was reached; and, hence, the curves in Fig. 18(*b*) cover stresses only below the yield strength. The values for the yield strength were taken from the yield strength versus striking velocity curves, Fig. 2(*a*) and (*b*).

The forces within the test section are in fair agreement with the forces in the larger diameter section near the pendulum end at the instant at which the yield strength is reached. This is important as the yield strength in the test section was determined from measurements in the large-diameter section. This fair agreement leads to the same Equation [2] which resulted from the previous analysis.

Heat Effects in Lubricating Films

By A. C. HAGG,[1] EAST PITTSBURGH, PA.

Heat effects in lubricating films are analyzed on the basis of simple shear of the lubricant, Reynolds logarithmic formula relating lubricant viscosity and temperature, and an equation relating the heat generation and heat flow in the film. The film-temperature dependence on velocity is determined, and the result is used to obtain the shearing stress and shearing rates. The formulas thus derived are useful in analyzing the performance of oil-film bearings. Experiments have been carried out with measurement of shaft- and bearing-surface temperatures, as well as friction; the tests support the analytical results. An approximate means for judging the importance of film heating in a given case in terms of velocity and lubricant viscosity is suggested.

Nomenclature

THE following nomenclature is used in the paper:

Symbol			Dimensions
θ	=	temperature at any point in film	θ
θ_1	=	temperature at surface of bearing	θ
θ_2	=	temperature at surface of journal	θ
θ_0	=	maximum temperature in film	θ
h	=	film thickness	L
y	=	distance from bearing surface to point in film	L
U	=	velocity of journal	LT^{-1}
u	=	velocity of lubricant at y	LT^{-1}
u_0	=	velocity of lubricant where $\theta = \theta_0$	LT^{-1}
μ	=	viscosity of lubricant	$ML^{-1}T^{-1}$
μ_1	=	viscosity of lubricant where $\theta = \theta_1$	$ML^{-1}T^{-1}$
μ_2	=	viscosity of lubricant where $\theta = \theta_2$	$ML^{-1}T^{-1}$
μ_0	=	viscosity of lubricant where $\theta = \theta_0$	$ML^{-1}T^{-1}$
α	=	coefficient in expression for viscosity	$ML^{-1}T^{-1}$
β	=	coefficient of exponent in expression for viscosity	θ^{-1}
S	=	shearing stress in lubricant	$ML^{-1}T^{-2}$
H	=	heat flow normal to surfaces at y	MT^{-3}
K	=	thermal conductivity of lubricant	$MLT^{-3}\theta^{-1}$

Introduction

The first considerations of heat effects in lubricating films were approximations based upon the assumption that the viscosity of the lubricant was not appreciably affected by the temperature differences within the film; the formal results were confined to defining the temperature distribution across the film.[2] Later, Kingsbury devised a graphical method for solving the temperature-distribution problem when the temperature variation is considerable;[3] the method also yields the shearing stress and other film characteristics.

The purpose of the present consideration of heat effects in lubricating films was to obtain usable formulas defining film conditions, taking account of the variable viscosity across the film thickness, and to check experimentally the results for comparatively high journal velocities, and high shear rates.

1 Analysis

The analysis is based on (1) simple shear of the lubricant as defined by Newton's law of viscosity; (2) Reynolds' logarithmic formula relating lubricant viscosity and temperature; and (3) Fourier's equation written for the heat generation and heat flow in the film. Further, it is assumed that the lubricant flow is laminar in character and bounded by parallel planes, and that the conduction of heat through the lubricant is not affected by its motion; normal temperature gradients are assumed to occur in the region of the boundary layers of the film and surfaces. The change in heat conductivity with temperature of ordinary lubricants is small and will be considered negligible

We can write the following three equations

$$S = \mu \frac{du}{dy} \quad [1]$$

$$\mu = \alpha e^{-\beta\theta} \quad [2]$$

$$H = S(u - u_0) = -K \frac{d\theta}{dy} \quad [3]$$

Film Temperatures

Substituting Equations [1] and [2] in Equation [3]

$$(u_0 - u)du = \frac{K}{\alpha} e^{\beta\theta} d\theta \quad [4]$$

Integrating

$$u_0 u - \frac{1}{2}u^2 = \frac{K}{\alpha\beta} e^{\beta\theta} + C \quad [5]$$

Evaluating the constant of integration, at $u = 0$, $\theta = \theta_1$

$$C = -\frac{K}{\alpha\beta} e^{\beta\theta_1}$$

Substituting the value of C in Equation [5] and solving for θ

$$\theta = \frac{1}{\beta} \ln \left(e^{\beta\theta_1} + \frac{\alpha\beta u_0}{K} u - \frac{\alpha\beta}{2K} u^2 \right) \quad [6]$$

where the value of u_0 can be obtained from Equation [4] by integrating between the limits $(U, 0)$ and (θ_2, θ_1)

$$\int_0^U (u_0 - u)du = \int_{\theta_1}^{\theta_2} \frac{K}{\alpha} e^{\beta\theta} d\theta$$

and

$$u_0 = \frac{U}{2} + \frac{K}{\alpha\beta U} \left(e^{\beta\theta_2} - e^{\beta\theta_1} \right) \quad [7]$$

Contributed by the Applied Mechanics Division and the Special Research Committee on Lubrication and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1944, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of authors and not of the Society.

[3] "Heat Effects in Lubricating Films," by Albert Kingsbury, *Mechanical Engineering*, vol. 55, 1933, pp. 685–688; discussion, vol. 56, 1934, pp. 120, 121.

Equation [7] can also be written

$$u_0 = \frac{U}{2} + \frac{K}{\beta U}\left(\frac{1}{\mu_2} - \frac{1}{\mu_1}\right) \quad \ldots\ldots [7a]$$

At the point of maximum temperature, $u = u_0$ and thus

$$\theta_0 = \frac{1}{\beta}\ln\left(e^{\beta\theta_1} + \frac{\alpha\beta}{2K}u_0^2\right) \quad \ldots\ldots [8]$$

In many practical cases, the heat conduction axially along a journal is negligible after equilibrium conditions have been reached; thus the journal can be considered as neither receiving nor giving up heat, and $u_0 = U$ and $\theta_0 = \theta_2$. Dividing Equation [8] by $e^{\beta\theta_1}$ the temperature drop across the film is

$$(\theta_2 - \theta_1) = \frac{1}{\beta}\ln\left(1 + \frac{\beta\mu_1}{2K}U^2\right) \quad \ldots\ldots [9]$$

For small values of $\frac{\beta\mu_1}{2K}U^2$ compared to unity, the right side of Equation [9] closely approaches $\frac{\mu_1}{2K}U^2$, and we can write to a close approximation

$$(\theta_2 - \theta_1) = \frac{\mu}{2K}U^2 \quad \ldots\ldots [10]$$

or

$$(\theta_0 - \theta_1) = \frac{\mu}{2K}u_0^2 \quad \ldots\ldots [10a]$$

Equation [10] corresponds to the simplified result obtained on the assumption that the viscosity of the lubricant is not appreciably affected by temperature differences within the film.[3]

Shearing Stress

The value of the shear stress can be obtained from Equations [1] and [2] combined with a previous result Equation [6], relating θ as $f(u)$, thus

$$Sdy = \alpha e^{-\beta[f(u)]}\,du \quad \ldots\ldots [11]$$

where

$$f(u) = \frac{1}{\beta}\ln\left(e^{\beta\theta_1} + \frac{\alpha\beta u_0}{K}u - \frac{\alpha\beta}{2K}u^2\right)$$

taking the logarithm of Equation [11]

$$\ln Sdy = \ln\alpha - \beta[f(u)] + \ln du$$

or

$$Sdy = \frac{\alpha\,du}{\left(e^{\beta\theta_1} + \frac{\alpha\beta u_0}{K}u - \frac{\alpha\beta}{2K}u^2\right)} \quad \ldots\ldots [12]$$

using the following relations

$$\left.\begin{aligned} a &= e^{\beta\theta_1} \\ b &= \frac{\alpha\beta u_0}{K} \\ m &= -\frac{\alpha\beta}{2K} \\ q &= b^2 - 4am \end{aligned}\right\} \quad \ldots\ldots [13]$$

the solution of Equation [12] is

$$Sy = \frac{-2\alpha}{\sqrt{q}}\tanh^{-1}\frac{2mu + b}{\sqrt{q}} + C \quad \ldots\ldots [14]$$

at $y = 0$, $u = 0$, and the constant of integration is

$$C = \frac{2\alpha}{\sqrt{q}}\tanh^{-1}\frac{b}{\sqrt{q}}$$

and

$$S = \frac{2\alpha}{y\sqrt{q}}\left[\tanh^{-1}\frac{b}{\sqrt{q}} - \tanh^{-1}\frac{2mu + b}{\sqrt{q}}\right] \quad \ldots [15]$$

Remembering that at $y = h$, $u = U$, Equation [15] becomes

$$S = \frac{2\alpha}{h\sqrt{q}}\left[\tanh^{-1}\frac{b}{\sqrt{q}} - \tanh^{-1}\frac{2mU + b}{\sqrt{q}}\right] \quad \ldots [16]$$

which is the general result desired.

Equation [16] can be converted to the normal nomenclature by making use again of the relations [13] and Equation [8], thus the shearing stress becomes

$$S = \frac{1}{h\sqrt{\frac{\beta}{2K\mu_0}}}\left[\tanh^{-1}\sqrt{\frac{\beta\mu_0}{2K}}u_0 + \tanh^{-1}\sqrt{\frac{\beta\mu_0}{2K}}(U - u_0)\right] \quad \ldots\ldots [17]$$

An important special case occurs when the maximum temperature is at the moving surface, i.e., $u_0 = U$, and $\mu_0 = \mu_2$, and thus Equation [17] reduces to

$$S = \frac{1}{h\sqrt{\frac{\beta}{2K\mu_2}}}\tanh^{-1}\sqrt{\frac{\beta\mu_2}{2K}}U \quad \ldots\ldots [18]$$

Another special case is when the boundary surfaces are at the same temperature, i.e., $u_0 = \frac{U}{2}$, and the shearing stress becomes

$$S = \frac{2}{h\sqrt{\frac{\beta}{2K\mu_0}}}\tanh^{-1}\frac{1}{2}\sqrt{\frac{\beta\mu_0}{2K}}U \quad \ldots\ldots [19]$$

Equations [17], [18], and [19] reveal that for a given minimum viscosity in the lubricant film, the shearing stress increases at an increasing rate with increase in velocity U. The velocity is finally limited by the infinite rate at which the shearing stress increases, i.e., when the arguments reach unity. Doubtless the assumptions upon which the development is based break down before the limiting condition is reached, and probably the maximum velocity thus defined is somewhat low. With the help of Equations [2] and [8], we can substitute for μ_2 in Equation [18] its value

$$\mu_2 = \frac{\mu_1}{1 + \frac{\beta\mu_1}{2K}U^2} \quad \ldots\ldots [20]$$

and we can see that, with a given maximum viscosity, the shearing stress increases at a decreasing rate with increase in U. A maximum shear stress is finally reached, and with further increase in U the shear stress diminishes slowly. A curve showing this effect, calculated on the basis of a typical mineral oil, is given in Fig. 1. It is expected that the theory would be valid, at least to velocities corresponding to the maximum shear stress.

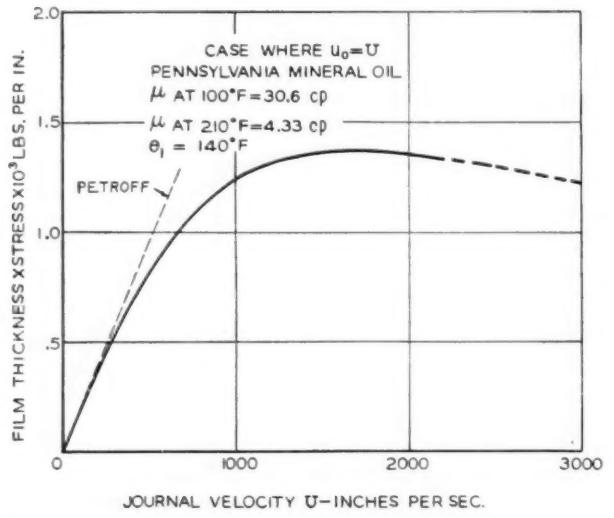

FIG. 1 SHEARING STRESS FOR CONSTANT BEARING TEMPERATURE

It can be noted that for small values of U, Equations [17], [18], and [19] reduce to a good approximation

$$S = \mu \frac{U}{h} \quad \ldots\ldots\ldots\ldots\ldots\ldots [21]$$

which is the basis for Petroff's equation.

RATE OF SHEAR

The rate of shear in the film can be obtained for all values of μ, and, consequently, for all values of u by rewriting Equation [11]

$$\frac{du}{dy} = \frac{S}{\alpha e^{-\beta[f(u)]}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [11a]$$

Similarly for any value of θ, u, μ, or $\frac{du}{dy}$ the corresponding value of y/h can be obtained from Equations [15] and [16].

2 EXPERIMENTS

Equations [9] and [18] of the analysis were chosen as a basis for designing the experiments and apparatus because it appeared that the condition of negligible heat flow to or from a journal could be closely approached, and in a steady state. Under this condition, film heating is disclosed most prominently in the effect upon friction; moreover, the maximum and minimum temperatures in the film occur at the journal and bearing surfaces, respectively, and measurement of journal and bearing temperatures leads to a direct check on the derived results. The independence of the temperature drop on the film thickness enhances the attractiveness of the latter test. The velocity distribution, and the temperature distribution in the film under the test conditions are shown in Fig. 2.

APPARATUS AND TEST PROCEDURES

The apparatus, as designed and used for the tests is shown in section in Fig. 3. A ground and polished plug shaft $1^1/_2$ in. diam of hardened tool steel was arranged to rotate in a steel ring. The bearing surface was a tin-base babbitt metal about $^1/_{32}$ in. thick, considerable care being taken to obtain a uniformly good bond between the babbitt metal and the steel to avoid the possibility of any abnormal temperature gradients at or near the

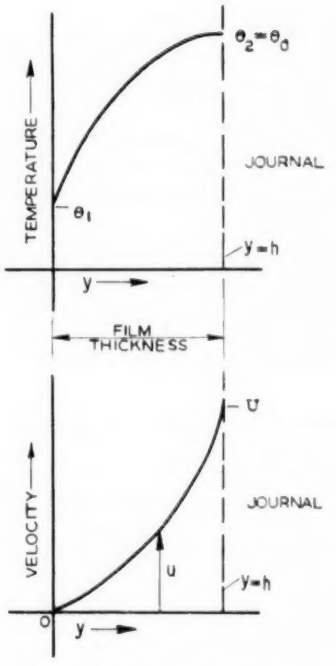

FIG. 2 FILM TEMPERATURE AND VELOCITY DISTRIBUTION UNDER TEST CONDITIONS

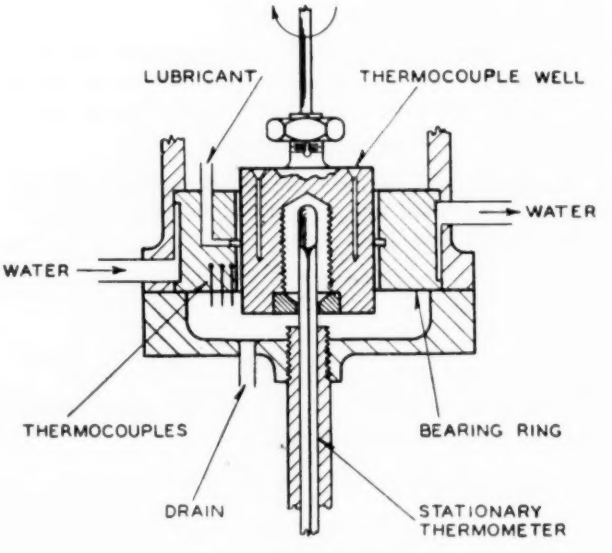

FIG. 3 TEST MACHINE

bonding area. The outer surface of the ring was arranged for water cooling, which arrangement afforded a simple thermal means for measuring the bearing friction.

The loss of heat from the plug shaft through normal modes of heat transfer was calculated to be negligibly small under contemplated conditions, compared to the heat generated within the film. Thus it was concluded that the shaft temperature would be very nearly uniform throughout. To determine this temperature, the bulb of a mercurial thermometer was arranged to project into an axial hole in the shaft; the radial clearance between the stationary thermometer and the hole entrance being made as small as practicable, or about 0.005 in. Under test

conditions, the oil pan and thermometer support, and the enclosed volume were at a temperature not far removed from the shaft temperature, so that any small interchange of air and oil vapor between the oil-pan volume and the shaft cavity, or heat conduction along the thermometer barrel, was believed to have negligible effect on the thermometer reading.

The temperature of the bearing surface was determined by the extrapolation of temperature data obtained by means of thermocouples at several radii. The extrapolation was simplified by recalling the formula for the outward radial heat conduction in a ring or plate; viz.

$$\theta = -\frac{H}{2\pi K} \ln r + C$$

Thus, the temperature data can be plotted on semi-logarithmic co-ordinates, and the extrapolation made conveniently by a straight line. A typical extrapolation is shown in Fig. 4.

The emf's of the copper-constantan thermocouples were indicated on a Leeds and Northrup 8657-C potentiometer, and calibrated against the shaft thermometer. It is believed that, relatively, the temperatures could be determined within $^1/_2$ deg F.

The lubricating system was a recirculating type with the supply reservoir kept under reduced pressure of 1 mm of mercury abs to eliminate absorbed air in the lubricant. The lubricant was pumped from the reservoir and supplied to the test bearing at a gage pressure of 10 to 15 psi. Two low-viscosity mineral oils were used in the tests; their viscosity characteristics being calculated from Saybolt readings made before and after each test. The accepted values were believed to be accurate to within ±3 per cent.

Speed measurements were made with a General Radio "Strobotac," the calibration against line frequency being carefully checked before and after each reading. The accuracy of the speed measurements is considered to be within ±0.5 per cent.

Test runs were carried out under steady-state conditions as indicated by constant temperature readings. Measurements of speed, temperatures, and friction were made in order; the measurements being repeated until three successive sets of data were in good agreement. The average values of these data were accepted as a test result. The friction values included minor corrections as determined from the bearing end leakage, and temperature gradients in the machine frame.

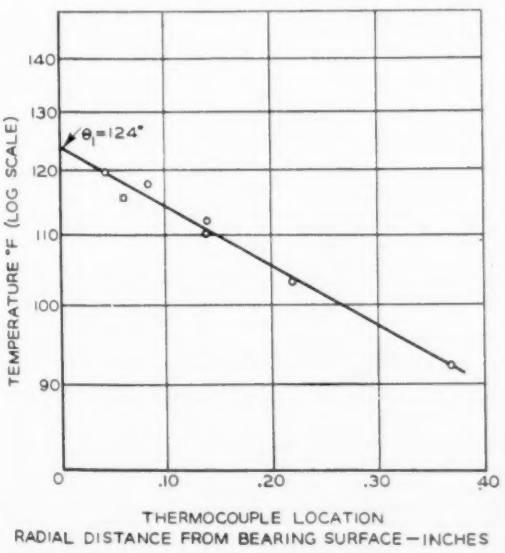

FIG. 4 TYPICAL EXTRAPOLATION FOR BEARING TEMPERATURE

TEST RESULTS AND COMPARISON WITH THEORY

The principal test results are given in Table 1; the dimensional units employed are the inch, the pound, the second, and deg F. The given values of the film thickness were determined from the average of a number of careful measurements of bearing and shaft diameters, and corrected for thermal-expansion effects. The basic measurements were made with telescopic and micrometer gages.

TABLE 1 TEST DATA

Run no.	Journal speed U, ips	Film temperature at journal θ_2, deg F	Film temperature at bearing θ_1, deg F	Film temperature drop ($\theta_2 - \theta_1$) deg F	Shearing stress S, psi	Film thickness h, in. × 10^3	Oil thermal conductivity[b] K, lb/sec per deg F	Oil[a]
1	786	136.5	125	11.5	0.787	0.60	0.017	A
2	790	136	124	12.0	0.805	0.60	0.017	A
3	1180	179	159	20.0	0.744	0.55	0.0165	A
4	1290	179	156	23.0	0.882	0.55	0.0165	A
5	935	144.5	121	23.5	0.815	1.20	0.017	B
6	1035	155.5	131	24.5	0.780	1.20	0.017	B
7	1185	160.5	127.5	33.0	0.750	1.15	0.0165	B
8	780	143	125	18.0	0.660	1.20	0.017	B

[a] For oil A: μ at 130 F = 4.44 cp; μ at 170 F = 2.76 cp. $\alpha = 3.06 \times 10^{-6}$ lb-sec/in.^{2}; $\beta = 1.20 \times 10^{-2}$ reciprocal deg F.
For oil B: μ at 130 F = 7 cp, μ at 170 F = 4.04 cp. $\alpha = 5.94 \times 10^{-6}$ lb-sec/in.^{2}; $\beta = 1.36 \times 10^{-2}$ reciprocal deg F.
[b] From J. F. D. Smith, Ind. and Eng. Chem., vol. 22, 1930.

It can be noted from the table that the temperature difference across the film was considerable in each case, and, consequently, the conclusions can hardly be influenced by small errors in the temperature measurements.

The comparison of theory and experiment can be made conveniently by plotting the results in dimensionless form. Multiplying Equation [9] by β, we have

$$\beta(\theta_2 - \theta_1) = \ln\left(1 + \frac{\beta\mu_1}{2K} U^2\right) \quad \ldots\ldots\ldots\ldots [9a]$$

and the dimensionless parameters are $\beta(\theta_2 - \theta_1)$ and $\frac{\beta\mu_1}{2K} U^2$.

Similarly Equation [18] can be rewritten as

$$h\sqrt{\frac{\beta}{2K_{\mu_2}}}\, S = \tanh^{-1}\sqrt{\frac{\beta\mu_2}{2K}}\, U \quad \ldots\ldots\ldots\ldots [18a]$$

and the dimensionless parameters are $h\sqrt{\frac{\beta}{2K_{\mu_2}}}\, S$ and $\sqrt{\frac{\beta\mu_2}{2K}}\, U$.

The resulting curves are shown in Figs. 5 and 6.

Referring to Fig. 5, the measured temperature drops across the film are in relatively close agreement with theory. These results are considered the more significant because of their independence on film thickness. The trend of the test points on oil B suggest some error in the accepted μ, or K or in both.

The measured shearing stresses in the film, shown in Fig. 6, are also in good agreement with theory, although the scatter of the test points is more pronounced than in the case of the film-temperature drops. Inaccuracies, which are difficult to avoid in the many measurements required in this test, probably account for the discrepancies.

The foregoing considerations of theory and experiment suggest an importance of heat effects in lubricating films; it appears that the degree of importance should be qualified by some convenient criterion involving the principal operating variables of velocity and lubricant viscosity.

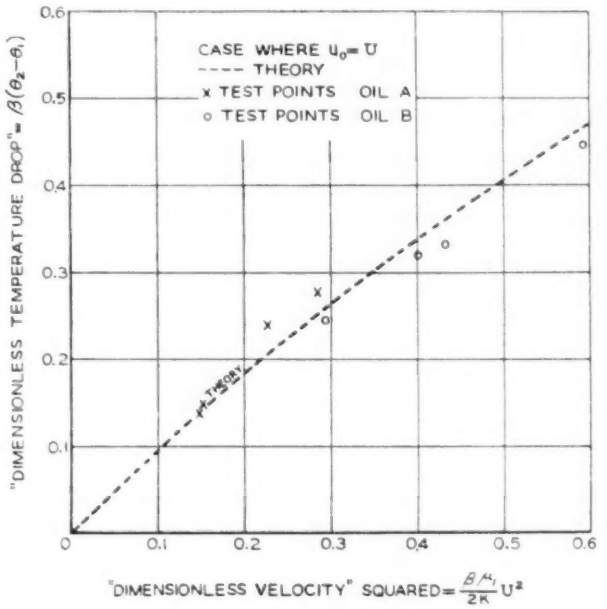

FIG. 5 TEMPERATURE DROP ACROSS OIL FILM

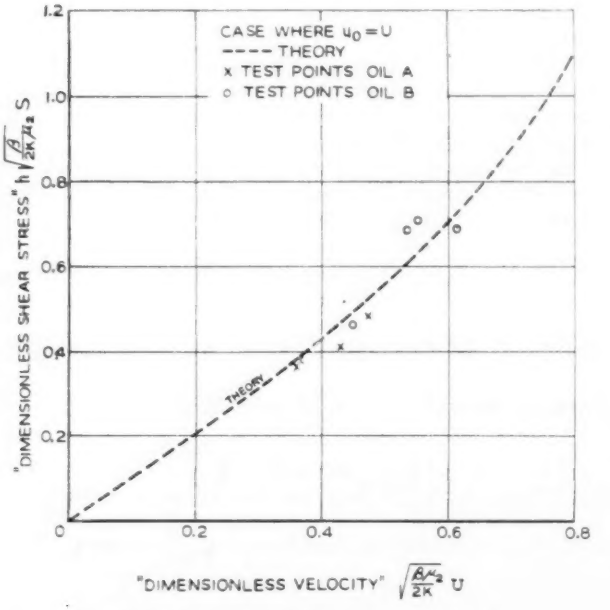

FIG. 6 SHEARING STRESS IN OIL FILM

The effect of operating variables on shearing stress are defined for limiting conditions of bearing and shaft temperatures by Equations [18] and [19]. The appropriate comparison with the shear stress, as defined by Equation [21] and evaluated using the maximum film viscosity, is an indication of the effect of film heating. Letting S_1 and S_2 refer to the shearing stress, as defined by Equations [18] and [21], respectively, we might write the percentage decrease in shear stress due to film heating

$$\text{Per cent decrease} = \frac{S_2 - S_1}{S_2} \quad \ldots\ldots\ldots\ldots [22]$$

Using an average value of $K = 0.0165$ and of $\beta = 0.015$, with the help of Equation [20], we can determine the approximate values of lubricant viscosity and velocity for a given percentage effect on shear stress. The results have been determined for 2, 5, and 10 per cent decrease in shearing stress; for the cases where film heating is manifest most prominently, Equation [18]; and where heat effects are least pronounced, Equation [19]. These results, as shown in Fig. 7, afford an approximate means for judging the importance of film heat effects. It should be remembered that, when the heat carried away by end leakage of the lubricant is appreciable compared to the total heat generated, the film heat effects are diminished.

SUMMARY

Formulas have been derived for the temperature distribution in lubricating films, and the shearing stress has been evaluated taking account of the variable viscosity across the film thickness. The results are useful in analyzing the performance of oil-film bearings. The formulas for shearing stress are useful in determining the friction in high-speed, lightly loaded guide or journal bearings.

Experimental results are in good agreement with theory for velocities up to 1290 ips, and shearing rates in excess of 2×10^6 reciprocal seconds. The viscosity characteristics of the oils tested were apparently not influenced by shear rate within the limits of the experiments.

The approximate effect of film heating in a given case can be judged from Fig. 7.

ACKNOWLEDGMENT

The author wishes to express his thanks to Mr. R. E. Peterson and to Mr. M. D. Hersey for their interest and suggestions, and also to Mr. Carl Green for carefully carrying out the test program.

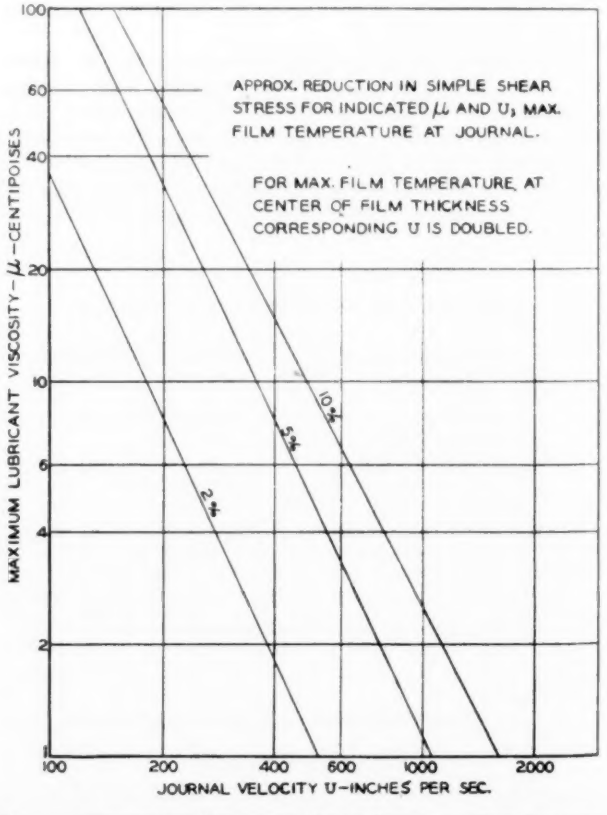

FIG. 7 APPROXIMATE EFFECT ON SHEAR STRESS BY FILM HEATING

Shrink-Fit Stresses and Deformations

By A. W. RANKIN,[1] SCHENECTADY, N. Y.

In this paper are derived the expressions for the stresses in a solid cylinder of infinite length caused by the action of an applied radial stress distributed uniformly over a single circumferential ring of finite length on the surface of the cylinder. An example of stresses of this type would be a long solid shaft with a uniform pressure applied on the surface for a short axial length. The practical worth of the results presented in this paper lie in their approximate applications to shrink fits. Test measurements of shaft deformations due to shrink pressures are included to illustrate the application of the theoretical results.

Nomenclature

The following nomenclature is used in the paper:

a = one half of axial length over which radial stress p is applied

a_0, a_1 = constants in solution for ϕ

E = modulus of elasticity

i = $\sqrt{-1}$

i_n = partial Bessel defined by $I_n(u) = \dfrac{e^u}{\sqrt{2\pi u}}\, i_n(u)$

I_n = modified Bessel of nth order and first kind, defined by $J_n(i\lambda r) = i^n I_n(\lambda r)$

J_n = Bessel of nth order and first kind

k = constant giving "effective" length of a long shaft subjected to a radial stress applied over a short axial length

m = constant which takes the values of m_1 and m_2 only

m_1 = $\dfrac{a + z}{r_0}$

m_2 = $\dfrac{a - z}{r_0}$

p = applied radial stress

r = radial distance

r_0 = shaft radius; also used to denote inside radius of ring to be shrunk on shaft

r_1 = outside radius of ring to be shrunk on shaft

u = radial deformation

u_0 = total shrink allowance

u_r = deformation of shrink ring

u_s = deformation of shaft surface

z = axial distance

$\gamma_{1.0}$ = $(1 - 2\nu - \rho) i_0(\lambda r_0) + \left(\lambda r_0 + \dfrac{\rho}{\lambda r_0}\right) i_1(\lambda r_0)$

$\gamma'_{1.0}$ = $(1 - 2\nu - \rho) I_0(\lambda r_0) + \left(\lambda r_0 + \dfrac{\rho}{\lambda r_0}\right) I_1(\lambda r_0)$

δ = *average* deformation of shaft surface within the planes of $z = \pm a$

λ = variable of integration used in Fourier integral. (Note that the variable λ would disappear if the indicated integrations could be completed; λ has in itself no direct physical significance)

ν = Poisson's ratio ($\nu = 0.30$ has been used for all the numerical work of this paper)

ρ = $2(1 - \nu) + \lambda r_0 \dfrac{i_0(\lambda r_0)}{i_1(\lambda r_0)}$

σ_r = radial stress

$\bar{\sigma}_r$ = radial-stress component

σ_θ = tangential stress

$\bar{\sigma}_\theta$ = tangential-stress component

σ_z = axial stress

$\bar{\sigma}_z$ = axial-stress component

τ_{rz} = shear stress

$\bar{\tau}_{rz}$ = shear-stress component

ϕ = stress function

General Considerations

In a considerable number of shrink-fit problems, a ring of short axial length is shrunk on a shaft whose length is so much greater than the length of the shrink ring that for practical purposes it may be considered infinite. It then becomes of great practical importance to determine the relation in the shaft between the radial stress on the outer surface and the radial deformation of this surface in order to calculate the resulting shrink-fit pressure between the ring and the shaft.

In an actual shrink-fit problem, a determination of the actual stresses would be extremely complex since it would be necessary to consider the stress distribution in the short ring as well as in the long shaft. It is well known, however, that the actual radial stress between the short ring and the long shaft is essentially constant in magnitude along the axial length of the shrink ring except close to the ends at which point the radial stress reaches a high value. Since the increase in the radial stress occurs only close to the ends, it follows that a good approximation to the average deformation of the shaft surface could be obtained by ignoring the radial-stress variations and considering only a long shaft with a uniform radial stress applied to the surface over a ring of short axial length. Such an approximation will not give the true stress distribution present in an actual shrink fit, but the average shrink pressure so calculated should be much closer to the true average than is now ordinarily calculated.

It is the purpose of this paper to present an analysis based on the uniform-stress conditions outlined previously, and to show how the results of this analysis may be used in shrink-fit problems; the physical conditions of the subject analysis are illustrated in Fig. 1.

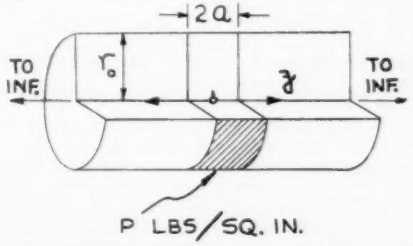

Fig. 1 Illustration of Physical Conditions of Subject Problem

---

[1] Central Station Engineering Division, formerly of Turbine Generator Engineering Division, General Electric Company.

Presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1944, for public2tion at a later date. Discussion received after the closing date will be returned.

Note:. Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Curves will be given showing the radial, tangential, axial, and shear stresses throughout a long solid cylinder in which the applied radial stress is distributed on the shaft surface over a single circumferential band whose length is 15 per cent of the shaft diameter; charts are also given from which similar curves may be plotted for cases in which the length of the band over which the radial stress is applied varies from zero up to the diameter of the cylinder. Curves are plotted showing the radial deformation of the shaft surface for various ratios of band length to shaft diameter; also, a simple curve is given from which may be calculated the *average* radial deformation of the shaft surface under the band over which the applied radial stress is distributed. Also included are test data to illustrate the validity of the theoretical results.

It should be noted at this point that the method employed in the present analysis is given in some detail by Timoshenko (1),[2] although without any numerical results; an approximation to the present problem is also treated by Föppl (2), although again without giving any numerical results. The work of Timoshenko (1) actually considers an applied radial-stress system which would represent an infinite series of rings shrunk on a shaft, and is not directly applicable to the present problem which considers only one shrink ring. Timoshenko's solution considers an applied stress system which can be represented by a Fourier series rather than the stress system of the present problem which requires a Fourier integral representation.

The work of Föppl (2) assumes the applied force to be concentrated on the surface on a ring of infinitesimal length (thereby resulting in infinite stresses under the applied force). It would be necessary to apply still another integration in Föppl's analysis in order to consider the present case of radial stresses applied over a ring of finite length.

Methods of Analysis Based on Uniform-Stress Conditions

A series solution of the uniform-stress problem of this paper was published by M. V. Barton (3),[3] using a Fourier series of the general type given by Timoshenko (1), but with the fundamental period of the series sufficiently large so that the effects of neighboring pressure rings were small. The larger the fundamental period of the series the closer will the stress distribution approach that of a single ring, but the slower will be the convergence. Especially is this true around the points of discontinuity of the Fourier series as these are the points to exhibit the slowest convergence. The solution presented in the present paper, however, considers the stress distribution of a single ring directly and presents the results in Fourier integrals; the integrals are then evaluated to any desired degree of accuracy by using numerical integration in conjunction with the Si (x) and Ci (x) functions (4).

Comparison of the Fourier integral results with the series results of Barton (3) show close correspondence in all except minor details. In particular, the stress curves of the integral solution give slightly higher stresses near the ends of the applied stress p (z close to $\pm a$) for values of r approaching r_0, but these differences are never large enough to be of importance.

Assumptions

The major assumptions used in the present analysis are those in general use in most stress calculations; namely, it is assumed that the material is homogeneous and continuously distributed, is isotropic, perfectly elastic, and that the stresses do not exceed the elastic range. In addition to these general assumptions, the following are used to simplify the present specific problem:

1 It is assumed that there is no restraint to movement in the axial, or z, direction.

2 It is assumed that no bore hole is present in the shaft.

3 All the calculations have been based upon a value of Poisson's ratio $\nu = 0.30$.

Results

The radial deformation of the surface of a cylinder subjected to a radial stress p, distributed over the entire peripheral surface, may be put in the following form if it is assumed that σ_z and τ_{rz} (axial and shear stresses, respectively) are negligible

$$u = \frac{(1 - \nu) r_0 p}{E} \qquad [1a]$$

Similarly, the average deformation of the surface of the shaft of the present problem $\left(\text{average between the cross sections } \frac{z}{r_0} = \pm \frac{a}{r_0}\right)$ may be put in the following form

$$\delta = \frac{(1 - \nu) r_0 p}{kE} \qquad [1b]$$

The value of the constant k has been calculated for various values of the ratio $\frac{a}{r_0}$, and these are plotted in Fig. 2. The practical use of Equation [1b] is shown in the numerical example in the section, "Stress and Strain Curves, and Discussion."

Curves showing the distribution of the radial, tangential, axial, and shear stresses for the ratio $\frac{a}{r_0} = 0.150$ are given in Figs. 3 to 6, inclusive. In Fig. 7 has been plotted the direction of one of the principal stresses for the same value of the ratio $\frac{a}{r_0}$, and several stress trajectories are shown in this figure; the second principal stress is at right angles to the principal stress shown in Fig. 7, while the third principal stress is the σ_θ stress and is in the circumferential direction.

In Fig. 8 has been plotted the radial deformation of the shaft surface for the ratio of $\frac{a}{r_0} = 0.150$. Note that all these curves have been plotted against the ratio $\frac{z}{r_0}$, or axial distance expressed as a decimal of the shaft radius.

Fig. 9 gives the radial deformation of the shaft surface for several values of $\frac{a}{r_0}$, but on this curve the abscissa is $z/2a$, or axial distance expressed as a decimal of the axial length of the applied load. The latter abscissa was chosen for Fig. 9 so that the limit which the deformation approaches as $\frac{a}{r_0}$ approaches infinity may be clearly shown.

The radial, tangential, axial, and shear stresses in the solid cylinder of the subject problem are given explicitly by the infinite integrals Equations [18a] to [18d], inclusive, of the Appendix. Since, however, these expressions cannot be integrated, it is necessary to resort to numerical integration, and for that reason the curves given in Figs. 10 to 13, inclusive, have been prepared. The expressions evaluated by these curves are termed "stress

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

[3] The solution of reference (3) was unfortunately overlooked until the major portion of the present paper had been completed. Because of the importance of the approximate application to the universal problem of shrink fits, which was not discussed in detail in reference (3), it was felt that the integral and series methods presented very desirable complementary solutions.

components" since these curves are used to determine the actual stresses. The latter are obtained from the stress components by the following relations

$$\left.\begin{aligned}\sigma_r\left(\frac{r}{r_0},\frac{a}{r_0},\frac{z}{r_0}\right) &= \bar{\sigma}_r\left(\frac{r}{r_0},m_1\right)+\bar{\sigma}_r\left(\frac{r}{r_0},m_2\right)\\ \text{with } \bar{\sigma}_r\left(\frac{r}{r_0},-m\right) &= -\bar{\sigma}_r\left(\frac{r}{r_0},+m\right)\end{aligned}\right\}\quad\ldots[2a]$$

$$\left.\begin{aligned}\sigma_\theta\left(\frac{r}{r_0},\frac{a}{r_0},\frac{z}{r_0}\right) &= \bar{\sigma}_\theta\left(\frac{r}{r_0},m_1\right)+\bar{\sigma}_\theta\left(\frac{r}{r_0},m_2\right)\\ \text{with } \bar{\sigma}_\theta\left(\frac{r}{r_0},-m\right) &= -\bar{\sigma}_\theta\left(\frac{r}{r_0},+m\right)\end{aligned}\right\}\quad\ldots[2b]$$

$$\left.\begin{aligned}\sigma_z\left(\frac{r}{r_0},\frac{a}{r_0},\frac{z}{r_0}\right) &= \bar{\sigma}_z\left(\frac{r}{r_0},m_1\right)+\bar{\sigma}_z\left(\frac{r}{r_0},m_2\right)\\ \text{with } \bar{\sigma}_z\left(\frac{r}{r_0},-m\right) &= -\bar{\sigma}_z\left(\frac{r}{r_0},+m\right)\end{aligned}\right\}\quad\ldots[2c]$$

$$\left.\begin{aligned}\tau_{rz}\left(\frac{r}{r_0},\frac{a}{r_0},\frac{z}{r_0}\right) &= -\bar{\tau}_{rz}\left(\frac{r}{r_0},m_1\right)+\bar{\tau}_{rz}\left(\frac{r}{r_0},m_2\right)\\ \text{with } \bar{\tau}_{rz}\left(\frac{r}{r_0},-m\right) &= +\bar{\tau}_{rz}\left(\frac{r}{r_0},+m\right)\end{aligned}\right\}\quad\ldots[2d]$$

Stress and Strain Curves, and Discussion

In Fig. 2 is plotted a curve giving, for various values of $\frac{a}{r_0}$, the *average* radial deformation of the shaft surface under the band over which the radial stress is applied. By average deformation is meant the average radial deformation of the shaft surface between the planes $z = \pm a$. This is the curve whose use is recommended for calculating shrink fits and shrink-fit pressures between a ring of short axial length and a solid shaft whose length is much longer than that of the ring.

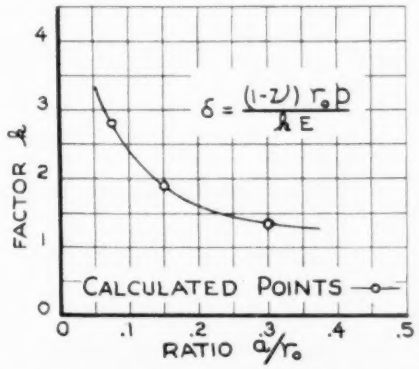

Fig. 2 Factor k for Computing Average Deformation on Radius of Shaft Surface Under Applied Radial Stress

As an illustration of the use of Fig. 2, assume that a ring of inner radius r_0 and outer radius r_1, and of short axial length, is shrunk on a solid shaft of much greater length, with a shrink of u_0 inches on the radius. If p is the average radial pressure between the ring and the shaft, the radial movement of the inside of the short ring will be

$$u_r = \frac{r_0 p}{E}\left[\frac{(1+\nu)+(1-\nu)\left(\frac{r_0}{r_1}\right)^2}{1-\left(\frac{r_0}{r_1}\right)^2}\right]\quad\ldots\ldots[3]$$

From Fig. 2, the average deformation of the surface of the solid shaft will be

$$u_s = \frac{(1-\nu)r_0 p}{kE}\quad\ldots\ldots[4]$$

with the value of k selected from Fig. 2 for the given ratio of $\frac{a}{r_0}$.

The total deformation must equal the specified shrink, or

$$u_0 = u_r + u_s\quad\ldots\ldots[5]$$

Solving for the radial pressure in terms of u_0

$$p = \frac{\frac{u_0}{r_0}E}{\left[\frac{(1+\nu)+(1-\nu)\left(\frac{r_0}{r_1}\right)^2}{1-\left(\frac{r_0}{r_1}\right)^2}+\frac{(1-\nu)}{k}\right]}\quad\ldots\ldots[6]$$

As a numerical example, assume the following

$r_0 = 10$ in. $\quad r_1 = 18$ in. $\quad a = 1.5$ in. $\quad \frac{u_0}{r_0} = 1.0 \times 10^{-3}$

$\nu = 0.30 \quad E = 30 \times 10^6 \quad k = 1.9$ (Fig. 2)

Substituting in Equation [6] gives

$$p = 11{,}700 \text{ psi}$$

If the effect of that portion of the shaft beyond the ring is neglected, then $k = 1$ in Equation [6], and the radial pressure between the ring and the shaft would be

$$p = 10{,}300 \text{ psi}$$

Consideration of the entire shaft has therefore increased the shrink pressure over 10 per cent.

Proceeding to Fig. 3, the radial stress σ_r is there plotted for the ratio $\frac{a}{r_0} = 0.150$. It is interesting to note here that for this ratio of $\frac{a}{r_0}$, the radial pressure at the center of the shaft is only 30 per cent of the applied radial stress instead of being equal to the
